secretagogue expected to gain popularity, given it is well tolerated with lower likelihood of false-positive results.[26] In prepubertal children, measurement of IGF-I concentrations may be useful in evaluating GH deficiency.[27] The diagnosis of GH deficiency in children, often without the need for provocative testing, is established if the child exhibits all three conditions: (a) auxological criteria, (b) hypothalamic–pituitary defect, and (c) deficiency of at least one additional pituitary hormone.[28] Failure of linear growth is an almost universal presenting feature of childhood GH deficiency.

Childhood GH deficiency may or may not continue into adulthood. Most adults with GH deficiency have overt pituitary disease and present with nonspecific clinical disorders distinct from pediatric GH deficiency. Adult GH deficiency presumably

Clinical Presentation and Diagnosis of Growth Hormone Deficiency in Adults[25,26,29-32]

General

The patient likely will have a history of childhood-onset GH deficiency; hypothalamic or pituitary disorder; or the presence of three or four other pituitary hormone deficiencies caused by head trauma, tumor, infiltrative diseases, surgery, or radiation therapy.

Symptoms

- Reduced strength and exercise capacity
- Defective sweating (eg, reduced sweating)
- Psychological problems
- Low self-esteem
- Depression
- Fatigue or listlessness
- Sleep disturbance
- Anxiety
- Social isolation
- Emotional lability and impaired self-control
- Poor marital and socioeconomic performance

Signs

- Increased fat mass (especially abdominal obesity)
- Reduced lean body mass
- Reduced muscle strength
- Reduced exercise performance
- Thin, dry skin; cool peripheries; poor venous access
- Depressed affect, labile emotions
- Impaired cardiac function as evidenced by abnormal echocardiography or stress test results

Laboratory Tests

- ITT remains the gold standard test using a peak GH cut-point of 5 ng/mL (mcg/L).
- GST is an alternative test using body mass index (BMI)–appropriate cut-points as follows: GH cut-point of 3 ng/mL (mcg/L) for normal-weight and overweight patients (BMI 25 to 30 kg/m^2) with a high pretest probability; GH cut-point of 1 ng/mL (mcg/L) for obese (BMI > 30 kg/m^2) and overweight patients with a low pretest probability.
- A newer alternative is the macimorelin test with a GH cut-point of 2.8 ng/mL (mcg/L).
- The presence of three or more pituitary hormone deficiencies with a low IGF-I concentration does not require further stimulation test.
- Increased low-density lipoprotein cholesterol, total cholesterol, triglycerides; decreased high-density lipoprotein cholesterol.
- Reduced bone mineral density associated with an increased risk of fracture.
- Increased insulin resistance and prevalence of impaired glucose tolerance.
- GH deficiency may be accompanied by the loss of other pituitary hormones.

is associated with an increased risk of death from cardiovascular diseases.[24]

▶ *Treatment*

Desired Outcomes The goal of treatment for GH deficiency is to correct associated clinical symptoms.[23] In children, prompt diagnosis and early initiation of treatment are important to maximize final adult height. In adults, the goal is to achieve normal physiologic GH concentrations in an attempt to reverse metabolic, functional, and psychological abnormalities.[25,29]

Pharmacologic Therapy KEY CONCEPT Recombinant GH therapy is the main pharmacologic treatment for GH deficiency in both children and adults. It promotes skeletal, visceral, and general body growth; stimulates protein anabolism; and affects bone, fat, and mineral metabolism (see Table 47–1).[2] GH therapy requires subcutaneous or intramuscular administrations, given as daily injections. It is recommended to administer GH injections in the evening to mimic physiologic endogenous GH secretion.[26] Many preparations of synthetic GH (somatropin) are available with a variety of injection devices to make administration more appealing and easier. Zomacton is only approved for use in children, and other somatropin products such as Humatrope, Norditropin, Nutropin, Genotropin, Omnitrope, and Saizen are approved in both children and adults. The long-acting GH (LAGH) preparations are available in China and South Korea but currently under development in the United States.[30]

KEY CONCEPT Although comparative trials have not been conducted to date, recombinant GH products appear to have similar efficacy for treating GH deficiency as long as the regimen follows currently approved guidelines.[26] GH secretion decreases with age; therefore, older adults with GH deficiency often require substantially lower replacement doses than younger individuals. The optimal therapeutic approach is to initiate GH therapy at lower doses and titrate according to clinical response, adverse effects, and IGF-I concentrations.[26,30] Table 47–3 lists the recommended GH replacement doses for children and adults.[25,26,28] Conventional weight-based regimens are not recommended in adults due to lack of evidence supporting higher dosages in heavier individuals and greater potential for adverse effects.[25,29,31] For elderly patients, lower GH replacement doses often are adequate because of increased GH sensitivity.[29,31] Women with intact hypothalamic–pituitary–gonadal axis or on estrogen therapy (or oral contraceptives) generally require a higher GH dose than men due to decreased GH concentrations associated with estrogen.[26,31] Carefully monitor patients requiring replacement therapy with estrogens, thyroid hormones, or glucocorticoids because of potential interactions with GH therapy.[29] The potency of GH products is generally expressed as 3 international units (IU or mU) per 1 mg of protein.[25] Selection of an injection device depends on patient preference due to lack of differences in clinical outcomes among the various injection systems.[26]

Evidence has suggested that GH treatment in GH-deficient children can increase short-term growth and improve final adult height.[9] Beneficial effects of GH therapy in adults with GH deficiency have been demonstrated to normalize body composition and metabolic process; improve cardiac risk profile, bone mineral density, quality of life, and psychological well-being; and increase muscle strength and exercise capacity.[25,31] However, evidence for reduction in cardiovascular risks and mortality are still lacking with long-term use of GH replacement therapy.[33]

Practitioners should begin GH therapy as soon as possible to optimize long-term growth. As somatropin is synthetic human GH, there is no evidence that one commercial product is more advantageous than another, apart from differences in devices that are more user-friendly, dose per mg adjustments, and whether the product requires refrigeration. Patients should generally be started on a low dose guided by age, gender, and concomitant medications.[26] It is recommended that GH dose in pediatric patients does not continue beyond achievement of a growth velocity below 2 to 2.5 cm/year.[28] The decision to discontinue therapy prior to this should be individualized on factors such as

Table 47–3

Dose Recommendation for Growth Hormone Deficiency in Children and Adults[25,26,28]

	Growth Hormone Replacement Dose	Dose Titration
Children[28]	**Starting Dose**	• Evaluate every 3–6 months based on height and height velocity.
Prepubertal children	22–35 mcg/kg/day with individualization on subsequent dosing	• Monitor IGF-I and IGFBP-3 yearly. • Monitor TSH and T_4 for hypothyroidism. • Reduce dose if serum IGF-I concentration is substantially above normal after 2 years of therapy.
During puberty	Individualized dosing	• Against routine increase in dose to 700 mcg/kg/week. • Resume growth hormone at 50% of the dose used in childhood during transitions.[26]
Adults[25,26]	**Starting Dose**	• Increase dose by 0.1–0.2 mg/day at 1- to 2-month intervals based on clinical response, serum IGF-I concentrations, and side effects. Longer time intervals and smaller dose titration may be necessary in older adults and those with other comorbidities.
Age < 30 years	0.4–0.5 mg/day[a]	
Age 30–60 years	0.2–0.3 mg/day	
Age > 60 years	0.1–0.2 mg/day	
Concurrent diabetes, obesity, older age, or previous gestational diabetes	0.1–0.2 mg/day	
Hepatic impairment	–	• Clearance may be reduced in patients with severe hepatic dysfunction; specific dosing suggestions are not available.
Renal impairment	–	• Patients with chronic renal failure tend to have decreased clearance; specific dosing suggestions are not available.

[a]Might require a higher dose for patients transitioning from pediatric treatment.

IGFBP-3, insulin-like growth factor-binding protein 3; IGF-I, insulin-like growth factor-I; T_4, thyroxine; TSH, thyroid-stimulating hormone.

Patient Care Process: GH Deficiency in Children

Collect Information:

- Obtain a thorough history and physical examination (weight and height) that may indicate the possible presence of GH deficiency.
- Obtain GH and IGF-I concentrations.
- Review imaging tests of the hypothalamic–pituitary region to detect any anomalies.
- Speak with caregivers to identify signs and symptoms of GH deficiency, preferences and beliefs, health goals, and socioeconomic factors or barriers that affect medication access and other aspects of care.

Assess the Information:

- Assess the child's growth characteristics and compare the physical height with a population standard (eg, Centers for Disease Control and Prevention growth charts).
- Exclude other identifiable causes of growth failure.
- Assess the presence of other pituitary hormone deficiency.
- Assess risk factor for development of malignancy (history of cancer or active cancer).
- Assess if the patient has any contraindication, allergy, or drug interaction with GH therapy.

Develop a Care Plan:

- Calculate the appropriate GH therapy at the lower dosing range based on patient weight (see Table 47–3).

Implement the Care Plan:

- Initiate GH therapy based on patient preference (see Table 47–3).
- Discuss with caregivers and child the potential effectiveness and disadvantages of existing GH treatment options.
- Address any patient concern about long-term complications of GH deficiency, its management, and possible adverse effects of GH therapy.
- Educate regarding potential for lifelong replacement therapy.
- Use motivational interviewing and coping strategies to maximize adherence.

Follow-up: Monitor and Evaluate:

- Review child's medication adherence.
- Monitor response (increase in height and change in height velocity) and adverse effects of GH therapy (intracranial hypertension, slipped capital femoral epiphysis, and scoliosis progression). Individualized dose based on child's response.
- Continue GH therapy until child reaches satisfactory adult height, achieves documented epiphyseal closure, or fails to respond to treatment.
- Review and retest the child using adult GH deficiency diagnostic criteria when the child reaches final adult height.

growth plate fusion or failed response.[28] In patients transitioning from pediatric to adult care, it is important to retest after at least 1 month following discontinuation of GH therapy. In patients with persistent GH deficiency, it is suggested to resume GH therapy at 50% of the dose last used in childhood, and gradually titrate upward to avoid any adverse effect.[26] Resuming GH therapy in these patients is important to obtain full somatic maturation, normalization of body composition, and lipid metabolism in adulthood. The optimal duration of treatment with GH therapy remains unclear, but lifelong therapy may be required. However, if there is no therapeutic benefit after at least 12 to 18 months of treatment, discontinuing GH therapy may be appropriate.[25]

In both children and adults, treatment with GH may mask underlying central hypothyroidism and adrenal insufficiency.[34] Treatment with GH also may induce insulin resistance and lead to the development of glucose intolerance in patients with preexisting risk factors. Adults are more susceptible to dose-related adverse effects of GH-induced symptoms, such as edema, arthralgia, myalgia, and carpal tunnel syndrome, which may necessitate dose reductions in up to 40% of adults.

Children treated with GH replacement therapy rarely experience significant adverse effects. Benign increases in intracranial pressure related to GH therapy may manifest as headaches, visual changes, or altered concentrations of consciousness. This condition is generally reversible upon discontinuation of treatment. Often, GH therapy can be restarted with smaller doses without symptom recurrence. There is still no compelling evidence that GH replacement therapy is associated with an increased risk of cancers in children without prior history or risk factors.[26,35,36] It remains unclear if risk is affected in patients considered high risk. Survivors of childhood cancer may have an increased risk of abnormal growth of tissues with GH treatment, but it does not appear to increase the risk of cancer reoccurrence.[35] The risk of cancer was unrelated to duration or cumulative dose of GH treatment, but cancer mortality risk increases significantly with increasing daily dose of GH in previous cancer survivors.[36]

Nevertheless, GH replacement therapy is contraindicated in all patients with active malignancy.[26] If considering GH therapy, it would be prudent to wait for at least 1 year in children (5 years in adults) after cancer remission with the understanding that GH may potentially increase the risk of tumor recurrence.[26] Because deaths have been reported with the use of GH in children with Prader–Willi syndrome who are severely obese or suffer from respiratory impairments, use of GH is contraindicated in these individuals. Evidence from the long-term surveillance study, Safety and Appropriateness of GH treatments in Europe (SAGhE), remains inconclusive regarding GH therapy and its risk of increased morbidity.[33] Therefore, further surveillance monitoring is warranted.

► *Outcome Evaluation*

- Children with GH deficiency should be evaluated by a pediatric endocrinologist every 3 to 6 months. Monitor for an increase in height and change in height velocity to assess response to GH therapy.[24,26] Every effort should be made to maximize height before the onset of puberty. After final adult height is reached and GH is discontinued for at least

Patient Care Process: GH Deficiency in Adults

Collect Information:

- Obtain a thorough history and physical examination that may indicate the possible presence of GH deficiency, history of childhood GH deficiency, or the presence of other pituitary hormone deficiencies.
- Obtain GH and IGF-I concentrations after appropriate provocative testing.
- Review imaging tests of the hypothalamic–pituitary region to detect any anomaly.
- Perform complete medication history. Identify allergies to medications and other substances.
- Speak with patient to identify signs and symptoms of GH deficiency, preferences and beliefs, health goals, and socioeconomic factors or barriers that affect medication access and other aspects of care.

Assess the Information:

- Assess the patient's clinical signs and symptoms to determine the severity of GH deficiency.
- Assess the presence of other pituitary hormone deficiency.
- Assess the presence of metabolic abnormalities and cardiovascular and fracture risks.
- Assess risk factor for development of malignancy (history of cancer or active cancer).
- Assess if the patient has any contraindication, allergy, or drug interaction with GH therapy.

Develop a Care Plan:

- Determine if GH therapy is indicated. Initiate the appropriate GH therapy at the lower dosing range based on patient characteristics (see Table 47–3).

Implement the Care Plan:

- Initiate GH therapy based on patient preference and characteristics (see Table 47–3).
- Discuss with patient the potential effectiveness and disadvantages of existing GH treatment options.
- Address any patient concern about long-term complications of GH deficiency, its management, and possible adverse effects of GH therapy.
- Discuss with patient how to reduce the modifiable cardiovascular, metabolic, and fracture risk factors.
- Educate regarding potential for lifelong replacement therapy.
- Use motivational interviewing and coping strategies to maximize adherence.

Follow-up: Monitor and Evaluate:

- Review medication adherence.
- Assess the efficacy and adverse effects of GH therapy and consider if the patient's therapy requires any dose adjustment based on IGF-I concentration, patient response, and adverse effects.
- Monitor for improvement of metabolic, cardiovascular, bone mineral density, mood, and body composition parameters to assess response to GH therapy.

1 month, retest and reevaluate the patient using the adult GH-deficiency diagnostic criteria.[25,26]

- Although GH and IGF-I concentrations do not always correlate with growth response, measure IGF-I concentrations yearly to assess adherence to therapy and patient response. If the IGF-I concentration levels are above the laboratory-defined normal range for age or pubertal stage of the patient, the dose should be reduced.[28] IGF-I concentration may be used as a guide to gradually reduce replacement dose after epiphyseal closure.
- Routine monitoring of fasting lipid profile, bone mineral density, and body composition in children is not typically required during GH replacement but should be done before and after discontinuation of therapy.[24,28]
- In adults, measurement of serum IGF-I, along with careful clinical evaluation, appears to be the most reliable way to assess the appropriateness of the GH dose. Measure IGF-I serum concentrations 1 to 2 months during dose titration, and at approximately 6- to 12-month intervals once maintenance doses are achieved.[26] If there is no apparent or objective benefit after at least 12 to 16 months of treatment, therapy may be discontinued.[26]
- Continuously monitor for dose-related adverse effects such as edema, arthralgia, myalgia, and carpal tunnel syndrome.
- Evaluate psychological well-being.
- If initial bone DEXA scan is abnormal, reassess every 2 to 3 years.[26]
- When maintenance therapy is achieved, assess body composition (BMI, waist circumference, waist-to-hip ratio), metabolic status (fasting glucose concentration, FT_4 serum, hemoglobin A1c), cardiac risk factors (eg, fasting lipid profile), and hypothalamic–pituitary–adrenal axis function (eg, morning serum cortisol response to ACTH stimulation) at 6- to 12-month intervals.[26]

PROLACTIN

Prolactin is an essential hormone for normal production of breast milk after childbirth. It also plays a pivotal role in a variety of reproductive functions. Prolactin is regulated primarily by the hypothalamus–pituitary axis and secreted solely by the lactotroph cells of the anterior pituitary gland. Under normal conditions, secretion of prolactin is predominantly under inhibitory control by dopamine. Increases of hypothalamic thyrotropin-releasing hormone in primary hypothyroidism can stimulate the release of prolactin.

Hyperprolactinemia

▶ *Epidemiology and Etiology*

Hyperprolactinemia affects women of reproductive age more than men, and the estimated prevalence in women treated with hyperprolactinemia is 90 cases per 100,000 person years.[37] The etiologies of hyperprolactinemia are presented in Table 47–4.[4,9,23,37] Any medication that antagonizes dopamine or stimulates prolactin release can induce hyperprolactinemia.[9,23] Therefore, it is important to exclude medication-induced hyperprolactinemia from other common causes such as pregnancy, primary hypothyroidism, benign prolactin-secreting pituitary adenoma (prolactinoma), and renal insufficiency. Prolactinomas are the most common pituitary tumors. They are classified as

Patient Encounter 2, Part 1

A 34-year-old man presents to the primary care clinic for his annual wellness visit. He expresses concerns about his difficulty with training for an upcoming triathlon. He states his endurance has significantly decreased over the last few months, and his usual weight training exercises have become too challenging to continue. He started seeing a psychiatrist 3 months ago for symptoms of depression and anxiety. He is experiencing difficulty falling asleep and started taking melatonin. He becomes tearful stating that he had a motorcycle accident last year that resulted in a grade 3 concussion.

PMH: Depression, anxiety

FM: Mother with anxiety; father with hypertension

SH: Married, program analyst; sexually active

Meds: Sertraline 100 mg daily, melatonin 3 mg nightly

ROS: Head injury, weakness, anxiety, depression, sleep problems

PE: Reduced strength

HEENT: Ophthalmic examination reveals normal visual acuity and fields

VS: BP 118/67 mm Hg, P 80 beats/min, RR 16 breaths/min, T 36.6°C (97.9°F)

CV: RRR, normal S1, S2; no murmurs, rubs, or gallops

Abd: Soft, nontender, nondistended

Rectal: Heme (–) stool

Based on the information available, what signs and symptoms are suggestive of GH deficiency?

What could be a possible cause of GH deficiency in this patient?

What diagnostic tests should be performed to confirm the patient's diagnosis of GH deficiency?

microprolactinomas if they are less than 10 mm in diameter and as macroprolactinomas if they are 10 mm or larger in diameter.[37] In general, microprolactinomas rarely increase in size, but macroprolactinomas have the potential to enlarge and invade the surrounding tissues.[38]

Patient Encounter 2, Part 2

Macimorelin test: GH level of 0.9 ng/mL (mcg/L)

Lipid Panel: Total Cholesterol: 207 mg/dL (5.35 mmol/L), low-density lipoprotein (LDL) cholesterol:140 mg/dL (3.62 mmol/L), high-density lipoprotein (HDL) cholesterol: 35 mg/dL (0.91 mmol/L), triglycerides (TG): 160 mg/dL (1.81 mmol/L)

Impaired glucose tolerance test: 105 mg/dL (5.8 mmol/L) while fasting

Given this additional information, what pharmacologic treatment would be appropriate to recommend for this patient?

Table 47–4

Causes of Hyperprolactinemia[4,9,23,37]

Physiologic Causes
Pregnancy
Stress (including exercise and hypoglycemia)
Breast stimulation
Breastfeeding
Coitus
Sleep
Meal

Increased Prolactin Production
Ovarian: polycystic ovary syndrome
Oophorectomy (removal of an ovary)
Pituitary tumors
  Adenomas
  Microprolactinoma (< 10 mm diameter)
  Macroprolactinoma (≥ 10 mm diameter)
  Hypothalamic stalk interruption (prevent dopamine from reaching the pituitary)
Hypophysitis (inflammation)
Ectopic tumors

Hypothalamic Prolactin Stimulation
Primary hypothyroidism
Adrenal insufficiency

Reduced Prolactin Elimination
Chronic renal failure
Hepatic cirrhosis

Neurogenic Causes
Chest wall injury (eg, surgery, herpes zoster, burns)
Spinal cord lesions

Abnormal Molecules
Macroprolactinemia

Medications
Dopamine antagonists: antipsychotics[a], phenothiazines, metoclopramide, domperidone
Prolactin stimulators: methyldopa, reserpine, selective serotonin reuptake inhibitors, 5HT$_1$ receptor agonists, estrogens, progestins, gonadotropin-releasing hormone analogs, benzodiazepines, tricyclic and tetracyclic antidepressants, monoamine oxidase inhibitors, protease inhibitors, histamine$_2$-receptor antagonists, opioids, cocaine
Other: verapamil

Seizures

Idiopathic (Unknown)

[a] Atypicals (olanzapine and clozapine) other than risperidone may cause an early but transient elevation in prolactin.

▶ *Pathophysiology*

Hyperprolactinemia is a condition of elevated serum prolactin. It is the most common endocrine disorder of the hypothalamic–pituitary axis. High prolactin concentrations inhibit the release of gonadotropin-releasing hormone by the hypothalamus and subsequently suppress secretion of LH and FSH from the anterior pituitary (see Figure 47–1). High prolactin concentrations result in reduced gonadal hormone concentrations, often leading to reproductive dysfunction and galactorrhea (inappropriate breast milk production).

In combination with clinical symptoms, one or more serum prolactin concentrations greater than 25 ng/mL (mcg/L) will confirm the diagnosis of hyperprolactinemia in women.[37] A number of physiologic factors such as eating, exercise, and stress can transiently

Clinical Presentation and Diagnosis of Hyperprolactinemia[9,37]

General

Hyperprolactinemia most commonly affects women of reproductive age and is rare in men.

Signs and Symptoms

Premenopause women

- Headache and compromised or loss of vision caused by the prolactin-secreting tumor and its close proximity to the optic structures.
- Oligomenorrhea (infrequent menstruation), amenorrhea, galactorrhea, infertility, decreased libido.
- Increased body weight may be associated with a prolactin-secreting pituitary tumor.
- The degree of hypogonadism generally is proportionate to the degree of prolactin elevation.
- Excessive hair growth (hirsutism) and acne also may be present owing to relative androgen excess compared with low estrogen concentrations.

Men

- Decreased libido, decreased energy, erectile dysfunction, impotence, decreased sperm production, infertility, gynecomastia, and, rarely, galactorrhea.
- Impotence is unresponsive to treatment and is associated with reduced muscle mass, loss of pubic hair, and osteoporosis.

Laboratory Tests

- Prolactin serum concentrations at rest will be greater than 20 ng/mL (mcg/L) in men or 25 ng/mL (mcg/L) in women with at least three measurements.
- Obtain β-human chorionic gonadotropin (β-hCG) concentration to exclude pregnancy.
- Obtain TSH concentration to exclude primary hypothyroidism.
- Obtain blood urea nitrogen and serum creatinine tests to exclude renal failure.

Other Diagnostic Tests

- Perform MRI to locate the tumor, exclude a pseudoprolactinoma, and validate the diagnosis.
- Consider a bone mineral density test in patients with long-term hypogonadism.

Additional Clinical Sequelae

- The prolonged suppression of estrogen in premenopausal women with hyperprolactinemia leads to decreases in bone mineral density and significant risk for development of osteoporosis.
- Risk for ischemic heart disease may be increased with untreated hyperprolactinemia.

Adapted, with permission, from Jordan JK, Sheehan AH, Munir K. Pituitary gland disorders. In: DiPiro JT, Yee GC, Posey LM, Haines ST, Nolin TD, Ellingrod V, eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York City, NY: McGraw-Hill; c2020.

elevate prolactin concentrations.[9] If an intravenous line is present or planned, it is prudent to wait at least 2 hours after line insertion before measuring serum prolactin to decrease detecting transient physiologic increases in prolactin concentration.[9,23,37] Although medication-induced hyperprolactinemia is typically associated with prolactin concentrations of 25 to 100 ng/mL (mcg/L), metoclopramide, risperidone, and phenothiazines have been associated with concentrations greater than 200 ng/mL (mcg/L). However, prolactin concentrations greater than 500 ng/mL (mcg/L) are almost always associated with the presence of a macroprolactinoma.[37]

▶ *Treatment*

Desired Outcomes Because hyperprolactinemia is often associated with hypogonadism, the goals for management of hyperprolactinemia are as follows[37]:

- Normalize prolactin concentration.
- Restore normal gonadal function and fertility.
- Prevent development of osteoporosis.
- If a pituitary tumor is present:
  - Ablate or reduce tumor size to relieve tumor mass effect.
  - Preserve normal pituitary function.
  - Prevent progression of pituitary tumor or hypothalamic disease.

General Approaches to Treatment Management of drug-induced hyperprolactinemia is to discontinue the offending agent, if clinically feasible, and replace it with an appropriate alternative that does not cause hyperprolactinemia.[37] When the offending agent cannot be discontinued or dosage cannot be reduced, cautious use of hormone replacement, oral contraceptives, pharmacologic treatment for osteoporosis, aripiprazole, or dopamine agonists may be considered depending on the patient's clinical circumstances.[39] Treatment options for the management of hyperprolactinemia include (a) clinical observation, (b) pharmacologic therapy with dopamine agonists, (c) transsphenoidal pituitary adenomectomy, and (d) radiation therapy. Clinical observation and close monitoring are justifiable in patients with asymptomatic elevation of prolactin.[37] KEY CONCEPT Dopamine agonists are the first-line treatment of choice for all patients with symptomatic hyperprolactinemia; transsphenoidal surgery and radiation therapy are reserved for patients who are resistant to or severely intolerant of pharmacologic therapy (see Figure 47–5).[4,37] However, in patients with underlying psychiatric symptoms, use of dopamine agonists in addition to antipsychotic therapy may exacerbate the underlying psychosis and should be used with caution in consultation with a mental health clinician.[39]

Pharmacologic Therapy Dopamine is the principal neurotransmitter responsible for the inhibition of prolactin secretion from the anterior pituitary. Thus, dopamine agonists are the main pharmacologic therapy used for the management of hyperprolactinemia. Treatment with dopamine agonists has proven to be extremely effective in normalizing serum prolactin concentration, restoring gonadal function, decreasing tumor size, and improving visual fields.[37] Patients with macroprolactinomas

Surgery or radiotherapy required in rare cases

FIGURE 47–5. Approaches to patients with hyperprolactinemia.[4,37] In patients with hyperprolactinemia, the first step is to rule out secondary causes before comprehensive pituitary imaging with magnetic resonance imaging (MRI) and testing. Patients with asymptomatic hyperprolactinemia can be closely monitored with clinical observation without medical treatment. Patients with symptomatic prolactinoma warrant treatment with dopamine agonist. Dosage of the dopamine agonist will need to be adjusted based on patient response; in rare cases, surgery or radiotherapy may be considered in patients with lack of desirable response. (Modified from Melmed S. Pituitary-tumor endocrinopathies. N Engl J Med. 2020;382(10):937–950.)

generally require a higher dose to normalize prolactin concentrations compared with patients with microprolactinomas.[40]

Two dopamine agonists—bromocriptine and cabergoline—are used for the management of hyperprolactinemia (Table 47–5).[41] Because these two dopamine agonists are ergot derivatives, they are contraindicated in combination with potent cytochrome P450 subfamily IIIA polypeptide 4 (CYP3A4) inhibitors, including protease inhibitors, azole antifungals, and some macrolide antibiotics. Furthermore, ergot derivatives can cause constriction of peripheral and cranial blood vessels. These medications are also contraindicated in patients with uncontrolled hypertension, severe ischemic heart disease, or peripheral vascular disorders.

Bromocriptine Bromocriptine directly binds to the D2 dopamine receptors, which helps normalize prolactin concentration and reduces tumor size in patients. Treatment with bromocriptine may also restore menses and fertility in women and improve testosterone secretion, sperm count, and erectile function in men. However, bromocriptine is rarely used in practice due to the inconvenience of daily dosing. Adverse effects such as nausea, dizziness, and orthostatic hypotension further limit 5% to 10% of patients from continuing treatment. To reduce risk of adverse effects and improve patient adherence, bromocriptine may be initiated at bedtime or be administered vaginally (2.5 mg/day) at low dose.[38,42]

Cabergoline Cabergoline has a higher affinity for D2 dopamine receptors than bromocriptine and possesses a long half-life, allowing for once or twice weekly administration. Cabergoline appears to be better tolerated than bromocriptine and may be more effective in normalizing prolactin concentrations and

Table 47–5

Comparison of Dopamine Agonists for Treatment of Hyperprolactemia[41]

	Bromocriptine (Parlodel)	Cabergoline
Starting dose	1.25–2.5 mg/day at bedtime	0.5 mg/week or 0.25 mg twice/week
Titrating dose	2.5 mg increments every 2–7 days	0.25 mg twice weekly increment, up to 1 mg twice weekly every 2–4 months
Usually effective dose	2.5–15 mg/day	1–2 mg/week
Maximal dose	20 mg/day	1 mg twice weekly
Dosing frequency	Two to three divided doses per day	Once or twice weekly
Dosage in hepatic insufficiency	May be required in acute hepatitis or cirrhosis; no guidelines are available	Dose reductions may be recommended for patients with severe hepatic failure (Child-Pugh scores of 10 or higher)
Dosage in renal failure	None	None
Adverse effects	Dizziness, headache, syncope, nausea, vomiting, gastrointestinal cramps, orthostatic hypotension, nasal congestion	Similar but orthostatic hypotension less common
Cost	Moderately expensive	More expensive

restoring menses.[43] It is also effective in treating hyperprolactinemia in patients who are resistant to or intolerant of bromocriptine and in men and women with microprolactinomas and macroprolactinomas.[37,43] Given its favorable safety and efficacy profile and ease of administration, cabergoline has replaced bromocriptine as first-line therapy for the management of hyperprolactinemia.[37] Withdrawal of pergolide from the US market due to increased risk for valvular heart disease raised concerns about the safety of cabergoline. However, to date, cabergoline use in patients with hyperprolactinemia[44] or prolactinoma[45] has not been associated with clinically significant valvular heart disease. However, increased prevalence of asymptomatic mild tricuspid regurgitation was reported in 20% of patients treated with cabergoline; patients should seek cardiac evaluation if cardiac murmurs develop.[44]

Nonpharmacologic Therapy In a small number of patients who have failed or are intolerant of dopamine agonists, transsphenoidal adenomectomy may be necessary.[37] Surgical treatment is also considered in patients with nonprolactin-secreting tumors or macroprolactinomas that jeopardize the optic chiasm.[40] Nonetheless, surgical intervention does not reliably lead to long-term cure and may cause permanent complications. Radiation therapy is reserved for failures of both pharmacologic therapy and surgery.[37] However, normalization of prolactin concentration with radiation therapy may take 20 years to show full benefit, and radiation-induced hypopituitarism may require lifelong hormone replacement.

Management of Hyperprolactinemia in Pregnancy Most women with hyperprolactinemia require dopamine agonist therapy to achieve regular ovulatory cycles and pregnancy. Because restoration of the ovulatory cycle may occur immediately after initiation of therapy, it is necessary to caution patients regarding their potential to become pregnant and ensure adequate contraception when beginning therapy.[40]

Overall, there is reassuring evidence that bromocriptine use during pregnancy does not increase fetal malformations, spontaneous abortions, preterm deliveries, or multiple births.[37,46] Although experience during pregnancy is limited, cabergoline does not appear to be teratogenic.[41] Despite these data, continuation of dopamine agonists during pregnancy is generally not recommended. KEY CONCEPT Women who become pregnant while taking a dopamine agonist should discontinue treatment to minimize fetal exposure.[37]

Microadenomas rarely cause complications during pregnancy. However, untreated macroprolactinomas carry an approximate 31% risk of tumor enlargement.[37] Therefore, monitor female patients with macroprolactinomas closely for the development of headache and visual impairments. Baseline and routine visual field examinations are essential. Evidence of abnormal visual fields may indicate tumor growth and should be followed by an MRI. If tumors enlarge, bromocriptine is the preferred choice over cabergoline because of greater tolerability and efficacy with similar safety experience with this drug during pregnancy.[46]

▶ *Outcome Evaluation*

- Assess patients for tolerability to dopamine agonists.
- Monitor clinical symptoms associated with hyperprolactinemia every month for the first 3 months to assess therapeutic efficacy and assist with dose titration.
- Evaluate the patient for symptoms, such as headache, visual disturbances, menstrual cycles in women, and sexual function in men, to assess clinical response to therapy.[37]
- When the prolactin concentration is normalized and clinical symptoms of hyperprolactinemia have resolved, monitor prolactin concentration every 6 to 12 months.
- If the prolactin concentration is well controlled with dopamine agonist therapy for 2 years with significant tumor reduction, gradually taper therapy to the lowest effective dose or consider discontinuing therapy.[37] Check prolactin concentration after each dose reduction.
- If the prolactin concentrations remain unchanged for 1 year at the reduced dose, dopamine agonist therapy may be discontinued. Prolactin should be measured after 3 months and yearly thereafter.
- In patients with macroprolactinomas, monitor visual field at baseline and repeat the test 1 month after initiation of a dopamine agonist.
- Repeat the MRI in 1 year after initiating therapy or in 3 months in patients with macroprolactinoma or if an increase in symptoms or rise in prolactin concentration suggests the presence of tumor growth.[37]
- Discontinuation of therapy in patients with macroprolactinomas usually leads to tumor regrowth and recurrence of hyperprolactinemia. This decision warrants careful consideration.

Patient Care Process: Hyperprolactinemia

Collect Information:

- Review the available diagnostic data to determine tumor size and location.
- Perform complete medication history. Identify allergies to medications and other substances.
- Review the medical history, relevant laboratory tests, and physical assessment findings.
- Speak with patient and review records to identify signs and symptoms of hyperprolactinemia, preferences and beliefs, health goals, and socioeconomic factors or barriers that affect medication access and other aspects of care.

Assess the Information:

- Assess the patient's clinical signs and symptoms and prolactin level to determine the severity of hyperprolactinemia.
- Exclude other common causes of hyperprolactinemia (Table 47–4).
- Review patient's medication list to exclude medication-induced hyperprolactinemia (Table 47–4).
- Determine if the patient has a coexisting prolactin-secreting tumor and impact of the tumor.
- Assess the presence of hyperprolactinemia complications.
- Assess if the patient has any contraindication, allergy, or drug interaction to dopamine agonists.
- Determine the patient's plan regarding pregnancy because this influences treatment selection.

Develop a Care Plan:

- Initiate the appropriate dopamine agonist at the lowest effective dose for management of hyperprolactinemia (see Table 47–5). Consider if the patient's therapy requires any dose adjustment.

Implement the Care Plan:

- Discuss potential effectiveness and disadvantages of existing treatment options.
- Address any patient concern about long-term complications of hyperprolactinemia, its management, and possible adverse effects of existing dopamine agonists.
- Educate patient about risks associated with hyperprolactinemia.
- Use motivational interviewing and coaching strategies to maximize adherence.

Follow-up: Monitor and Evaluate:

- Evaluate safety and efficacy of dopamine agonist. When appropriate, be sure to make dose adjustments (Table 47–5).
- Monitor patient adherence to treatment plan using multiple sources of information.
- Monitor patients' prolactin level. If the prolactin concentration remains normal for 2 years, reassess the need to continue treatment.
- Consider bone mineral density tests in patient with long-term hypogonadism.

Abbreviations Introduced in This Chapter

AACE	American Association of Clinical Endocrinologists
ACTH	Adrenocorticotropic hormone or corticotropin
ADH	Antidiuretic hormone or vasopressin
β-hCG	β-Human chorionic gonadotropin
BMI	Body mass index
CRH	Corticotropin-releasing hormone
CYP3A4	Cytochrome P450 subfamily IIIA polypeptide 4
DEXA	Dual-energy X-ray absorptiometry
ESRD	End-stage renal disease
FSH	Follicle-stimulating hormone
FT_4	Free thyroxine or T_4
GABA	γ-Aminobutyric acid
GH	Growth hormone or somatotropin
GHIH	Growth hormone–inhibiting hormone or somatostatin
GHRH	Growth hormone–releasing hormone
GI	Gastrointestinal
GnRH	Gonadotropin-releasing hormone
GST	Glucagon-stimulation test
HDL	High-density lipoprotein
$HgbA_{1c}$	Glycated hemoglobin A1c
IGF	Insulin-like growth factor
IGFBP-3	Insulin-like growth factor-binding protein 3
IM	Intramuscular
ITT	Insulin tolerance test
LAGH	Long-acting growth hormone
LAR	Long-acting release
LDL	Low-density lipoprotein
LFT	Liver function test
LH	Luteinizing hormone
LHRH	Luteinizing hormone–releasing hormone
MRI	Magnetic resonance imaging
MSH	Melanocyte-stimulating hormone
OGTT	Oral glucose tolerance test
PRH	Prolactin-releasing hormone
SAGhE	Safety and Appropriateness of Growth hormone treatments in Europe
SC	Subcutaneous
SR	Slow release
SRL	Somatostatin receptor ligand
T_3	Triiodothyronine
T_4	Thyroxine
TG	Triglycerides
TRH	Thyrotropin-releasing hormone
TSH	Thyroid-stimulating hormone or thyrotropin
ULN	Upper limit of normal

Pregnancy and Lactation: Therapeutic Considerations

Rebecca H. Stone

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the principles of embryology and teratology.
2. Identify known teratogens and drugs of concern during lactation.
3. Compare the main sources of drug information relevant to pregnancy and lactation.
4. Evaluate and communicate the risks of a drug when taken during pregnancy or lactation.
5. Apply a systematic approach to counseling on the use of drugs during pregnancy and lactation.
6. Recommend the appropriate dose of folic acid to prevent congenital anomalies.
7. Describe physiologic changes during pregnancy and their impact on pharmacokinetics.
8. Choose an appropriate treatment for common conditions in a pregnant or lactating patient.

INTRODUCTION

This chapter will provide the general principles needed to interpret available evidence regarding medication use during pregnancy and lactation, choose an appropriate treatment and dosing strategy for common conditions in pregnancy, and counsel patients in a helpful and supportive way.

EPIDEMIOLOGY AND ETIOLOGY

Background Risks of Anomalies in Pregnancy

Table 48–1 describes the baseline risks of congenital anomalies and some obstetrical complications. This information is essential to evaluate risks associated with medication use and counsel pregnant patients.

Causes of Congenital Anomalies

Although the risk of drug-induced teratogenicity is of concern, the actual risk of birth defects from most drug exposures is small. Medications are associated with less than 1% of all congenital anomalies, although they may also interact with genetic factors.[3] It is important to evaluate and optimize drug use in pregnant patients and patients planning a pregnancy.

Other causes of anomalies include genetic causes in 25% of cases (inherited disease, gene mutation, chromosomal disorder), maternal infections (1%), maternal conditions (1%–3%; eg, pregestational diabetes, obesity), multifactorial heredity (23%–50%), and unknown causes (34%–43%).[3] Theoretical concerns regarding paternal exposure to genotoxic medication are reported, but currently no medication taken by a man has been proven teratogenic.

PATHOPHYSIOLOGY

Age of Pregnancy

The age of pregnancy can be defined as gestational or postconceptional age (PCA). Gestational age (GA) is the term used in clinical practice. It is calculated from the first day of the last menstruation or by ultrasound dating.

PCA, calculated from the day of conception, is 14 days shorter than GA if the menstrual cycle is 28 days. Some references in the field of teratology and embryology refer to PCA to describe stages of pregnancy.

Principles of Embryology

Pregnancy is divided into three development phases: implantation and predifferentiation, organogenesis (or embryogenesis), and

Table 48–1

Occurrence of Select Obstetrical Complications and Risk of Congenital Anomalies in the General Population[1-3]

	Risk of Occurrence in Population (%)
Spontaneous abortion/miscarriage (pregnancy loss that occurs after the pregnancy is known and before 20 weeks of GA; risk increases with higher maternal age)	10–15
Congenital anomalies (percentage of live births):	
• Minor malformations	14
• Major malformations at birth	3
• Major malformations at 2 years old	6
Preterm birth (< 37 completed weeks gestation)[a]	9.9
Low birth weight (< 2500 g)[b]	8.3

[a]United States data from 2016 to 2018.

[b]United States data from 2018.

GA, gestational age.

Table 48–2

Phases of Embryonic and Fetal Development[3]

Phase of Development	Stage of Pregnancy[a]	Development Description	Potential Complications
Implantation and predifferentiation	0–14 days after conception (14–28 days after LMP)	Very little contact between the blastocyst and mother's blood Pluripotent cells, capacity to repair a damage Cells are fragile, miscarriage before pregnancy is detected if too many are destroyed	Spontaneous abortion; even if stopped during this period, long half-life drugs could affect organogenesis
Organogenesis (embryogenesis)	From day 14 until the 9th week after conception (From day 28 until the 11th week after LMP)	Organs are being formed; most critical period for structural anomalies Organs are being formed at different times; sensitivity for each organ differs Refer to Figure 48–1 for the time frame of organ formation	Major or minor structural anomalies; Spontaneous abortion; neurologic impairment
Fetogenesis	After the organogenesis and until birth	The fetus grows Organs begin to function (eg, glomerular filtration) Active cell growth, proliferation, and migration (eg, CNS)	Fetal growth retardation; functional deficit (eg, renal insufficiency), neurologic impairment; spontaneous abortion, stillbirth; neonatal complications

[a] Stage of pregnancy based on a menstrual cycle of 28 days.

CNS, central nervous system; LMP, last menstrual period.

fetogenesis. Table 48–2 describes these phases and possible drug effects if taken during these phases, and Figure 48–1 illustrates the critical periods of human in utero development. KEY CONCEPT The risk of birth defects is usually higher during organogenesis.

▶ *Teratogens*

KEY CONCEPT Health professionals should know which medications have teratogenic risk. A teratogen is an exogenous agent that can modify normal embryonic or fetal development.[3] Teratogenicity can manifest as structural anomalies, functional deficit, cancer, growth restriction, neurologic impairment, or death (spontaneous abortion, stillbirth).

In utero exposure to medication near delivery can also lead to transient neonatal complications, such as withdrawal or side effects (eg, opioids, selective serotonin reuptake inhibitors, antipsychotics, lithium).[4]

Teratogenic exposure is a term preferred over *teratogen* as it considers level (dose) and timing of exposure during pregnancy to determine whether it could lead to a higher risk of a specific malformation.

Criteria have been proposed to determine whether a causal relationship between congenital anomalies and a medication is plausible when analyzing scientific documentation (teratogenic effect).[5,6] Exposure to the medication must have happened during the critical period of development of the organ for which a malformation is noticed (Figure 48–1). In addition, a pattern of anomaly or a specific syndrome must be reproducible in at least two studies conducted in different populations. A rare anomaly associated with a rare exposure is also indicative of a teratogenic effect (eg, ear anomalies and isotretinoin).

Other criteria, listed below, are considered:

- Strength of the association
- Same effects observed in animal studies
- Biological plausibility based on pharmacologic effect

Patient Encounter, Part 1

A 38-year-old patient comes to your office after a positive urine pregnancy test. You collect the following data:

Estimated Gestational Age: 8 weeks, regular menstrual cycles of 30 days

PMH: Type 2 diabetes mellitus (T2DM) diagnosed 8 years ago, hypertension and hypothyroidism diagnosed 2 years ago, obesity (BMI 42 kg/m^2), previous spontaneous singleton preterm birth at 35 weeks gestation

FH: T2DM, hypertension

SH: Latina origin. Paralegal. No use of alcohol or illicit substances. Smokes four to six cigarettes per day. Not very physically active, but tries to respect low-carb diet

Meds: Metformin 1 g orally twice daily with meals, dulaglutide 1.5 mg subcutaneously once weekly, glargine insulin 20 U subcutaneously at night, lisinopril 10 mg daily, levothyroxine 50 mcg orally once daily before breakfast

Allergy: Penicillins

ROS: Morning nausea; tiredness

VS: Wt 284 lb (129 kg), Ht 69 in. (175 cm), BP 118/72 mm Hg with large cuff, pulse 74 beats/min, RR 12 breaths/min

How will you confirm gestational age?

What prenatal workup would you perform at this time?

What is the appropriate counseling at this time?

What are the risks of drugs taken in the first weeks of pregnancy? What resources will you use to find the appropriate information?

What adjustments, if any, are needed for her current medication therapy?

Functional defects and minor anomalies

FIGURE 48–1. Embryonic and fetal development. The horizontal bars represent potential sensitivity to teratogens. The colored areas represent the more critical times. Embryonic period is in postconceptional weeks. (Reprinted with permission from Moore KL. The Developing Human. New York, NY: Elsevier, p. 976: copyright 1974.)

- Higher incidence of the anomaly in the population with the period of use of the medication (eg, thalidomide and limb anomalies)
- Dose–response relationship

With these criteria, there are approximately 30 medications or classes of medications that are considered teratogens (Table 48–3). Others are not necessarily safe: it is important to not interpret a lack of data as an absence of risk. A medication on this list is not necessarily contraindicated as severity and occurrence of malformations vary from one agent to another. Some can be used when benefits outweigh potential risks.

RISK EVALUATION

Desired Outcomes

The goal of drug selection during pregnancy and lactation is to treat conditions effectively when necessary while minimizing risk to the developing embryo/fetus or the neonate.

Medication and Pregnancy

▶ *Data Published on Medication Safety During Pregnancy*

Most available data on drug safety during pregnancy come from postmarketing reports: case reports or case series, epidemiological research using population/prescription databases or using questionnaires, manufacturer registries, or specialized pregnancy registries. Clinicians are encouraged to refer their patients taking medication to a pregnancy registry; a list of pregnancy registries is available on the Food and Drug Administration (FDA) website (www.fda.gov/pregnancyregistries).

Animal studies, now mandatory before marketing a medication, can identify high-risk medications and prevent congenital anomalies. However, they have limitations; different species do not share the same pharmacodynamics and pharmacokinetics, and animal studies usually test much higher doses than those used in clinical settings.[6]

▶ *Sources of Information on the Use of Drugs During Pregnancy and Lactation*

KEY CONCEPT Health-care professionals should be able to compare the main sources of drug information relevant to pregnancy and lactation. Some specialized information sources provide data on the use of medications during pregnancy and lactation (Table 48–4).

The Pregnancy and Lactation Labeling Rule (PLLR), was approved by the FDA and has been in effect since June 30, 2015.[8] This rule requires that the labels of all prescription drugs and biologic products approved after June 30, 2001 include narrative summaries of the risk of using them during pregnancy and lactation, presentation of data supporting the summaries, and an update of the information presented when it is outdated. It replaces the categories A, B, C, D, and X that were required before. Letters have long been criticized by experts because it is too simplistic and can lead to a misinterpretation of risk.

Drugs that were approved before June 30, 2001 do not have to include the information requested by the PLLR in the label, but manufacturers have to remove the categories A, B, C, D, and X. Manufacturers of medication approved between June 30, 2001 and June 30, 2015 have a 3- to 5-year period to comply with the PLLR.[8]

Table 48–3

Medications With Proven Teratogenic Effects in Humans[4-7]

Drug or Drug Class	Teratogenic Effects	Critical Period[a]
Alkylating agents	Malformations of many different organs	Organogenesis
Amiodarone	Transitory hypothyroidism (risk of 17%, goiter in some cases) or transitory hyperthyroidism	From 12th week after LMP
Androgens (danazol, testosterone)	Masculinization of genital organs in female fetus	From ninth week after LMP
Angiotensin-converting enzyme inhibitors; angiotensin II receptor antagonists	Renal failure, anuria, oligohydramnios, pulmonary hypoplasia, intrauterine growth restriction, limbs contracture, skull hypoplasia	Avoid in second and third trimesters. Concern with use in first trimester due to conflicting data
Anticonvulsants (first generation) • Carbamazepine • Phenytoin • Phenobarbital • Valproic acid, divalproex	NTD (carbamazepine and valproic acid); oral cleft, skeletal, urogenital, craniofacial, digital, and cardiac malformations Major malformations: up to 5%–10% depending on the agent used, with variation with dosage used (10%–15% or more for valproic acid) Valproic acid: abnormal neurologic development	Organogenesis for structural anomalies Valproic acid: whole pregnancy for neurologic impairment
Corticosteroids (systemic)	Oral cleft (risk of 3–4/1000 vs 1/1000 in general population)	Organogenesis (most critical period for palate formation: 8 and 11 weeks after LMP)
Diethylstilbestrol	Girls: cervical or vaginal adenocarcinoma, incidence: 1/1000. Structural genital anomalies (eg, of cervix, vagina) Boys: genital anomalies, spermatogenesis anomalies	First and second trimesters
Fluconazole	Skeletal and craniofacial malformations, cleft palate (with chronic oral dose ≥ 400 mg/day); cardiac septal closure anomaly (single oral dose >150 mg); miscarriage (single oral dose ≥150 mg)	Cardiac anomaly during first trimester. Others not defined, cases are reported where exposure was throughout pregnancy
Iodine (supraphysiologic dosage)	Hypothyroidism, goiter	From 12th week after LMP
Isotretinoin, other systemic retinoids (acitretin, bexarotene, etretinate), and high dose of vitamin A (vitamin A > 10,000 IU/day not recommended)	Spontaneous abortion, CNS, skull, eyes and ears malformations, micrognathia, oral cleft, cardiac malformations, thymus anomalies, mental retardation: estimated risk at 25%–30% (may be higher for neurologic development impairment) Isotretinoin and bexarotene: discontinue 1 month before pregnancy, isotretinoin prescribed under a special program called iPLEDGE Acitretin: discontinue 3 years before pregnancy	Organogenesis (risk of teratogenic effect after organogenesis not excluded)
Lithium	Cardiac malformations: risk of 0.9%–6.8% (higher risks in small studies) (baseline risk ~1%) Includes Ebstein anomaly: risk estimated at 0.05%–0.1%	Cardiac organogenesis (5–10 weeks after LMP)
Methimazole/propylthiouracil	Methimazole: aplasia cutis, choanal atresia, esophageal atresia, omphalocele, minor facial anomalies, growth delay; risk of 2%–4% Methimazole/propylthiouracil: fetal hypothyroidism in 1%–5% of newborns, goiter	First trimester Second and third trimesters
Methotrexate	Spontaneous abortion, CNS, and cranial malformations (large fontanelles, hydrocephalia, incomplete cranial ossification, craniosynostosis), oral cleft, ear, skeletal and limb malformations, mental retardation; discontinue at least one ovulatory cycle before pregnancy	Organogenesis (8–10 weeks after LMP for structural anomalies but some exceptions reported)
Misoprostol	Moebius syndrome ± limb anomalies ± CNS anomalies Abortion, preterm birth	Organogenesis Throughout pregnancy for abortion/preterm birth
Mycophenolate mofetil, mycophenolic acid	Anomalies including ear anomalies, oral cleft, micrognathia, ophthalmic, cardiac, and digital anomalies (risk of structural anomalies estimated from 20%–25%); spontaneous abortion (30%–50%)	Organogenesis (risk unknown after)
Nonsteroidal anti-inflammatory drugs	In utero closure of ductus arteriosus (constriction is rare before 27 weeks, 50%–70% at 32 weeks [GA]) and neonatal pulmonary hypertension Renal toxicity and oligohydramnios possible after prolonged use from second half of second trimester from 20 weeks of gestational age	Third trimester
Penicillamine	Cutis laxa Joints and CNS anomalies Risk probably low	Not defined
Tetracyclines	Teeth discoloration	From 16 weeks after LMP

(Continued)

Table 48–3

Medications With Proven Teratogenic Effects in Humans[4-7] (*Continued*)

Drug or Drug Class	Teratogenic Effects	Critical Period[a]
Thalidomide	Limb anomalies (amelia, phocomelia) Cardiac, urogenital, gastrointestinal, and ear malformations Risk of 20%–50% Prescribed under Thalomid REMS program	34–50 days after LMP
Trimethoprim	Cardiac and urogenital malformations, NTD, oral cleft; overall risk probably < 6%	Organogenesis
Warfarin/acenocoumarol	Before 6 weeks: baseline risk of anomalies Taken between 6 and 12 weeks: nasal hypoplasia, epiphysis dysplasia, vertebral malformations, rarely ophthalmic anomalies, scoliosis, hearing loss; risk estimated of 6%–10% and possibly dose-dependent 12 weeks after LMP: rarely, heterogeneous CNS anomalies	Between weeks 6 and 12 after LMP; some risks persist after

[a]Stages of pregnancy in this table are calculated after last menstrual period (gestational age) and not after conception to be more clinically useful.

CNS, central nervous system; LMP, last menstrual period; NTD, neural tube defect.

Communication of Information

Communication of data on medication use during pregnancy can be challenging:[9,10]

- Data may be limited or contradictory.
- Taking medications during pregnancy is a source of anxiety.
- Pregnant patients tend to overestimate their risk of an anomaly associated with medication use and to underestimate their risk associated with undertreating their condition.

KEY CONCEPT Health-care professionals should be able to evaluate and communicate the risks of a drug when taken during pregnancy or lactation. The objective is to give precise data that will help the patient make an informed decision for her health and her baby's health. Information should include a well-grounded assessment of risks, including baseline risks in the general population, risks associated with the medication, and risks of not treating the disease during pregnancy.[9]

When discussing risks[9]:

- Use absolute numbers instead of relative numbers (eg, risk of fetal malformation is approximately 3% at baseline and 6% with exposure to antiepileptic medications. Therefore, exposure to antiepileptic medication increases the absolute risk of malformation by 3%, while the relative risk of malformation doubles).
- Use negatively and positively framed information at the same time (eg, 3% chance of having a child with a malformation; 97% chance of having a child without malformation).
- Use the same denominator when discussing probabilities.

To determine a woman's risk of birth defects, obtain accurate and thorough medical, obstetrical, and pharmacotherapeutic histories (including over-the-counter medications and natural health products) and exposures to alcohol, tobacco, and other recreational drugs.[9]

KEY CONCEPT With all this information, the health-care professional should be able to apply a systematic approach to counseling on the use of drugs during pregnancy and lactation.

Preconception Care

Adverse pregnancy outcomes, including prematurity, low birth weight, and birth defects, are major health concerns. A late start in prenatal care can delay the identification and modification of risk factors that can affect pregnancy outcomes. Strategies to improve pregnancy outcomes include treating nutritional deficiencies, adequate folic acid, avoiding alcohol, substance abuse and nicotine use, optimizing the management of chronic illnesses and genetic disorders, screening for infections, vaccination (including preconception vaccine optimization and administration of influenza and Tdap during pregnancy), pregnancy planning, and reaching a healthy weight.[11]

Folic Acid

Anencephaly and spina bifida, with an estimated annual prevalence of 6.5 cases per 10,000, are the most common neural tube defects (NTDs) from an inadequate closure of the embryonic neural tube early in pregnancy.[12] Multivitamins containing folic acid reduce NTD and other congenital anomalies including oral clefts and cardiovascular, limb, and urinary tract malformations.[12,13] **KEY CONCEPT** All patients capable of childbearing should be counseled on the appropriate dose of folic acid to prevent congenital anomalies. The American College of Obstetricians and Gynecologists (ACOG) and the US Preventive Services Task Force recommend that all patients capable of pregnancy take 0.4 to 0.8 mg of folic acid daily, beginning 1 month before pregnancy and through the first 2 to 3 months, to prevent NTD.[12,14] Patients at higher risk of NTD (eg, personal or family history of NTDs, use of antiseizure medications [valproic acid and carbamazepine], maternal diabetes, obesity, and mutations in folate-related enzymes) should take higher daily doses of folic acid (eg, 1–5 mg).[12]

▶ *Impact of Physiologic Changes During Pregnancy on Pharmacokinetics*

KEY CONCEPT Several physiologic changes during pregnancy have an impact on pharmacokinetics.

Absorption Decreased gastrointestinal transit can delay drug peak effect, prolonging the time of contact of drugs with the intestinal mucosa, and possibly enhancing absorption of certain drugs. Higher gastric pH may affect absorption of weak bases or acids. Pregnancy physiologic changes may also increase skin, tissue, and lung absorption.[15]

Distribution Volume of distribution increases for most drugs during pregnancy due to plasma volume expansion and the presence of amniotic fluid, the placenta, and the fetus, thus decreasing maximal drug concentrations. In addition, hypoalbuminemia and decreased protein binding increase free fraction (active portion) of some medications.[15]

Metabolism During pregnancy, the activity of some isoenzymes is increased (eg, CYP3A4, CYP2A6, CYP2D6, CYP2C9), while activity of others is decreased (eg, CYP1A2, CYP2C19). Net impact on drug effect is often unpredictable since there is a wide interindividual variability, and some drugs are metabolized by several isoenzymes.[15]

Renal Elimination Renal blood flow and glomerular filtration increase significantly during pregnancy. The impact of this is more important for drugs that are eliminated in the urine, which results in a decrease in their half-lives.

Table 48–5 shows clinical recommendations based on pharmacokinetic changes during pregnancy for several drugs.[15]

Medication and Lactation

According to the latest policy statement from the American Academy of Pediatrics (AAP), mothers should breast-feed exclusively for 6 months and continue for 1 year if possible.[16]

Table 48–5

Altered Pharmacokinetics During Pregnancy: Clinical Implications and Management[15]

Drugs	Pharmacokinetic Changes	Recommendations and Monitoring[a]
Aminoglycosides	↑ V_d, ↑Cl, ↓ $t_{1/2}$	Monitor peaks and troughs; increase doses if necessary
Antiretrovirals	Variable Cl and C_{max}	Monitor clinical response; drug levels can be useful to adjust some drug dosages
Caffeine	↑ $t_{1/2}$ ↓ Cl (T_1, T_2, T_3)	Risk of more frequent and prolonged side effects; decrease caffeine consumption
Carbamazepine	↑ Cl ↓ $t_{1/2}$	Measure free fraction (preferably); increase dose according to clinical response and levels
Digoxin	↑ Cl ↓ C_{max}	Adjust according to clinical response and plasma levels; digoxin-like immunoreactive substance might interfere with measurement
Fluoxetine and other SSRIs	↑ Cl (T_3)	Increase dose according to clinical response
Heparin LMWH	↑ Cl (T_1, T_2, T_3)	For high-risk patients (mechanical valves, new clot on therapeutic dosing) or CKD, follow anti-XA levels. Use twice-daily administration for high-risk patients
Lamotrigine	↑ Cl (T_1, T_2, T_3)	For epilepsy: measure drug levels at least every trimester; increase dose according to clinical response and levels
Levothyroxine (LT_4)	↓ff	Increase dose at the beginning of pregnancy; follow TSH levels every 4–6 weeks until 20 weeks and once in early T_3
Lithium	↑ Cl (T_1, T_2, T_3) ↓ $t_{1/2}$	Measure drug levels every trimester and monthly in T_3; increase dose according to levels if necessary
Nicotine	↓ $t_{1/2}$ ↑ Cl (T_2, T_3)	Higher doses might be required (smoking cessation) at T_2 and T_3; however, higher nicotine plasma levels possible (increased transdermal absorption)
Nifedipine	↑ Cl (T_3)	Monitor clinical effect; increase doses/frequency if necessary. Use twice daily for extended release formulation if > 40 mg/day
Phenytoin	↓ C_{total}, ff ↑ Cl (T_3) ↓ $t_{1/2}$	If benefits out-weigh risks for use during pregnancy, measure free fraction; adjust dose according to clinical response, levels and signs of toxicity.
Valproic acid	↓ C_{total} ↑ ff	If benefits out weigh risks for use during pregnancy, measure free fraction if prepregnancy reference level available; dose will remain the same in most cases. Increase dose according to clinical response and levels

[a]Resume prepregnancy dosage after delivery in case of dosage adjustment for altered pharmacokinetics.

↑, increase; ↓, decrease; ↔, unchanged; CKD, chronic kidney disease; Cl, clearance; C_{max}, maximum serum concentration; C_{total}, total concentration; ff, free fraction; LMWH, low-molecular-weight heparin; SSRI, selective serotonin reuptake inhibitor; T, trimester; $t_{1/2}$, elimination half-life; V_d, volume of distribution.

▶ *Drug Transfer Into Breast Milk*

To study drug effects, breast-fed infant's serum drug levels could be measured to evaluate safety; however, these data are often unavailable. In most instances, the approximate quantity of drug ingested by the breast-fed infant is estimated using published measured drug concentrations in breast milk. With these data, the percentage of pediatric dose or, if a pediatric dose is not available, the relative infant dose (percentage of weight-adjusted maternal dose) can be calculated, assuming an average of 150 mL/kg/day of milk ingested by a breast-fed infant.

Percentage of pediatric dosage =

$$\frac{\text{Quantity of medication taken from milk by the baby (mg/kg/day)}}{\text{Usual initial pediatric dose (mg/kg/day)}} \times 100$$

Weight adjusted maternal dose or relative infant dose =

$$\frac{\text{Quantity of medication taken from milk by the baby (mg/kg/day)}}{\text{Maternal dose adjusted by weight (mg/kg/day)}} \times 100$$

In the latter equation, maternal dose refers to the dose used by patients in a published study or a case report, not to the dose of the actual patient.

Usually, a percentage of less than 10% of the pediatric dose or, when a pediatric dose is not available, a percentage of less than 10% of weight adjusted maternal dose is generally accepted as safe in full-term healthy infants unless a drug has a toxic side-effect profile.[17]

▶ *Drug Pharmacokinetics*

If clinical data are unavailable on drug transfer into breast milk, then drugs that are highly protein bound, have a high molecular weight, have a short half-life, have no active metabolites, and are well tolerated by children could be preferred.[17] In addition, drugs that are not orally absorbed should not cause systemic adverse effects in the breast-fed infant.

▶ *Drugs of Concern During Breast-Feeding*

KEY CONCEPT Most drugs are safe during breast-feeding. However, some drugs are of concern and require a more thorough assessment by the clinician (Table 48–6). One should also consider additive side effects of several medications.

CONDITIONS PREVALENT IN PREGNANCY AND LACTATION

KEY CONCEPT When possible, treat conditions occurring during pregnancy with nonpharmacologic treatments instead of drug therapy.

KEY CONCEPT Evaluate the need for treatment, including benefits and risks, and possibility of delaying treatment after pregnancy or breast-feeding.

For chronic diseases, please refer to the relevant chapters.

Iron-Deficiency Anemia

Anemia during pregnancy is defined as a hemoglobin level less than 11 g/dL (110 g/L; 6.83 mmol/L).[18] Maternal symptoms include fatigue, palpitations, and decreased exercise tolerance and resistance infections. Fetal risks are prematurity, low birth weight, and perinatal death. All pregnant patients should be screened for anemia, and those with iron deficiency should be treated with oral iron preparations in addition to prenatal vitamins.[18] Iron supplementation decreases the prevalence of maternal anemia

Table 48–6

Drugs of Concern During Breast-Feeding[4,17]

Drug or Class	Comments
Drugs that can decrease the breast milk production	
Clomiphene	Has been used to suppress lactation
Ergot derivatives (bromocriptine, cabergoline, ergotamine)	Have been used to suppress lactation
Estrogens	Contraceptives with ethinyl estradiol should be delayed for 3–6 weeks postpartum to decrease effect on lactation and prevent thrombosis
Pseudoephedrine	Do not use in patients with low milk production; a few doses will probably not have effect
Drugs for which use during breast-feeding may expose the neonate to a significant quantity and may necessitate a strict follow-up	
β-Blocking agents (acebutolol, atenolol, sotalol)	Neonatal β-blockade reported Concern for acebutolol, atenolol, and sotalol, but other β-blocking agents such as metoprolol, propranolol, and labetalol are safe
Amiodarone	May accumulate (long half-life); possible neonatal thyroid and cardiovascular toxicity
Antineoplastics	Neonatal myelosuppression possible
Chloramphenicol	Severe adverse effects reported when used to treat babies (blood dyscrasia, gray baby syndrome)
Ergotamine	Symptoms of ergotism (vomiting and diarrhea) reported
Illicit drugs	Unknown contents and effects
Lamotrigine	A breast-fed infant could have blood concentrations between 10% and 50% of maternal blood concentrations (variable but can be in therapeutic range); monitor for CNS side effects (sedation, hypotonia, weight gain, and poor sucking) and rash
Lithium	Up to 50% of maternal serum levels have been measured in infants; cases of infant toxicity (lethargy, cyanosis, electrocardiogram anomalies, dysthyroidism, tremors) reported; if breast-feeding, monitor infant serum lithium, creatinine, urea, and TSH levels every 4–12 weeks and other side effects (jitteriness, feeding problems, signs of dehydration)
Phenobarbital/primidone	Drowsiness and reduced weight gain reported; up to 25% of a pediatric dose can be ingested via breast milk; monitor for CNS adverse effects (sedation, hypotonia, weight gain, and poor sucking)
Radioactive iodine-131	No breast-feeding for days to weeks to achieve nonsignificant radiation levels (long radioactive half-life); monitor radioactive levels in milk before allowing breast-feeding; for diagnostic purposes, prefer Tc99m or iodine-123
Tetracyclines	Chronic use may lead to dental staining or decreased epiphyseal bone growth (theoretical)

CNS, central nervous system, TSH, thyroid stimulating hormone.

at delivery and reduces transfusion requirements. It is unclear whether supplementing nonanemic pregnant patients will improve perinatal outcomes but it reduces maternal fatigue.[18]

Nausea and Vomiting of Pregnancy (NVP)

As many as 80% of pregnant patients suffer from nausea or vomiting.[19] Taking a prenatal vitamin for 1 month before pregnancy may reduce the incidence and severity of nausea and vomiting of pregnancy (NVP). Nonpharmacologic measures, such as lifestyle (rest, avoidance of nausea triggers) and dietary changes (small/frequent meals, fluid restriction during meals, avoiding spicy/fatty foods, consuming crackers upon awakening, high protein snacks) may be considered for initial management. Acupuncture and acupressure may also be helpful.[19]

Early treatment with pyridoxine (vitamin B6) or a combination of pyridoxine and doxylamine is recommended to prevent progression to more severe NVP such as hyperemesis gravidarum. When insufficient, diphenhydramine, prochlorperazine, promethazine, ondansetron, or metoclopramide can be prescribed (Table 48–7).[19]

Pain

Pregnant or lactating patients may experience pain from preexisting conditions or from temporary pathologies (eg, musculoskeletal conditions, fibromas, migraine, etc.).

The general principles of treatment are[4,20]

- Maximize nonpharmacological measures.
- Acetaminophen is the safest analgesic during pregnancy.
- Avoid nonsteroidal anti-inflammatory drugs (NSAIDs) during the third trimester; short-term (< 72 hours) courses can be used under medical supervision during the first and second trimesters.
- Opioids are not associated with a higher risk of malformations. However, close neonatal monitoring is necessary due to possible withdrawal if opioids are taken regularly near delivery.
- Pregnancy and lactation safety data are limited for some medications (eg, pregabalin, gabapentin) and their use should be evaluated on a case-by-case basis.
- For migraine, sumatriptan can be used when other medications are not sufficient or indicated.

Urinary Tract Infections

Urinary tract infections, even asymptomatic, are associated with preterm birth, low birth weight, and preeclampsia, and treatment reduces these risks.[21,22] Untreated bacteriuria leads more often to pyelonephritis due to physiologic changes of the urinary tract.[21] Screening for asymptomatic bacteriuria is performed in the first trimester but may be repeated in high-risk patients (eg. preexistent DM, sickle cell disease, and neurogenic bladder).[21,22] Uropathogens are the same as for nonpregnant patients,[21] including multidrug-resistant strains; antibiograms are warranted. Differential diagnosis of dysuria includes sexually transmitted infections.

Antimicrobial therapy is considered for asymptomatic patients with $\geq 10^8$ colony forming units (cfu)/L or symptomatic patients with $\geq 10^5$ cfu/L of a uropathogen on a clean-catch mid-stream specimen.[22] Treatment options include β-lactams, nitrofurantoin, and fosfomycin (Table 48–7). Trimethoprim-sulfamethoxazole should be avoided during organogenesis (congenital malformations) and near term (theoretical risk of **kernicterus**).[4] Quinolones are reserved for resistant infections due to theoretical concerns of arthropathy.[4] Initiate in-hospital intravenous (IV) antibiotics for pyelonephritis.

Repeat urine culture 7 days after treatment. Suppressive prophylaxis (Table 48–7) up to 6 weeks after delivery is indicated for persistent bacteriuria despite two treatment courses, recurrent cystitis, or after a single pyelonephritis episode.[22]

Preterm Labor

Preterm birth is defined as a delivery before 37 completed weeks (< 259 days). Preterm birth, especially before 32 weeks of pregnancy, is the major cause of short- and long-term neonatal mortality and morbidity. In case of a premature delivery threat, depending on the GA, the following should be started, antenatal corticosteroids for fetal pulmonary maturation, an antibiotic to lower the risk of neonatal group B streptococcal disease, and magnesium sulfate for fetal neuroprotection.[23,24] Tocolytics can be administered in preterm labor and antibiotics in preterm premature rupture of membranes (PPROM) to prolong pregnancy.[24]

▶ *Antenatal Corticosteroids*

Administration of antenatal corticosteroids to the mother to accelerate the maturation of the fetal lungs decreases incidence and severity of neonatal respiratory distress syndrome, intraventricular hemorrhage, necrotizing enterocolitis, and death.[23] Provide a single course of antenatal corticosteroids (betamethasone or dexamethasone) to patients between 24 0/7 and 33 6/7 weeks of gestation at risk of delivery within 7 days (Table 48–7).[23] It may also be considered starting at 23 0/7 weeks or between 34 0/7 and 36 6/7 weeks if they did not receive a previous course. A single repeat course can be considered after 7 to 14 days if at less than 34 0/7 weeks and at risk of delivery within 7 days.[23]

▶ *Tocolytic Agents*

Tocolytics are used when preterm labor occurs before 33 6/7 weeks to delay delivery to complete a course of corticosteroids and allow transfer of the mother to a center with neonatal intensive care facilities. Tocolytics include magnesium sulfate, β-mimetics (terbutaline), prostaglandin inhibitors (indomethacin), oxytocin receptor blockers (atosiban, not available in the United States), and calcium channel blockers (nifedipine) (Table 48–7).[24,25] Tocolytic agents can prolong pregnancy for up to 48 hours. Magnesium sulfate is associated with significant maternal adverse effects, and indomethacin cannot be used after 32 weeks of pregnancy.[24]

FDA issued a warning regarding the use of terbutaline for tocolysis due to the risk of serious maternal adverse effects. Accordingly, its use should be limited to short-term inpatient use.[24]

▶ *Neuroprotection*

Magnesium sulfate given to patients at imminent risk of delivery before 32 0/7 weeks gestation decreases the incidence of subsequent neurologic morbidities like cerebral palsy (Table 48–7).[24,26,27]

▶ *Antibiotics for PPROM*

In the presence of PPROM, 2 days of parenteral ampicillin/erythromycin followed by 5 days of oral amoxicillin and erythromycin are associated with a delay of delivery and reduction in maternal and neonatal morbidity (Table 48–7).[27] Patients with PPROM should receive adequate intrapartum Group B *Streptococcus* (GBS) prophylaxis for the first 48 hours to prevent neonatal infection (refer to section on "GBS infection").[27,28]

Table 48–7

Medication Dosing Recommendations During Pregnancy and Lactation[12,18-50]

Drug	Dosage	Comments
Micronutrients and Vitamins		
Folic acid	0.4–0.8 mg po daily	Dosage necessary to reach RDA: 0.6 mg (pregnancy), 0.5 mg (breast-feeding)
	1–5 mg po daily	If higher risk of having a child with NTD
Iron	60–200 mg (elemental iron) po per day (divided doses if > 60–100 mg of elemental iron)	Doses to treat iron-deficiency anemia
Nausea and Vomiting		
First choices		
Diphenhydramine or dimenhydrinate	25–50 mg po four times daily as needed	Will likely cause sedation. Do not drive under the effect of these medications
Doxylamine	12.5 mg po three to four times daily as needed	
Pyridoxine	25 mg po three times daily as needed	Dose up to 200 mg daily have been used
Doxylamine + pyridoxine	10/10 mg: days 1 and 2 take two pills at bedtime; day 3 may take one pill in the morning and two at bedtime; may increase to one pill in the morning, one in the afternoon and two at bedtime (four pills daily) 20/20 mg: day 1 take one pill at bedtime; day 2 may take one pill in the morning and one at bedtime (two pills daily)	Increase to next dose if nausea persists FDA approved agents: Diclegis (10/10 mg), Bonjesta (20/20 mg) Off label: separate doxylamine and pyridoxine products
Second choices		
Metoclopramide	5–15 mg po three to four times daily as needed	Older maternal age and higher dose increase risk of extrapyramidal effects
Ondansetron	4–8 mg po three times daily as needed	QT prolongation, first trimester use associated with small increase in cardiovascular malformations and cleft palate
Prochlorperazine	25 mg twice daily as needed	Phenothiazine use with metoclopramide increases risk of extrapyramidal effects
Promethazine	12.5–25 mg four times daily as needed	Phenothiazine use with ondansetron increases risk of QT interval prolongation
Urinary Tract Infections		
Asymptomatic bacteriuria and uncomplicated acute cystitis		
Nitrofurantoin	100 mg po four times daily for 3–7 days 100 mg po twice daily (macrocrystalline—Macrobid) for 3–7 days	Avoid use in G6PD deficiency
Cefadroxil	1000 mg po twice daily for 3–7 days	
Cefprozil	500 mg po twice daily for 3–7 days	
Cephalexin	500 mg po twice daily for 3–7 days	
Amoxicillin	500 mg po three times daily for 3–7 days	Check for local resistance before prescribing
Fosfomycin	3 g po single dose	
Acute pyelonephritis		
Ampicillin + gentamicin	1–2 g IV every 6 hours + 1.5 mg/kg/dose IV every 8 hours	Switch to oral antibiotic after 48 hours afebrile and treat for a total of 10–14 days, for example: • Cephalexin 500 mg po four times daily • Cefprozil 500 mg po twice daily • Amoxicillin clavulanate 875/125 mg po twice daily
Cefazolin	1–2 g IV every 8 hours	
Cefuroxime	0.75–1.5 g IV every 8 hours	
Ceftriaxone	1–2 g IV or IM every 24 hours	
Prophylaxis		
Nitrofurantoin	50–100 mg po daily at bedtime or postcoitally as needed	Start after the end of the treatment for pyelonephritis and continue until 4–6 weeks after delivery
Cephalexin	250 mg po at bedtime or postcoitally as needed	Nitrofurantoin should be preferred to prevent resistance to cephalosporins
Fetal Lung Maturation		
Betamethasone	12 mg IM every 24 hours for two doses	A single rescue course may be considered after at least 1 or 2 weeks of treatment if gestational age is < 34 0/7 weeks and the patient is likely to give birth within the next week
Dexamethasone	6 mg IM every 12 hours for four doses	

(*Continued*)

Table 48–7

Medication Dosing Recommendations During Pregnancy and Lactation[12,18-50] (*Continued*)

Drug	Dosage	Comments
Tocolytic Agents		
Indomethacin	50 mg oral load, then 25–50 mg po every 6 up to 48 hours	Avoid after 32 weeks of pregnancy; reports of increased risk of maternal postpartum hemorrhage, and neonatal complications (eg, premature closure of the ductus arteriosus, renal insufficiency, patent ductus arteriosus, necrotizing enterocolitis) are worrisome
Magnesium sulfate	4 g IV over 30 minutes, then continuous IV infusion of 2 g/hour up to 48 hours	Contraindicated in patients with myasthenia gravis; maternal pulmonary edema and cardiac arrest have been reported Monitor blood magnesium levels Use with caution if renal impairment, contraindicated if renal failure
Nifedipine (short acting)	10–30 mg oral load (divided over at least 1 hour if > 10 mg used), then 10–20 mg every 4–8 up to 48 hours	Avoid in patients with hypotension and preload-dependent cardiac lesions such as aortic insufficiency
For neuroprotection or prevention of eclampsia		
Magnesium Sulfate	4 g IV over 30 minutes, then continuous IV infusion of 1 g/hour	Contraindicated in patients with myasthenia gravis; maternal pulmonary edema and cardiac arrest have been reported; treatment limited to 24 hours for neuroprotection Monitor blood magnesium levels Use with caution if renal impairment; contraindicated if renal failure
Preterm Premature Rupture of Membranes		
Ampicillin	2 g IV every 6 hours for 48 hours followed by amoxicillin	Ampicillin/amoxicillin are used with erythromycin
Amoxicillin	250 mg po three times daily for 5 days	
Erythromycin base	250 mg IV every 6 hours for 48 hours followed by 333 mg po three times daily for 5 days	
Preterm Labor Prevention		
17-α-Hydroxyprogesterone	250 mg IM each week	Start at 16–24 weeks' gestation if previous preterm delivery
Progesterone (micronized)	100 mg (capsules) or 90 mg (8% gel) intravaginally daily (previous preterm delivery) 200 mg intravaginally daily (short cervix)	Start at 16–24 weeks' gestation if previous preterm delivery and before 24 weeks if short cervix
Group B *Streptococcus*		
Penicillin G	5 million units IV initially, then 2.5–3 million units IV every 4 hours until delivery	First choice
Ampicillin	2 g IV initially, then 1 g IV every 4 hours until delivery	
Cefazolin	2 g IV initially, then 1 g IV every 8 hours until delivery	
Clindamycin	900 mg IV every 8 hours until delivery	Only if isolate proven sensitive to clindamycin and erythromycin, or sensitive to clindamycin and testing for inducible clindamycin resistance is negative
Vancomycin	1 g IV every 12 hours until delivery	If other options are inappropriate
Cervical Ripening/Induction of Labor		
Misoprostol	25 mcg (1/4 of 100 mcg tablet) vaginally every 3–6 hours	Check for **uterine tachysystole** with or without fetal heart rate changes. Off label use
Dinoprostone	0.5 mg gel in cervical canal, or 1–2 mg vaginal gel 10 mg extended-release vaginal insert in posterior fornix	Do not use if previous uterine surgery including cesarean section Check for uterine tachysystole with or without fetal heart rate changes
Oxytocin	Low-dose regimen: 0.5–2 mU/min, with 1–2 mU/min increase every 15–40 minutes according to contractions High-dose regimen: 6 mU/min with 3–6 mU/min increases every 15–40 minutes according to contractions	Check for uterine tachysystole and water intoxication
Postpartum Hemorrhage Treatment		
Oxytocin	10 U IM or 10–40 U per 500–1000 mL as continuous intravenous infusion	Use normal saline or lactated Ringer's; caution with bolus if cardiac disease
Methylergonovine	0.2 mg IM every 2–4 hours	Do not use in patients with hypertension, preeclampsia or cardiovascular disease

(*Continued*)

Table 48–7

Medication Dosing Recommendations During Pregnancy and Lactation[12,18-50] (*Continued*)

Drug	Dosage	Comments
Carboprost tromethamine	0.25 mg IM or intramyometrial every 15–90 minutes up to eight doses	Use with caution if asthma
Misoprostol	600–1000 mcg PO or PR	Off label use
Tranexamic acid	1 g IV over 10 minutes (repeat once if bleeding persists)	Off label use
Hyperthyroidism		
Methimazole	5–15 mg po once or twice daily (total daily dose: 10–30 mg)	Preferred agent in second and third trimesters Risk of malformation in first trimester
Propylthiouracil	50–100 mg po one to three times daily (100–600 mg divided in three daily doses)	Preferred agent in first trimester Risk of hepatotoxicity
Severe Hypertension		
Labetalol	Start with 10–20 mg IV over 2 minutes; repeated 20–80 mg every 15–30 minutes (max 300 mg/24 hours) Or 1–2 mg/min IV drip Oral formulation can be acceptable if patient is asymptomatic and no other option is available	Can exacerbate asthma symptoms May cause fetal bradycardia
Nifedipine (short acting)	10–20 mg po; could be repeated after 20 minutes, then 10–20 mg every 2–6 hours (max 180 mg/24 hours)	May cause headache, flushing, dizziness, reflex tachycardia, and maternal pulmonary edema
Hydralazine	5 mg IV or IM; repeated 5–10 mg IV every 20–40 minutes (max 20 mg IV) Or 0.5–10 mg/hour IV drip	May cause reflex tachycardia, headaches
Nonsevere Hypertension		
First choices		
Labetalol	200–2400 mg divided in two to three divided doses	Can exacerbate asthma symptoms. May cause tiredness, headaches, hepatotoxicity
Nifedipine extended release	30–120 mg po daily	May cause tachycardia, headaches, lower limb edema
Second choices		
Methyldopa	500–3000 mg divided in two to four daily doses—max 750 mg per dose	Less effective than first line agents, may cause drowsiness, depression, hemolytic anemia, positive antinuclear antibodies
Hydrochlorothiazide	12.5–50 mg po once daily	May cause hypokalemia, dehydration
Bacterial Vaginosis		
Metronidazole	250 mg po three times daily for 7 days or 500 mg orally twice a day for 7 days 0.75% vaginal gel, once or twice daily for 5 days	Can be used in all trimesters For metronidazole and clindamycin, use oral formulation during pregnancy if treatment aim is to prevent PTB
Clindamycin	300 mg po twice daily for 7 days 2% cream, 5 g intravaginally at bedtime for 7 days 100-mg ovules intravaginally at bedtime for 3 days	
Vulvovaginal Candidiasis: Refer to Chapter 85		
Mastitis		
Outpatient treatment		
Dicloxacillin	500 mg po four times daily	Treat for 10–14 days
Cephalexin	500 mg po four times daily	
Amoxicillin 875 mg + clavulanate 125 mg	One tablet po twice daily	
Inpatient treatment for more severe cases		
Oxacillin	2 g IV every 4 hours	Treat IV for 24–48 hours until afebrile then continue with outpatient treatment
Nafcillin	2 g IV every 4 hours	
Clindamycin	600–900 mg IV every 8 hours	
Vancomycin	1 g IV every 8–12 hours	If MRSA suspected or proven
Breast Candidiasis		
Mother		
Clotrimazole, miconazole, or nystatin	Topical cream	After each feeding and for 1 week after symptoms have resolved; also treat infant even if asymptomatic
Fluconazole	200–400 mg po for one dose followed by 100–200 mg po daily	If topical treatment not efficacious, add fluconazole; use until 1 week after symptoms have resolved (minimum of 2 weeks); also treat infant even if asymptomatic

(*Continued*)

Table 48–7

Medication Dosing Recommendations During Pregnancy and Lactation[12,18-50] (*Continued*)

Drug	Dosage	Comments
Infant		
Nystatin oral solution	100,000–200,000 U (1–2 mL) to be swabbed into infant's mouth four times daily, after feedings	
Clotrimazole or miconazole topical cream	Apply in a thin layer in infant's mouth four times daily, after feedings	
Other treatments for candidiasis		
Gentian violet 0.5%–1% solution	To be swabbed into infant's mouth once daily for 5 days before a feeding	Not preferred treatment, may stain clothes and skin, can cause mouth irritation/ulceration If nipples or mouth are not violet after application and the feeding, reapply the treatment

IM, intramuscular; IV, intravenous; MRSA, methicillin-resistant *Staphylococcus aureus*; NTD, neural tube defect; po, orally; PR, per rectum; PTB, preterm birth; RDA, recommended daily allowance.

Clinical Confirmation and Associated Problems of Pregnancy and Lactation

Confirmation of Pregnancy

- Positive urine or blood human chorionic gonadotropin followed by positive ultrasound, fetal heart sounds, and/or fetal movement.

Pregnancy Dating and Gestational Age

- Calculated from the first day of the last menstrual period (LMP).
- An ultrasound between 10 + 0 and 13 + 6 weeks determines gestational age based on crown-rump length and identifies multiple pregnancies.
- Due dates typically are estimated at 40 weeks of gestation; however, infants delivered between 37 and 42 weeks are considered full term.

Pregnancy Symptoms

- First trimester: Menstrual spotting, missed menses, fatigue, breast tenderness, increased urination, mood swings, nausea/vomiting, headache, heartburn, constipation
- Second trimester: Frequent urination, heartburn, constipation, dry skin, edema, **linea nigra**, **melasma**
- Third trimester: Backache, edema, shortness of breath, insomnia

Routine Pregnancy Visits

- In an uncomplicated pregnancy, visits should occur monthly until 28 weeks of gestation, every 2 to 3 weeks from 28 to 36 weeks of gestation, and then weekly until delivery.
- Assess for each of the following at each visit:
  - Blood pressure
  - Weight
  - Urine protein (dipstick)
  - Uterine size
  - Fetal heart rate
  - Fetal movement

Routine Lab Testing for Normal Pregnancies (First Trimester Unless Otherwise Indicated)

- Hemoglobin and hematocrit for anemia (repeated at 26–32 weeks)
- Blood type, Rh, red blood cell antibody screening
- Human immunodeficiency virus
- Venereal Disease Research Laboratory (VDRL) slide test for syphilis
- Rubella immunity
- Varicella immunity
- Hepatitis B surface antigen
- Urinalysis with culture for bacteriuria
- Gonorrhea and chlamydia
- Cervical cytology
- Screens for Down syndrome and neural tube defects (NTDs) NTDs (between 11 and 20 weeks)
- Gestational diabetes screening (at 24–28 weeks)
- Group B *Streptococcus* (GBS) screening (at 35–37 weeks)
- Patients at high risk for these conditions should be tested at the first visit:
  - Hypothyroidism
  - Type 2 diabetes
  - Sickle cell disease or thalassemia
  - Hepatitis C
  - Tuberculosis
  - Bacterial vaginosis

▶ *Progesterone*

Progesterone is used to reduce the risk of preterm birth in patients with singleton gestation and a prior spontaneous singleton preterm delivery and should be initiated between 16 and 24 weeks of gestation.[29,30] Administration of progesterone is also recommended in the setting of a very short cervix (≤ 20 mm) by transvaginal ultrasound before or at 24 weeks of gestation (Table 48–7).[29,30]

Group B *Streptococcus* Infection

A total of 10% to 30% of pregnant patients are colonized by GBS at term. IV antibiotics are effective in reducing the incidence of early-onset neonatal GBS infection when administered to high-risk groups including patients with GBS vaginal/rectal colonization, GBS bacteriuria in the current pregnancy, and those who previously delivered a neonate with GBS disease.[28]

All patients should be screened for colonization using a vaginal–rectal swab between 36 and 37 weeks. If treatment is indicated, it should be started at the time of membrane rupture or onset of labor, whichever comes first and continued until delivery (Table 48–7). All patients with unknown status should be treated if labor or PPROM occur before 37 weeks. IV penicillin G or ampicillin is preferred treatment. In instances of patient reported penicillin allergy, penicillin allergy testing is recommended, if available, to confirm appropriate therapy.[28] If penicillin-allergic, cefazolin (for nonanaphylactic penicillin reaction) or clindamycin (for anaphylactic penicillin reaction) can be used (refer to Table 48–7 to know when clindamycin can be used). If sensitivity to clindamycin is unknown, vancomycin should be administered.[28]

Induction of Labor

Induction of labor aims to achieve a vaginal delivery by stimulating uterine contractions before spontaneous labor. Cervical ripening is the process of cervical softening, thinning, and dilating, when the cervix is not favorable to delivery.

Mechanical methods for ripening include cervical dilators (hygroscopic dilator, Foley catheter) and extraamniotic saline infusion.[31-33] Pharmacological methods include prostaglandin E1 (eg, vaginal misoprostol) and E2 (eg, vaginal or cervical dinoprostone). Prostaglandins are used both for cervical ripening and induction of labor. The controlled-release vaginal dinoprostone is easily removed in case of uterine tachysystole, which helps to reverse it. Prostaglandins should not be used in patients with a previous cesarean section due to the increased risk of uterine rupture.[32,33]

When the cervix is deemed favorable, nonpharmacological options for producing contractions are membrane sweeping, nipple stimulation, and amniotomy.[31]

Oxytocin is the most frequently used pharmacological method of labor induction.[31] If a prostaglandin has been used, oxytocin needs to be delayed 30 to 60 minutes after the removal of dinoprostone controlled-release insert, 4 hours after the last dose of misoprostol, and 6 to 12 hours after the administration of dinoprostone gel.[31] A rare but serious complication of high cumulative dose of oxytocin is water intoxication due to its antidiuretic action.[32]

Postpartum Hemorrhage

Postpartum hemorrhage is defined by the ACOG as blood loss greater than or equal to 1000 mL or blood loss with signs or symptoms of hypovolemia within 24 hours after birth, regardless of route of delivery.[34] A blood loss greater than 500 mL after vaginal delivery is considered abnormal. Uterine atony accounts for up to 80% of primary postpartum hemorrhage, but other etiologies like genital or cervical trauma, retained placenta, and coagulopathies are also implicated.[34]

Oxytocin and carbetocin (long-acting analog of oxytocin) can prevent excessive blood loss associated with delivery and caesarian section. Of the treatment of postpartum hemorrhage, uterotonics (oxytocin, methylergonovine, carboprost tromethamine, and misoprostol) are effective in the presence of uterine atony. Methylergonovine should not be administered to patients suffering from hypertension or coronary artery disease. Carboprost tromethamine should be used with caution in asthmatic patients.[34] ACOG recommends that tranexamic acid, an antifibrinolytic agent, should be administered when uterotonics fail, and recent data indicate that it reduces mortality when given within 3 hours of birth.[34,35]

Nonpharmacologic approaches are also used, such as uterine massage or compression (tamponade). More invasive procedures ranging from transfusion to hysterectomy are used in unresponsive postpartum hemorrhages.[34]

Thyroid Disorders

Thyroid hormones increase by 50% from 7 to 16–20 weeks' gestation, then plateau until delivery. The thyroxine-stimulating hormone (TSH) reference range shifts downward by 0.5 mIU/L (μIU/mL) in the first trimester because of the beta-human chorionic gonadotropin (β-hCG) effect.[36] Universal screening of thyroid disorders in pregnancy is no longer recommended because identification and treatment of maternal subclinical hypothyroidism has not been shown to result in improved pregnancy outcomes or neurocognitive functioning in children.[36,37] Pregnant patients who are indicated for thyroid function testing are those with risk factors, such as a personal or family history of thyroid disease, type 1 diabetes, or clinical suspicion of thyroid disease. See Chapter 45 for further discussion on thyroid disorders.

Gestational (subclinical) hypothyroidism is defined by a TSH above normal pregnancy range and may be linked to adverse pregnancy outcomes. Replacement therapy is suggested for positive antithyroid peroxidase antibodies (anti-TPOAbs) and TSH above 2.5 mIU/L (strongly if above 4.0 mIU/L) or negative antibodies and TSH above 4.0 mIU/L (strongly if above 10.0 mIU/L).[36,37] To treat chronic hypothyroidism during pregnancy, initially increase prepregnancy levothyroxine dose (LT_4) by 30%. Once treatment is initiated, monitor TSH every 4 to 6 weeks until 20 weeks and once in the early third trimester to aim for TSH under 2.5 mIU/L.[36] Resume prepregnancy dosage at delivery.

Gestational hyperthyroidism is self-remitting and not associated with adverse outcomes. In Graves disease, propylthiouracil (PTU) is used until week 16 and then either continued or changed to methimazole thereafter (Tables 48–3 and 48–7).[37] Administer at the lowest effective dose to target free T_4 (FT_4) at or moderately above the reference range. Monitor fetus and neonate to detect signs of hypothyroidism (if antithyroid drugs) or hyperthyroidism (if mother is positive for thyroid-stimulating hormone receptors-stimulating antibodies [TSHR-Sabs]).

Monitor TSH levels 6 to 8 weeks after delivery in patients with thyroid disorders. Both LT_4 and antithyroid drugs can be used during lactation.[36,37]

Hypertension

Preexisting and gestational hypertension increase the risk of maternal and perinatal morbidity and mortality. Preeclampsia, caused by impaired placentation, may present with hypertension and multiple maternal complications or fetal distress. Delivery leads to cure, although transient flare or *de novo* preeclampsia occur postpartum.[38,39] Timing of delivery depends on maternal and fetal status and GA, but is not deferred past 37 weeks.[38] IV magnesium sulfate is used in prevention of eclampsia (Table 48–7).[26,38,39]

Treat severe hypertension (systolic above 160 mm Hg or diastolic above 110 mm Hg) promptly to avoid target-organ damage (Table 48–7).[38-41] It is recommended to maintain blood pressure levels between 120 to 160 and 80 to 110 mm Hg for pregnant patients with nonsevere hypertension.[40] In nonpreeclamptic hypertension, maintaining blood pressure control benefits the mother without harming the fetus.[42] Labetalol and extended release nifedipine are first-line treatments (Table 48–7).[40] Angiotensin-converting enzyme inhibitors (ACEi), angiotensin II receptor antagonists, renin inhibitors, or mineralocorticoid receptor antagonists are not recommended.[40]

The ACOG stratifies women into groups of low, moderate, or high risk for preeclampsia based on a prior maternal history of preeclampsia, diabetes, obesity, maternal age, and multiple other patient factors. To prevent preeclampsia and growth restriction, initiation of low-dose aspirin (75–160 mg daily) between 12 and 16 weeks gestation should be considered for moderate risk women and is recommended for high risk women. Additionally, calcium supplements (1.5–2.0 g elemental calcium/day) should be initiated if dietary calcium intake is low.[38,39]

Patients with hypertension around pregnancy and delivery should be instructed to monitor blood pressure up to 10 days postpartum and counseled regarding thresholds or symptoms requiring consultation.[38,39] An appointment 6 to 12 weeks postpartum is recommended to ensure correction of hypertension and proteinuria and for counseling on future pregnancies and long-term care.

Preexisting Diabetes Mellitus

For gestational diabetes mellitus (GDM) discussion, see Chapter 44. Hyperglycemia is teratogenic. Patients of childbearing age with preexistent diabetes should achieve a preconception hemoglobin A_{1c} less than 7% (0.07; 53 mmol/mol Hb) (ideally < 6.5% [0.065; 48 mmol/mol Hb]) to minimize risks of spontaneous abortions and malformations.[43] Refer to folic acid recommendations above.

Patients with preexisting DM should be screened for diabetic nephropathy and retinopathy.[43] Type 1 DM (T1DM) are tested for gestational hypothyroidism and anti-TPOAbs. Low-dose aspirin is indicated to reduce preeclampsia risks for patients with type 1 and type 2 diabetes and should be initiated as early as 12 weeks gestation and continued until delivery.[39]

Optimal control of glycemia throughout pregnancy reduces risks of macrosomia, delivery complications, fetal demise, preeclampsia, and neonatal complications.[43] Self-monitoring of blood glucose (SMBG) goals during pregnancy are fasting less than 95 mg/dL (5.3 mmol/L), premeal less than 100 mg/dL (5.6 mmol/L), 1 hour post meal less than 140 mg/dL (7.8 mmol/L), or 2 hour post meal less than 120 mg/dL (6.7 mmol/L). Standard treatment is insulin. Oral hypoglycemics are not as efficacious, cross the placenta, and long-term safety data are missing.[4,43] Continue medication until the patient is safely switched to insulin.

Intrapartum glucose is maintained between 70 mg/dL (3.9 mmol/L) and 110 mg/dL (6.1 mmol/L) to avoid fetal acidosis and neonatal hypoglycemia. Postpartum, resume two-thirds of prepregnancy insulin dosage. Metformin and insulin are safe during breast-feeding.[4]

Anticoagulation

Thromboembolic risk increases during pregnancy and up to 12 weeks postpartum. Anticoagulation with low-molecular-weight heparins or unfractionated heparin may be required antepartum and/or postpartum for some patients, even when not anticoagulated before pregnancy.[4,44] Dosage is specific to the underlying condition.

Warfarin is associated with a dose-dependent embryopathy when used between 6 and 12 weeks' gestation and with fetal and maternal bleeding when used near delivery (Table 48–3).[4,44] Its use is still recommended during pregnancy (except during those periods), in addition to low-dose aspirin, for prosthetic heart valves, which are highly thrombogenic.[44] Warfarin and heparins are safe to use during breast-feeding.[17] Direct oral anticoagulants (DOACs), which include direct thrombin inhibitors (dabigatran) and factor Xa inhibitors (rivaroxaban, apixaban, edoxaban, betrixiban), should be avoided during pregnancy and breast-feeding due to insufficient human safety and efficacy data.[44] Additionally, studies have demonstrated that these agents likely cross the placenta and are detectable in breast milk.[44]

Bacterial Vaginosis

Bacterial vaginosis is associated with spontaneous abortion, PPROM, chorioamnionitis, preterm birth, postcesarean wound

Patient Encounter, Part 2

Urine culture screening at 12 weeks reports more than 10^8 cfu/L of sensitive *Escherichia coli*. The patient was successfully treated with oral nitrofurantoin for 3 days, and urine culture a week later was negative. She tested negative for chlamydia and gonorrhea in the first trimester. At 20 weeks, she presents with polyuria and dysuria without fever or systemic symptoms. Urinalysis shows leucocytes and glycosuria, and urine culture is positive for *E. coli* again, and antibiogram does not indicate resistance to any antibiotic agents. Bacterial vaginosis testing is positive, with the presence of a homogenous, thin grayish-white vaginal discharge, vaginal pH greater than 4.5, positive whiff-amine test, clue cells on saline wet mount, and negative for pseudohyphae. She reports a history of repeated urinary tract and yeast infections, but denies symptoms after sexual intercourse or new sexual partner. Home blood glucose monitoring is at target in the fasting state and 1-hour post meals, but is elevated around 120 mg/dL (6.7 mmol/L) before lunch and dinner. Blood pressure is 148/84 mm Hg. She successfully quit smoking at 10 weeks.

Meds: Insulin glargine 40 U subcutaneously at bedtime, insulin aspart 10 U subcutaneously before every meal, labetalol 400 mg orally twice daily, aspirin 81 mg orally at bedtime, levothyroxine 75 mcg orally before breakfast, 17-α-hydroxyprogesterone 250 mg IM weekly until 36 weeks, and multivitamin containing folic acid 1 mg.

What treatment do you recommend at this time?

infection, postpartum endometritis, and pelvic inflammatory disease.[45-47] Oral or topical treatment with metronidazole or clindamycin is recommended for symptomatic pregnant and lactating patients.[45,46] Oral metronidazole or clindamycin is recommended to prevent preterm delivery in patients at high risk (Table 48–7).[46] Culture should be performed 1 month after completion of therapy since the cure rate is approximately 70%.[46]

Vulvovaginal Candidiasis

Only symptomatic vulvovaginal candidiasis should be treated in pregnant or lactating patients (Table 48–7).[45] Refer to Chapter 85.

Six- to seven-day treatments for intravaginal antifungal azoles are recommended during pregnancy to prevent recurrent episodes, but shorter courses are appropriate during breast-feeding. Oral flucanazole may be considered during lactation or if intravaginal azoles cannot be used, but should be used with caution because recent data indicate exposure during pregnancy may increase the risk of miscarriage.

Sexually Transmitted Infections

Table 48–8 presents the management of sexually transmitted infections during pregnancy and lactation, associated risks, and

Table 48–8

Management of Sexually Transmitted Infections During Pregnancy and Lactation[45,46]

	Indications for Treatment	Associated Risks During Pregnancy	When to Repeat Testing During Pregnancy	Other
Chlamydia trachomatis	All patients with a positive test, even if asymptomatic	Preterm labor; neonatal infection	Third trimester: < 25 years of age, those at increased risk of infection	Repeat testing 3–4 weeks and 3 months after therapy
Treatment	First choice: Azithromycin 1 g po once Alternative choices: Amoxicillin 500 mg po three times daily for 7 days Erythromycin base 500 mg po four times daily for 7 days or 250 mg po four times daily for 14 days Erythromycin ethylsuccinate 800 mg po four times daily for 7 days or 400 mg po four times daily for 14 days Doxycycline 100 mg po twice daily for 7 days only during lactation (contraindicated during pregnancy)			
Gonorrhea	All patients with a positive test, even if asymptomatic	Preterm labor, neonatal infection	Third trimester: if first screening positive or if at risk of reinfection	Repeat testing 2 weeks and 3 months after treatment
Treatment (uncomplicated infection of pharynx, cervix, urethra, rectum)	First choice: ceftriaxone 250 mg IM once + azithromycin 1 g po once Second choice during breast-feeding: ceftriaxone 250 mg IM once + doxycycline 100 mg po twice daily for 7 days (doxycycline contraindicated during pregnancy)			
Genital herpes simplex	Active lesions, disseminated; Starting at 36 weeks: prevention of recurrence at term	Neonatal infection, especially if acquired near time of delivery (30%–50%)	No routine testing recommended	Cesarean section if active genital lesions at delivery; evaluate newborn for herpes infection
Treatment	**First episode:** Acyclovir: 400 mg po three times daily for 7–10 days, or 200 mg five times daily for 7–10 days Valacyclovir: 1000 mg po twice daily for 7–10 days **Recurrent episodes:** Acyclovir: 400 mg po three times daily for 5 days, or 800 mg twice daily for 5 days, or 800 mg three times daily for 2 days Valacyclovir: 500 mg po twice daily for 3 days **Suppressive therapy:** start at 36 weeks of gestation (or earlier if at risk of preterm delivery) until delivery Acyclovir: 400 mg po three times daily Valacyclovir: 500 mg po twice daily			
Syphilis	All patients with confirmed positive serology	In utero fetal and neonatal infection; congenital malformations	At 28–32 weeks and at delivery if at risk of reinfection, if untested before, if positive serology in the first trimester, or if was previous stillborn at > 20 weeks	Therapy is efficacious to treat the fetus and prevent transmission; be aware of Jarisch–Herxheimer reaction; fetal evaluation should include ultrasounds
Treatment	Desensitize penicillin-allergic patients Primary, secondary, or early latent: Benzathine penicillin G 2.4 million units IM once Late latent or of unknown duration or tertiary: Benzathine penicillin G 2.4 million units IM three times at 1-week interval			
Trichomoniasis	Symptomatic patients	PPROM, preterm birth, low birth weight; neonatal infection		Therapy does not decrease perinatal mortality
Treatment	Metronidazole: 500 mg twice daily for 7 days, or 2 g po single dose Consider deferring breastfeeding for 12–24 hours after single 2 g dose			

IM, intramuscular; IV, intravenous; po, orally; PPROM, preterm premature rupture of membranes.

Patient Encounter, Part 3

At 38 weeks' gestation, the patient presents with rapidly progressing edema, unusual headache, blurry vision, and blood pressure persistently over 160/100 mm Hg. Her reflexes are brisk. 24 hour urine collection shows 350 mg/dL (3.5 g/L) protein, serum creatinine is 1.5 mg/dL (133 μmol/L). Remaining preeclampsia workup (complete blood count [CBC], liver enzymes, lactate dehydrogenase, and creatinine) is normal. Nonstress test is reassuring and cervix. Cervix is closed. The fetus had an estimated fetal weight at 50th percentile and was in cephalic position. Vaginal–rectal swab was positive for group B *Streptococcus* (GBS). She has a confirmed allergy to penicillin.

Meds: Insulin glargine 20 U subcutaneously at awakening, 25 U subcutaneously at bedtime, insulin aspart 20 U subcutaneously before every meal, labetalol 400 mg orally three times daily, aspirin 81 mg orally at bedtime, levothyroxine 100 mcg orally before breakfast, and multivitamin containing folic acid 1 mg.

What is your assessment of this patient's condition and what will you recommend now?

recommended follow-up.[45] Treatment of all recent sexual partners is mandatory.

Patient Encounter, Part 4

After 12 hours of labor, the patient delivers vaginally a 7.8 lb (3.5 kg) baby. She is not sure if she should breast-feed because of her chronic medications.

What treatment plan do you recommend after delivery?

What surveillance do you suggest for the newborn/baby?

Can she breast-feed while taking her medications?

Enhancement of Lactation

Insufficient milk production is diagnosed when breast-feeding cannot meet neonate's requirements. Several factors affect milk production including fatigue, stress, smoking, premature delivery, cesarean section, pain, and some medications (Table 48–6). Optimization of breast-feeding techniques is the first-line strategy. Prolactin is the main hormone linked to milk production. No drug is currently approved by the FDA or recommended by the American Academy of Breastfeeding for lactation enhancement, but dopamine antagonists, metoclopramide, and domperidone (not available in the United States), which increase prolactin levels, have been used for this purpose.[48,49] Metoclopramide's maternal adverse effects include fatigue, irritability, headache, and extrapyramidal symptoms. Domperidone has been associated with abnormal heart rhythm and sudden cardiac death in susceptible individuals; caution is advised when prescribing it with other drugs that prolong the QT interval or that inhibit its metabolism or for patients with underlying cardiac conditions.[48] Very few adverse effects in the infant have been reported.

Patient Care Process

Collect Information:

- Complete medical and obstetrical history.
- Inquire about disorders evolution and last follow-up with the treating physician.
- Conduct medication history (past/current treatments, compliance, efficacy, and safety).
- Verify immunization status.
- Assess for pregnancy signs and symptoms.
- Perform physical examination.
- Evaluate nutritional status and socioeconomic environment.
- Perform first trimester routine lab testing.
- Order serum drug levels.

Assess the Information:

- Evaluate benefits and risks for mother and fetus of continuing medications.
- Assess efficacy, safety, and patient adherence, and screen for drug interactions.
- Evaluate whether safer and more effective alternative are available.

Develop a Care Plan:

- Choose treatments with evidence of benefit and safety during pregnancy or that cannot be delayed until after delivery and/or after breast-feeding is finished (Table 48–7).
- Address patient concerns (risks of medication or of relapse if condition is untreated, prescription coverage and access to care).
- Treat pregnancy symptoms (eg, nausea) if needed.
- When possible, use nonpharmacologic treatments.

Implement the Care Plan:

- Recommend appropriate folic acid and multivitamins.
- Counsel on lifestyle (healthy diet, exercise, avoidance of tobacco, alcohol, and illicit or unnecessary drugs).
- Encourage breast-feeding. If breast-feeding, choose drugs with the best safety profile.
- Communicate information to all other health-care professionals to ensure continuity of care.

Follow-up: Monitor and Evaluate:

- Assess adherence, effectiveness, and safety of treatment at each prenatal visit.
- Review and repeat assessments as necessary.
- Monitor infants for birth defects, developmental delays, or unusual reactions, and report suspected drug-related reactions to the FDA or pharmaceutical companies.

Mastitis

Bacterial mastitis, seen typically within the first 6 weeks of breast-feeding, is characterized by localized signs of inflammation and engorgement. Fever, shivering, and malaise can occur. The most commonly encountered bacteria include *Staphylococcus aureus* (including methicillin-resistant), followed by *Streptococcus*, *Staphylococcus epidermidis*, and *Escherichia coli.*[50]

Cold or warm compresses and more frequent breast-feeding/breast pumping should be encouraged. Antibiotics (Table 48–7) and analgesics (eg, acetaminophen, NSAIDs) can be used to relieve pain.[17,50] Confirm abscess suspicion with ultrasound before surgical drainage.

Breast Candidiasis

Candidiasis (most commonly *Candida albicans*) presents with severe and persistent nipple pain, usually more intense during and immediately after breast-feeding. Breast-fed infants can be symptomatic or asymptomatic. It is recommended to breast-feed more frequently for a short period of time. Clothes and towels in contact with breasts and infant's mouth should be washed in hot water. Antifungal treatment must be given to mother and neonate simultaneously (Table 48–7). Analgesics (eg, acetaminophen, NSAIDs) can be used.[50]

ACKNOWLEDGMENT

The authors and editors wish to acknowledge and thank Drs. Ema Ferreira, Caroline Morin, and Marie-Lou Tardif, authors of this chapter in the first through fifth editions of this book.

Abbreviations Introduced in This Chapter

AAP	American Academy of Pediatrics
ACEi	Angiotensin-converting enzyme inhibitors
ACOG	American College of Obstetricians and Gynecologists
anti-TPOAbs	Antithyroid peroxidase antibodies
β-hCG	Beta-human chorionic gonadotropin
CNS	Central nervous system
DM	Diabetes mellitus
GA	Gestational age
GBS	Group B *Streptococcus*
GDM	Gestational diabetes mellitus
LMP	Last menstrual period
LT_4	Levothyroxine
NSAID	Nonsteroidal anti-inflammatory drug
NTD	Neural tube defect
OTIS	Organization of Teratology Information Specialists
PCA	Postconceptional age
PPROM	Preterm Premature Rupture of Membranes
PTU	Propylthiouracil
SMBG	Self-monitoring of blood glucose
STEPS	System for Thalidomide Education and Prescribing Safety
T1DM	Type 1 diabetes mellitus
T2DM	Type 2 diabetes mellitus
T_4	Thyroxine
TSH	Thyroxine-stimulating hormone
TSHR-Sabs	Thyroid-stimulating hormone receptors-stimulating antibodies
VDRL	Venereal Disease Research Laboratory

49 Contraception

Julia M. Koehler and Kathleen B. Haynes

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Discuss the physiology of the female reproductive system.
2. Compare the efficacy of oral contraceptives with that of other methods of contraception.
3. State the mechanism of action of hormonal contraceptives.
4. Discuss adverse effects, risks, and contraindications associated with the use of contraceptives and recommend strategies for minimizing or eliminating such risks.
5. Describe advantages and disadvantages of various contraceptives, including oral and nonoral formulations.
6. Cite important drug interactions that may occur with oral contraceptives.
7. Provide appropriate patient education regarding the use of oral and barrier methods of contraception.
8. Discuss how emergency contraception may be employed to prevent unintended pregnancy.

INTRODUCTION

Historically, the 1950s was an important time in the control of human fertility. It was during that decade that the first combination hormonal contraceptives (CHCs) were developed. Shortly after the discovery that the exogenous administration of hormones such as progesterone successfully blocked ovulation, the use of hormonal steroids quickly became the most popular method of contraception worldwide. CHCs are the most commonly used reversible form of contraception in the United States today, with an estimated 9.1 million women users.[1] Studies of women of childbearing age (15–49 years) in the United States estimate that 64.9% are currently using a contraceptive method.[1] Since the introduction of oral contraceptives, many additional contraceptive forms have been developed and are available for use in the United States, including transdermal systems, transvaginal systems, and intrauterine devices (IUDs). These additional forms of contraception offer women effective and potentially more convenient alternatives to oral contraceptives.

EPIDEMIOLOGY

According to the National Survey of Family Growth, approximately 6.37 million pregnancies occur annually in the United States.[2] It is estimated that nearly half of all pregnancies that occur each year in the United States are unintended, often either due to lack of or imperfect contraceptive use.[2,3] A survey of women of reproductive age in the United States between 2015 and 2017 revealed that approximately 35% were not using any form of contraception.[1] In addition, many women may use their chosen method of contraception imperfectly, which can increase the risk of unintended pregnancy. For patients with certain medical conditions, such as epilepsy, hypertension, ischemic heart disease, sickle cell disease, lupus, or thromboembolic mutations, unintended pregnancy can further increase the risk for adverse health events.[4,5] The provision of appropriate and adequate instruction to patients regarding how to use contraceptive methods effectively is essential to reduce the risk of unintended pregnancy and, for some women, the associated increase in risk for adverse health-related events.

Exposure to sexually transmitted infections (STIs) is also a concern for women who are sexually active. A 2019 STI surveillance report from the Centers for Disease Control (CDC) indicated that newly reported cases of chlamydia, gonorrhea, and syphilis are on the rise.[6] Given that not all methods of contraception protect the user against STIs, the provision of proper patient education by healthcare professionals regarding this risk is absolutely essential.

PHYSIOLOGY

The female menstrual cycle is divided into four functional phases: follicular, ovulatory, luteal, and menstrual.[4] The follicular phase begins the cycle, and ovulation generally occurs around day 14. The luteal phase then begins and continues until menstruation occurs.[4] The menstrual cycle is regulated by a negative-feedback hormone loop between the hypothalamus, anterior pituitary gland, and ovaries[4] (Figure 49–1).

Initially, the hypothalamus releases gonadotropin-releasing hormone (GnRH), which stimulates the anterior pituitary to produce follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The levels of FSH and LH released vary depending on the phase of the menstrual cycle. Just prior to ovulation, FSH and LH both are at their peak levels. The FSH helps to promote growth of the follicle in preparation for ovulation by causing granulosa cells lining the follicle to grow and produce estrogen. LH promotes androgen production by theca cells in the follicle, promotes ovulation and oocyte maturation, and converts granulosa cells to cells that secrete progesterone after ovulation.

FIGURE 49–1. Menstrual cycle events. [a]Estradiol: 40 pg/mL = 147 pmol/L; 250 to 400 pg/mL = 918 to 1468 pmol/L; 125 to 250 pg/mL = 459 to 918 pmol/L. [b]Progesterone: 1 ng/mL = 3.18 nmol/L; 10 to 15 ng/mL = 32 to 48 nmol/L. (FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; HCG, human chorionic gonadotropin LH, leutinizing hormone.) (Adapted with permission from Nelson AL, Shulman L. Menstrual cycle: normal patterns, menstrual disorders, and menstrually related problems. In: Hatcher RA, Nelson AL, Trussel J, et al. Contraceptive Technology, 21st ed. New York, NY: Ayer Company Publishers, Inc.; 2018:1–61.)

Conception is most likely to occur when viable sperm are present in the upper region of the reproductive tract at the time of ovulation. Fertilization occurs when a spermatozoan penetrates an ovum. Approximately 6 to 8 days after ovulation, attachment of the early embryo to the lining of the uterine cavity—implantation—occurs.

CLINICAL PRESENTATION AND DIAGNOSIS

Goals of Contraception/Desired Outcome

The most common goal of contraception is the prevention of pregnancy. However, some patients use contraceptive methods for other benefits, such as menstrual cycle regulation, reduction of premenstrual symptoms, or treatment of acne.

Choice of Contraceptives: Important Considerations

When helping a patient with contraceptive selection, the most important goal is selecting a safe, effective, and patient-centered option. It is imperative to explain the side effects, safety concerns, and noncontraceptive benefits of each alternative to the patient so that she may make an informed decision. Fertility goals vary for each patient. It must be determined whether the goal is to postpone conception, space out the next pregnancy, or avoid further pregnancy altogether. Also, a clinician must understand the patient's desire to have or not have a regular bleeding pattern, because many contraceptives will affect menses.

As discussed later in this chapter, contraindications exist for various forms of contraception. Patients may be evaluated by a healthcare professional to rule out medical contraindications to certain contraceptives, although a physical examination is not required and pharmacists can prescribe contraceptives in some states. Clinicians also should review family history for potential risks with certain forms of birth control.

Sexual behavior of the female must be determined to understand the risk for STIs. Women not in a monogamous relationship must consider their risk of STIs as a factor in their contraceptive decision. Some barrier methods protect against STIs, but hormonal contraceptives do not prevent STIs if used alone.

Personal preference plays a large role when determining the best contraceptive option. For instance, if a woman is not interested in using a method that interrupts sexual activity, then a diaphragm would be an inappropriate choice. Preference of the sexual partner may also be important. Certain agents such as male condoms require the male partner to play an active role in contraception. Patients must also consider their religious beliefs and cultural practices as some forms of birth control may violate certain religious rules or cultural beliefs.

Cost may also be an issue for patients. Insurance may not cover all forms of contraception, and patients may have to bear the entire cost for certain options.

Efficacy of Contraceptives

Table 49–1 shows the percentage of women who experience unintended pregnancy within 1 year of contraceptive use with ongoing sexual activity.[4]

TREATMENT

Oral Contraceptives (Combination)

CHCs contain a synthetic estrogen (either ethinyl estradiol [EE], which is pharmacologically active, or estradiol valerate, which is metabolized to estradiol and valeric acid) and one of several steroids with progestational activity. Progestins found in various oral contraceptives can include norethindrone, norethindrone acetate, ethynodiol diacetate, norgestrel, levonorgestrel, desogestrel, norgestimate, drospirenone, or dienogest.

The primary mechanism by which CHCs prevent pregnancy is through inhibition of ovulation. FSH and LH regulate the production of estrogen and progesterone by the ovaries. Secretion of estrogen and progesterone by the ovaries occurs in a cyclic manner, which determines the regular hormonal changes that occur in the uterus, vagina, and cervix associated with the menstrual cycle. Cyclic changes in the levels of estrogen and progesterone in the blood, together with FSH and LH, modulate the development of ova and the occurrence of ovulation. The estrogen component of CHCs is most active in inhibiting FSH release.[4] However, at sufficiently high doses, estrogens also may cause inhibition of LH release. In low-dose CHCs (≤ 35 mcg EE), the progestin component causes suppression of LH.[4] Ovulation is prevented by this suppression of the midcycle surge of both FSH and LH and mimics the physiologic changes that occur during pregnancy.

Although suppression of FSH and LH is the primary mechanism by which CHCs prevent ovulation, there are other mechanisms by which these hormones work to prevent pregnancy. Other mechanisms include reduced penetration of the egg by sperm, reduced implantation of fertilized eggs, thickening of cervical mucus to prevent sperm penetration into the upper genital tract, and slowed tubal motility, which may delay transport of sperm.[4]

Table 49–1

Unintended Pregnancy Rates: Percentage of Women Experiencing Unintended Pregnancy Within First Year of Use[4,7]

Method	Typical Use[a]	Perfect Use[b]
No method	85	85
Spermicide alone	21	16
Withdrawal	20	4
Fertility awareness–based methods	24	
Standard days method	12	5
Two-day method	14	4
Ovulation method	23	3
Symptothermal method	2	0.4
Sponge		
Parous women	27	20
Nulliparous women	14	9
Diaphragm with spermicide	17	16
Cervical cap	16–32	9–26
Condom with spermicide		
Female	21	5
Male	13	2
Combination pill and progestin-only pill	7	0.3
Transdermal patch	7	0.3
Vaginal ring	7	0.3
Depo-Provera	6	0.2
IUD		
ParaGard	0.8	0.6
Kyleena	0.2	0.2
Mirena	0.1	0.1
Liletta	0.1	0.1
Skyla	0.4	0.3
Implanon	0.05	0.05
Female sterilization	0.5	0.5
Male sterilization	0.15	0.1

[a] Among typical couples who initiate use of a method (not necessarily for the first time), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason.

[b] Among couples who initiate use of a method (not necessarily for the first time) and who use it *perfectly* (both consistently and correctly), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason.

IUD, intrauterine device.

Thus, in addition to inhibiting ovulation, CHCs induce changes in the cervical mucus and endometrium that make sperm transport and implantation of the embryo unlikely.[4]

Table 49–2 contains a partial listing of the many oral contraceptives available in the United States.[7] Since the mid-1960s, EE has been the primary estrogen used in most CHCs. However, the amount of EE used in CHCs has been reduced since that time, with most products now containing 35 mcg or less of EE. In addition, to reduce side effects and improve tolerability associated with oral contraceptive use, newer progestins and different routes of administration have been explored. In an attempt to minimize the undesirable androgenic side effects associated with the progestins of CHCs, the original synthetic progestins were modified to create "third generation" progestins (eg, desogestrel and norgestimate), and "fourth generation" progestins with antiandrogenic properties (eg, drospirenone).

Table 49–2

Selected Available Oral Contraceptives[7]

Estrogen (mcg/tablet)	Progestin (mg/tablet)	Examples of Brand Names
Monophasic Preparations		
EE (20)	Norethindrone acetate (1)	Blisovi Fe 1/20, Blisovi 24 Fe, Junel 1/20, Junel Fe 1/20, Junel Fe 24, Larin 1/20, Larin Fe 1/20, Larin 24 Fe, Loestrin 21 1/20, Loestrin Fe 1/20, Lomedia 24 Fe, Mibelas 24 Fe, Microgestin 1/20, Microgestin Fe 1/20, Minastrin 24 Fe, Tarina Fe 1/20, Taytulla
EE (20)	Levonorgestrel (0.09)	Amethyst
EE (20)	Levonorgestrel (0.1)	Aviane, Balcoltra[a], Falmina, Lessina, Lutera, Orsythia, Sronyx, Vienva
EE (20)	Drospirenone (3)	Beyaz[a], Gianvi, Loryna, Nikki, Vestura, Yaz
EE (20)	Desogestrel (0.15)	Azurette
EE (25)	Norethindrone (0.8)	Generess Fe, Kaitlib Fe
EE (30)	Desogestrel (0.15)	Apri, Desogen, Emoquette, Enskyce, Reclipsen
EE (30)	Levonorgestrel (0.15)	Altavera, Kurvelo, Levora, Marlissa, Portia
EE (30)	Drospirenone (3)	Ocella, Safyral[a], Syeda, Tydemy[a], Yasmin, Zarah
EE (30)	Norgestrel (0.3)	Cryselle, Elinest, Lo/Ovral-28, Low-Ogestrel
EE (30)	Norethindrone acetate (1.5)	Blisovi Fe 1.5/30, Junel 1.5/30, Junel Fe 1.5/30, Larin 1.5/30, Larin Fe 1.5/30, Loestrin 21 1.5/30, Loestrin Fe 1.5/30, Microgestin 1.5/30, Microgestin Fe 1.5/30
EE (35)	Norgestimate (0.25)	Estarylla, Femynor, Mili, Mono-Linyah, MonoNessa, Previfem, Sprintec
EE (35)	Norethindrone (0.4)	Balziva, Briellyn, Femcon Fe, Gildagia, Ovcon 35, Philith, Vyfemla, Wymza Fe, Zenchent, Zenchent Fe, Zeosa
EE (35)	Norethindrone (0.5)	Modicon, Nortrel 0.5/35, Wera
EE (35)	Norethindrone (1)	Alyacen 1/35, Cyclafem 1/35, Dasetta 1/35, Norinyl 1/35, Nortrel 1/35, Pirmella 1/35
EE (35)	Ethynodiol diacetate (1)	Kelnor 1/35, Zovia 1/35E
EE (50)	Norgestrel (0.5)	Ogestrel
EE (50)	Ethynodiol diacetate (1)	Zovia 1/50E
Biphasic Preparations		
EE (10)	Norethindrone acetate (1,0)	Lo Loestrin Fe[b]
EE (20,0,10)	Desogestrel (0.15,0,0)	Azurette[b], Bekyree[b], Kariva[b], Kimidess[b], Pimtrea[b], Viorele[b]
Triphasic Preparations		
EE (20,30,35)	Northindrone acetate (1)	Estrostep Fe, Tilia Fe, Tri-Legest Fe
EE (30,40,30)	Levonorgestrel (0.05,0.075,0.125)	Enpresse, Levonest, Myzilra, Trivora
EE (35)	Norgestimate (0.18,0.215,0.25)	Tri-Estarylla, Tri Femynor, Tri-Mili, Tri-Linyah, Tri-Nessa, Tri-Previfem, Tri-Sprintec
EE (35)	Norethindrone (0.5,1,0.5)	Aranelle, Leena, Tri-Norinyl
EE (35)	Norethindrone (0.5,0.75,1)	Alyacen 7/7/7, Cyclafem 7/7/7, Dasetta 7/7/7, Nortrel 7/7/7, Pirmella 7/7/7
EE (25)	Norgestimate (0.18,0.215,0.25)	Tri-Lo-Estarylla, Tri-Lo-Marzia, Tri-Lo-Sprintec
EE (25)	Desogestrel (0.1,0.125,0.15)	Caziant, Cyclessa, Velivet
Quadriphasic Preparations		
Estradiol valerate (3,2,2,1)	Dienogest (0,2,3,0)	Natazia
Extended Cycle Preparations		
EE (20)	Levonorgestrel (0.1)	Amethia Lo, Camrese Lo
EE (30)	Levonorgestrel (0.15)	Introvale, Jolessa, Quasense, Seasonale, Setlakin
EE (20,25,30,10)	Levonorgestrel (0.15,0)	Fayosim, Rivelsa, Quartette
EE (20,10)	Levonorgestrel (0.1)	LoSeasonique
EE (30,10)	Levonorgestrel (0.15)	Amethia, Ashlyna, Camrese, Daysee, Seasonique
Progestin-Only Preparations		
None	Norethindrone (0.35)	Camila, Errin, Deblitane, Heather, Jencycla, Jolivette, Nora-BE
None	Drospirenone (4,0)	Slynd

[a] Each tablet also contains 451 mcg of levomefolate calcium.

[b] Some references may classify as monophasic since the variation in hormone content does not occur during the first 3 weeks of the pill pack.

EE, ethinyl estradiol

CHCs are available in monophasic, biphasic, triphasic, and quadriphasic preparations. Monophasic preparations contain fixed doses of estrogen and progestin in each active pill. Although all four preparations contain both estrogens and progestins, biphasic, triphasic, and quadriphasic preparations contain varying proportions of one or both hormones during the pill cycle. These preparations were introduced to reduce a patient's cumulative exposure to progestins, as well as to mimic more closely the hormonal changes of the menstrual cycle. However, there is no evidence to suggest that the multiphasic preparations offer significant clinical advantage over monophasic pills.[7]

Most traditional CHCs are packaged as 21/7 cycles (ie, 21 days of active pills and 7 days of placebo). However, newer regimens offer either fewer hormone-free days per traditional, 28-day pill cycle, or extended (or in some cases continuous) cycles (84- or 365-day pill cycle), which may allow for fewer withdrawal bleeds per year and fewer menstrual-related side effects (eg, menstrual pain, bloating, headaches) for some women.

▶ Noncontraceptive Benefits of Combination Hormonal Contraceptives

In addition to preventing pregnancy, there are several noncontraceptive benefits associated with the use of CHCs.

Reduction in the Risk of Endometrial Cancer The risk of endometrial cancer among women who have used oral contraceptives for at least 1 and 10 years is approximately 40% and 80% less than the risk in women who have never used oral contraceptives, respectively.[4,8] There is additional evidence to suggest that this reduced risk may persist for up to 20 years following discontinuation of oral contraceptives.[4,8]

Reduction in the Risk of Ovarian Cancer When compared with women who have never used oral contraceptives, women who have used oral contraceptives for at least 1 year are less likely to develop ovarian cancer than those who have never used oral contraceptives. While there is evidence to suggest the reduced risk of ovarian cancer may persist for years following discontinuation of oral contraceptives,[9] a recent study suggested possible attenuation of the protective effect of CHCs against ovarian cancer with use after 35 years of age.[10]

Improved Regulation of Menstruation and Reduction in the Risk of Anemia Women who take oral contraceptives typically experience more regular menstrual cycles. In general, oral contraceptive use is associated with less cramping and dysmenorrhea.[4,7] Also, women who take oral contraceptives experience less blood loss with each menstrual period.[4,11] Some studies suggest that oral contraceptive use decreases overall monthly menstrual flow by 60% or more and conserves hemoglobin and ferritin levels, which may be particularly beneficial in women who are anemic or at risk for anemia.[4] In addition, some CHC formulations contain iron, which may also minimize the risk for anemia. (See **Unique Oral Contraceptives** section.) For more information on menstruation-related disorders, see Chapter 50.

Reduction in the Risk of Fetal Neural Tube Defects While CHCs are not 100% effective at preventing pregnancy, it is possible that a woman may conceive while taking a CHC. In addition, many women may become pregnant very soon after discontinuing a CHC. To decrease the risk of neural tube defects in the fetuses associated with such pregnancies, a CHC formulation that contain a source of folate in every pill is also available.[4]

Relief from Symptoms Associated with Premenstrual Dysphoric Disorder CHCs have been widely used for the treatment of premenstrual dysphoric disorder (PMDD). Current evidence suggests that these agents are most effective at targeting the physical symptoms associated with the disorder and less effective in treating mood-related symptoms.[12] Although multiphasic CHCs have been used effectively in the treatment of PMDD, monophasic preparations may yield fewer mood swings and may be easier to manage. Several drospirenone-containing CHCs now carry a US Food and Drug Administration (FDA)-approved indication for PMDD, including Yaz, Beyaz, Gianvi, Loryna, Nikki, and Vestura.[7]

Prevention of Benign Breast Disease Women who use oral contraceptives are less likely to develop benign breast cysts or fibroadenomas and experience progression of such conditions.[4,7,13]

Prevention of Ovarian Cysts Because oral contraceptives suppress ovarian stimulation, women who take them are less likely to develop ovarian cysts.[7]

Decrease in Symptoms Related to Endometriosis CHC use has been linked to a decreased incidence of symptomatic endometriosis.[13] In women who suffer from endometriosis, the extended-cycle CHCs may provide the most effective relief from menstrual pain by reducing the total number of painful episodes per year.[4]

Improvement in Acne Control All CHCs can improve acne by increasing the quantity of sex hormone–binding globulin and thereby decreasing free testosterone concentrations.[14] Third-generation progestins, such as desogestrel and norgestimate, are believed to have less androgenic activity compared with older progestins, and drospirenone and dienogest are considered to be antiandrogenic.[14] However, it is not clear that CHCs containing any of these progestins confer any advantage over other CHCs with respect to their ability to improve acne control. Tri Femynor, Tri-Linyah, Tri-Mili, TriNessa, Tri-Previfem, and Tri-Sprintec (EE and norgestimate); Estrostep Fe, Tilia Fe, and Tri-Legest Fe (EE and norethindrone acetate); Yaz, Beyaz, Nikki, Loryna, and Gianvi (EE and drospirenone) each carry an FDA-approved indication for the treatment of acne.[4,7]

▶ Potential Risks of Combination Hormonal Contraceptives

Although there are many noncontraceptive benefits associated with the use of CHCs, their use is not without risk or potential for adverse effects.

Sexually Transmitted Infections Because the use of CHCs may decrease the use of selected barrier contraceptive methods (eg, latex condoms) that do protect against STIs, one of the most common potential risks associated with the use of oral contraceptives is the increased risk of acquiring an STI.[5] However, studies have failed to show an increased risk of HIV transmission, and there is no restriction on the contraceptive method per CDC.

Cardiovascular Events and Hypertension A World Health Organization (WHO) collaborative study found that high-dose (50 mcg or more of EE) oral contraceptive users with uncontrolled hypertension have an increased risk of experiencing a myocardial infarction or stroke.[15] Women who had the lowest risk for experiencing a myocardial infarction or stroke were those who did not smoke, took low-dose (containing ≤ 35 mcg of EE) oral contraceptives, and had their blood pressure checked prior to beginning oral contraceptives. Hypertension secondary to oral contraceptive use is thought to occur in up to 3% of women and believed to be attributed to the effect of estrogens and progestins on aldosterone activity.[4] Given this and the risk for cardiovascular events, women should have their blood pressure checked prior to initiating oral contraceptives, as well as periodically throughout oral contraceptive use. If blood pressure is ≥ 140 mm Hg systolic or ≥ 90 mm Hg diastolic, the risks outweigh advantages and there should be consideration to discontinue CHCs; if blood pressure is ≥ 160 mm Hg systolic or ≥ 100 mm Hg, then CHC use is not recommended.[5] Estrogen-containing contraceptives are not recommended for smokers who are 35 years of age or older or for women who experience migraine headaches with aura.[5]

Venous Thromboembolism It is believed that the estrogen component of CHCs stimulates enhanced hepatic production of clotting factors. CHCs have been associated with a two- to three-fold increase in the risk of venous thromboembolism compared with women who do not use oral contraceptives.[7] Contraceptive users at greatest risk for the development of VTE include those who are ≥ 40 years of age, obese, smoke, or have an inherited thrombophilia or a history of prior thromboembolism. It is important to note, however, that the increase in risk of VTE in oral contraceptive users is lower than that associated with pregnancy and the postpartum period.[7,16] Less androgenic progestins, such as desogestrel and drospirenone, have been reported to be associated with a higher risk of VTE.[17,18] Studies validating this risk have produced conflicting results. Two studies published in 2011 reported a two- to threefold greater risk of venous thromboembolic events in women using oral contraceptives containing drospirenone when compared with women using levonorgestrel-containing contraceptives.[19,20] A more recent 2015 case-control study of > 10,000 women with VTE also found that exposure to drospirenone and desogestrel was associated with a higher risk of VTE compared to exposure to levonorgestrel.[21] Conversely, the results of the International Active Surveillance Study of Women Taking Oral Contraceptives, published in 2014, demonstrated similar rates of venous and arterial thromboembolism in women taking CHCs containing drosperinone, levonorgesterol, or other progestins.[22] Most recently, a systematic review and meta-analysis of the association of CHCs on the risk of VTE demonstrated that compared to levonorgestrel-containing CHCs, all others showed a significant increase in risk.[23] In general, progestin-only contraceptives are preferred for women who are at increased risk of cardiovascular or thromboembolic complications, including women with a prior history of thromboembolic disease.[5,7]

Gallbladder Disease In women with preexisting gallstones, low-dose estrogen-containing oral contraceptives may enhance the potential for the development of symptomatic gallbladder disease and may worsen existing gallbladder disease.[4,5] Although this risk has not been demonstrated with the use of higher-dose oral contraceptives, CHCs containing estrogen should be used with caution in patients with a history of gallbladder disease or current gallbladder disease, especially if known cause is related to CHCs.

Hepatic Tumors Although the use of oral contraceptives is not associated with an increased risk for the development of hepatocellular carcinoma, long-term use of high-dose oral contraceptives has been associated with the development of benign liver tumors.[3] Because even benign liver tumors may pose significant risk to the patient, oral contraceptives should be discontinued if liver enlargement is noted on physical examination. In cases of either benign hepatocellular adenoma or hepatoma (malignancy), the use of CHCs is contraindicated.[5]

Cervical Cancer There appears to be an increased risk for the development of cervical cancer among long-term users of oral contraceptives, particularly among women who test positive for human papilloma virus (HPV), a known risk factor for cervical cancer.[4] It is uncertain whether this increase in risk is directly attributed to the use of oral contraceptives. Oral contraceptive users may use condoms less frequently, and as a result, this may increase their susceptibility to infection with HPV.

Breast Cancer Studies demonstrating a link between CHCs and breast cancer have generally produced conflicting results. A recent study suggested a small potential increase in risk for breast cancer development in both current and recent users of CHCs compared to women who had never used CHCs. In that study, an increased risk for breast cancer development was also associated with longer duration of CHC use as well as with CHC use before age 20 or before the first full-term pregnancy.[24] A recent retrospective cohort study evaluating the impact of family history on breast cancer risk in CHC users showed that in women with a family history who were considered to be a high or intermediate risk for breast cancer, CHC use did not increase the risk for breast cancer.[25]

KEY CONCEPT Medical eligibility criteria for contraceptive use (MEC) were first developed in 1996 and provide the clinician with guidance from the WHO on the safety of using various contraceptives in patients with select concomitant medical conditions or specific characteristics.[5] Clinicians can utilize the MEC to identify absolute and relative contraindications to the use of oral contraceptives.

Absolute and relative contraindications are listed in Table 49–3.[4,5]

Table 49–3

Conditions with Unacceptable Health Risk or with Theoretical or Proven Risks That Usually Outweigh the Advantages of CHC Use[3,4,5]

Conditions that represent an unacceptable health risk with CHC use

History of thromboembolic disease
History of stroke (or current cerebrovascular disease)
History of (or current) coronary artery disease, ischemic heart disease, or peripheral vascular disease
History of carcinoma of the breast (known or suspected)
History of any estrogen-dependent neoplasm (known or suspected)
Undiagnosed abnormal uterine or vaginal bleeding
Pregnancy (known or suspected)
Breastfeeding < 21 days postpartum
Heavy smoking (defined as 15 cigarettes or more per day) by women who are 35 years of age or older
History of hepatic tumors (benign or malignant)
Active liver disease
Migraine headaches with focal neurologic symptoms (aura)
Postpartum (during the first 21 days in women with additional risk factors for thromboembolism, including age ≥ 35 years, history of previous venous thromboembolism, preeclampsia, recent cesarean delivery, obesity, and smoking)

Conditions for which the theoretical or proven risks usually outweigh the advantages of CHC use

Smoking (< 15 cigarettes per day) at any age
Migraine headache disorder without focal neurologic symptoms
Hypertension (NOTE: WHO considers health risk posed by CHC use to be "unacceptable" when either systolic blood pressure is 160 mm Hg or more, or diastolic blood pressure is 90 mm Hg or more)
Fibroid tumors of the uterus
Breastfeeding > 21 days postpartum (with other risk factors for VTE such as > 35 years, previous VTE, transfusion at delivery, peripartum cardiomyopathy, obesity, postpartum hemorrhage, postcesarean delivery, preeclampsia, or smoking)
Superficial venous thrombosis (acute or history)
Multiple sclerosis with prolonged immobility
Diabetes mellitus
Family history of dyslipidemia
Sickle cell disease
Active gallbladder disease
Age > 50 years
Elective major surgery requiring immobilization (planned in the next 4 weeks)
Postpartum (during days 21 through 42 in women with additional risk factors for thromboembolism, including age ≥ 35 years, history of previous venous thromboembolism, preeclampsia, recent cesarean delivery, obesity, and smoking)

CHC, combination hormonal contraceptive; VTE, venous thromboembolism; WHO, World Health Organization

Adverse Effects of Oral Contraceptives and Their Management As with all medications, there are potential adverse effects with CHCs. KEY CONCEPT Many side effects can be minimized or avoided by adjusting the estrogen and/or progestin content of the oral contraceptive. It is also important to individualize the selection of oral contraceptives, because some women are at increased risk for potentially serious side effects.[26]

Common complaints with CHCs include headaches, nausea, vomiting, mastalgia, and weight gain, although a similar percentage of patients taking placebo also experience these side effects.[27] Given that oral contraceptives often are discontinued owing to side effects, proper counseling before initiation of CHCs is necessary.

Between 30% and 50% of women experience breakthrough bleeding or spotting when oral contraceptives are initiated. All side effects tend to resolve by the third or fourth cycle.[4] Before changing formulations, other more serious causes of bleeding or spotting, such as pregnancy, infection, and poor absorption of the oral contraceptive owing to drug interaction or gastrointestinal problems, should be ruled out. Once these causes have been ruled out, the timing of the spotting must be determined to adjust the formulation appropriately.

The most common side effects and ways to adjust therapy to minimize these side effects are listed in Table 49–4.[4,7,26]

As highlighted in Table 49–4, many of the side effects of CHCs may be minimized by adjusting the estrogen or progestin content of the preparation.

Table 49–4

Management of Adverse Effects of Oral Contraceptives[4,7,26]

Adverse Effect	Cause	Adjustment	Notes
Spotting/bleeding before finishing active pills	Insufficient progestin	Monophasic with increased progestin or triphasic with increasing progestin	
Continued bleeding after menses	Insufficient estrogen	Increase estrogen or triphasic with lower early progestin	
Midcycle bleeding	Difficult to determine	Increase estrogen and progestin	
Increased breakthrough bleeding in general	Insufficient estrogen	Increase estrogen or triphasic formulation	Will increase amount of withdrawal bleeding during menses
Acne, PMDD, hirsutism	Progestin with higher androgenicity (eg, norgestrel, levonorgestrel)	Switch to progestin with lower androgenicity such as norgestimate, norethindrone, or drospirenone	
Nausea, vomiting	Related to estrogen	Take at bedtime or with food; decrease estrogen or switch to a progestin-only product	Symptoms often resolve in 1–3 months
Constipation, bloating, distention	Related to progestin	Decrease progestin	Symptoms often resolve in 1–3 months
Headache	Must be evaluated because of warning sign for stroke – monitor blood pressure	If determined to not be serious, but still troublesome consider: a. Discontinue oral contraceptive b. Decrease estrogen c. Decrease progestin d. Eliminate pill-free interval for 2–3 cycles (when headaches occur during pill-free interval)	Discontinue oral contraceptive immediately if any neurologic symptoms or blurred vision
Decrease in libido, decreased vaginal lubrication	Insufficient estrogen	Increase estrogen or consider vaginal hormonal ring (NuvaRing)	Feelings of depression may coincide
Dyslipidemia in general	Progestin with higher androgenicity (eg, norgestrel, levonorgestrel)	Switch to progestin with lower androgenicity such as norgestimate, norethindrone, or drospirenone	Obtain a baseline lipid panel in women with risk factors for dyslipidemia—smoking, hypertension, family history of heart disease
Triglycerides > 350 mg/dL (3.96 mmol/L)	Related to estrogen	Decrease estrogen to 20–25 mcg or a progestin-only formulation[3]	
Mastalgia	Related to estrogen	Decrease estrogen or switch to an extended cycle formulation (see Unique Oral Contraceptives, later) if it occurs prior to menses	
Weight gain, fluid retention	Excess estrogen and progestin with higher androgenicity (eg, norgestrel, levonorgestrel)	Decrease estrogen and switch to progestin with lower androgenicity such as norgestimate, norethindrone or drospirenone	
Visual changes or disturbances with contact lenses	Related to estrogen	Use saline eye drops	Referral to ophthalmology if eye drops do not help
Melasma, chloasma	Related to estrogen stimulation of melanocyte production	Consider progestin-only product and use of sunscreen	Women with darker pigmentation are more susceptible; melasma may not be completely reversible on discontinuation

Patient Encounter Part 1

A 21-year-old nulliparous woman presents to your clinic requesting information on contraception. She specifically inquires about options that allow for fewer or no menstrual periods. You begin to take a history and determine that the patient is currently sexually active and not using any method of birth control. She weighs 125 lb (56.7 kg), is 67 in. (170 cm) tall, and has a blood pressure of 108/70 mm Hg. She has no history of smoking. She has a history of migraines without aura and anxiety. Her only medication is propranolol. On further questioning, you discover that she has a positive family history of breast cancer (her mother) and ovarian cancer (maternal grandmother), but no personal history. As you discuss various contraceptive options with the patient, it is clear that she has a preference for an oral contraceptive agent.

What additional information do you need to know before recommending a contraceptive for this patient?

Based on the information provided by the patient, what oral contraceptive agent would you recommend for the patient and why?

What education would you provide to this patient regarding risks associated with oral contraceptive use?

Progestin-Only Pills

For women unable to take estrogen-containing oral contraceptives, there are alternatives: oral contraceptives containing only a progestin, either norethindrone (Camilla, Errin, Heather, Jencycla, Jolivette, or Nora-BE) or drospirenone (Slynd). These agents are slightly less effective than CHCs but have other advantages over CHCs. Norethindrone-only products have generally not shown the same thromboembolic risk as estrogen-containing products. Therefore, women at increased risk for or with a history of thromboembolism may be candidates for norethindrone-only oral contraceptives. While CHCs containing drospirenone and EE have been linked to an increased risk for VTE, whether drospirenone-only oral contraceptives also increase this risk is not yet known.[28] In general, these products can minimize menses, and many women have amenorrhea after six to nine cycles. Drospirenone is antiandrogenic, so it may help improve acne in some women. Progestin-only products have been found safe to use in women who are nursing, so they are a viable option for women who breastfeed and desire hormonal contraception. In such patients, it should not be initiated until 42 days postpartum. Spotting or irregular bleeding may occur in some women, and this is a common cause for discontinuation. These products should be started on the first day of menses and taken at the same time every day to minimize risk for pregnancy. There is no pill-free or hormone-free period.

Unique Oral Contraceptives

Along with varying doses of estrogen and different progestins, formulation modifications among select CHC products may yield certain benefits in some patient situations.

Lo-Loestrin Fe (norethindrone/EE) is a biphasic product that contains a low-dose estrogen, a high amount of progestin, and medium androgenic activity. Similar to other low-dose estrogen CHCs, Lo-Loestrin Fe may offer a smaller margin of error when pills are missed but provide the potential advantage of fewer estrogen-related side effects (eg, nausea and breast tenderness). Unlike the typical 28-pill packs that contain 21 active tablets and seven placebo tablets, Lo-Loestrin Fe contains 24 combination hormone tablets, two estrogen-only tablets, and two placebo (iron-only) tablets. This product provides a shorter hormone-free interval and may allow for shorter menstrual periods and fewer menstrual-related symptoms, such as menstrual-related headaches, menorrhagia, and anemia.

There are several monophasic combinations that are packaged as a 91-day treatment cycles with 84 active tablets that are taken consecutively followed by seven placebo tablets. These include Amethia Lo, Camrese Lo, Introvale, Jolessa, Quasense, Seasonale, and Setlakin (levonorgestrel/EE). The extended cycle length of these products allows for one menstrual cycle per "season," or four per year. This type of formulation may be appealing to women with perimenstrual side effects or those at higher risk for anemia with menstrual bleeding. These products may improve anxiety, headache, fluid retention, dysmenorrhea, breast tenderness, bloating, and menstrual migraines. The risk of intermenstrual bleeding and/or spotting may be higher for patients taking these extended-cycle combinations than for patients taking typical 28-day-regimen CHCs.[4]

Amethia, Ashlynna, Camrese, Daysee, Seasonique, and LoSeasonique (levonorgestrel/EE) are also extended cycle preparations that are similar to those mentioned earlier, but instead these preparations contain seven tablets with low-dose estrogen rather than placebo. Menstruation-related problems that may improve with these extended-cycle preparations include menstrual-related headaches, menorrhagia, and anemia. In addition, endometriosis-related menstrual pain may be relieved by providing a continuous regimen without a pill-free interval.[29]

Yasmin and Yaz (drospirenone/EE) are examples of unique CHCs that contain the progestin drospirenone, which has antiandrogenic properties, but also showed antimineralocorticoid activity such as diuresis and hyperkalemia. Slynd (drospirenone) is the first approved progestin-only contraceptive containing drospirenone. Drospirenone has a unique application in young women who experience problems associated with producing too much androgen. Drospirenone is a spironolactone analog, and the 3-mg dose available in CHC preparations has antimineralocorticoid activity equal to 25 mg of spironolactone. Drospirenone can affect the sodium and water balance in the body, although it has not shown superior efficacy for side effects such as bloating compared with other oral contraceptives. Caution should be used in women with chronic conditions or in women taking other medications that may affect serum potassium. Yaz contains 24 active tablets and four placebo tablets, allowing for shorter menstrual periods and fewer menstrual-related symptoms, such as menstrual-related headaches, menorrhagia, and anemia.

In 2003, the FDA Advisory Committee for Reproductive Health Drugs recommended the development of a CHC tablet containing folic acid to minimize the risk of neural tube defects in cases of contraceptive failure. Beyaz, Safyral, and Tydemy are each combination tablets containing drospirenone and EE and 451 mcg of levomefolate calcium, the primary metabolite of folic acid. Beyaz has a shorter hormone-free pill interval, which may allow for shorter menstrual periods and fewer menstrual-related symptoms.

In addition to the prevention of pregnancy, Yaz, Beyaz, Safyral, Nikki, Loryna, and Gianvi; Tri-Femynor, Tri-Linyah, Tri-Mili, Tri-Previfem, and Tri-Sprintec (norgestimate/EE); and Estrostep Fe, Tilia Fe, and Tri-Legest Fe (norethindrone acetate/EE) each carry an FDA-approved indication for treatment of moderate acne vulgaris in females 15 years of age or older desiring contraception who have not responded adequately to conventional antiacne medication. This can help clinicians to streamline medications by serving dual purposes.

Bekyree, Kariva, Kimidess, Pimtrea, and Viorele (desogestrel/EE) have a unique dosing schedule. After the usual 21 active tablets, there are only two tablets with inert ingredients. The last five tablets in the package have 10 mcg of EE. In theory, this may minimize bleeding during the menstrual cycle, although the clinical significance of this dosing schedule has not been established. With each of these products, it is important to counsel patients to complete the entire pack and not to discard the last 7 days of medication.

Another unique formulation is a chewable tablet available to women who have difficulty swallowing medications. Femcon Fe (norethindrone/EE) has all 28 tablets in chewable form and has added spearmint flavoring.

Natazia is a quadriphasic CHC containing estradiol valerate and the progestin, dienogest. Estradiol valerate is metabolized endogenously to estradiol, and dienogest is a strong progestin with antiandrogenic activity. Natazia provides a unique estrogen step-down (estradiol valerate dose gradually decreases from 3 mg to 1 mg)/progestin step-up regimen (dienogest dose gradually increases from 0 mg to 3 mg), and this CHC offers the advantage of a shorter hormone-free interval. This results in fewer days of withdrawal bleeding and may help with menstrual-related headaches.

Finally, Quartette, Fayosim, and Rivelsa (levonorgestrel/EE) are extended-cycle, quadriphasic preparations that contain increasing doses of EE throughout the 91-day pill period. The increasing dose of EE is intended to reduce the rate of breakthrough bleeding or spotting.

Patient Encounter Part 2: Adverse Effects

After 2 months of taking Camrese Lo, she returns to your clinic complaining of heavy spotting during her sixth week of active pills. She reports no change or increase in frequency of her migraine headaches, and her blood pressure is 110/72 mm Hg. She is frustrated with the breakthrough bleeding and wants to explore other contraceptive options.

What are some potential causes of the breakthrough bleeding that the patient has been experiencing?

What strategy would you recommend to eliminate or minimize the potential adverse effects experienced by the patient?

Drug Interactions with Oral Contraceptives

EE is metabolized in the liver primarily via cytochrome P-450 (CYP450) 3A4. **KEY CONCEPT** When reviewing drug interactions of oral contraceptives, clinicians should be aware of the many drugs that may potentially interact with contraceptives—especially those that may reduce the effectiveness of contraceptives. Refer to Table 49–5

Table 49–5

Drug Interactions with CHCs[4,30]

Medication	Mechanism	Clinical Effect[a]
Anticonvulsants (carbamazepine, oxcarbazepine, phenytoin, phenobarbital, primidone, topiramate, and felbamate)	Increase metabolism of CHCs via induction of various cytochrome P450 enzymes	Decrease efficacy of CHCs (EE doses < 35 mcg are not recommended in women on these medications)
Bosentan	Increase metabolism of CHCs via induction of cytochrome P450 3A4 enzyme	Decrease efficacy of CHCs
Griseofulvin	Increase metabolism of CHCs	Decrease efficacy of CHCs; backup method of contraception is recommended
Lamotrigine	CHCs increase metabolism of lamotrigine via induction of glucuronidation	Decrease efficacy of lamotrigine; dose adjustment may be necessary
Nonnucleoside reverse transcriptase inhibitors (efavirenz, etravirine, nevirapine, rilpivirine)	Increase metabolism of CHCs	Decrease efficacy of CHCs; alternative method of contraception may be considered with efavirenz and consider continued contraception for 12 weeks after discontinuation of efavirenz
Protease inhibitors (atazanavir, darunavir, fosamprenavir, indinavir, nelfinavir, ritonavir, saquinavir, tipranavir)	Increase or decrease in metabolism of CHCs	Decrease efficacy of CHCs or increase side effects of CHCs; alternative method of contraception is recommended with fosamprenavir and may be considered with ritonavir-boosted protease inhibitors, atazanavir, and nelfinavir
Rifampin, rifabutin	Increase metabolism of CHCs	Decrease efficacy of CHCs; backup method of contraception is recommended
St. John's wort	Increase metabolism of CHCs via induction of various cytochrome P450 enzymes	Decrease efficacy of CHCs; avoid use with CHCs
Theophylline	CHCs decrease theophylline clearance by 34% and increase half-life by 33%	Increase side effects of theophylline
Modafinil, armodafinil	Increase metabolism of CHCs via induction of cytochrome P450 3A4 enzyme	Decrease efficacy of CHCs
Pitolisant	Increase metabolism of CHCs via induction of cytochrome P450 3A4 enzyme	Decrease efficacy of CHCs; use an alternative nonhormonal method of contraception during treatment and for at least 21 days after discontinuation

[a] With medications that decrease efficacy of CHCs, an alternative nonhormonal method of contraception or a back-up method during coadministration and for at least 28 days after discontinuation of the interacting medication is generally recommended, unless otherwise noted in the table

CHC, combined hormonal contraception; EE, ethinyl estradiol.

Data compiled in part from Ethinyl Estradiol/Levonorgestrel. Micromedex Solutions. Ann Arbor, MI: Truven Health Analytics, Inc.. Available at: http://www.micromedexsolutions.com. Accessed August 14, 2021.

for a list of some of the most common drug interactions seen with oral contraceptives.[4,26,30]

Nonoral Hormonal Contraceptives

KEY CONCEPT As an alternative to oral contraceptive pills, which must be taken daily to reliably prevent pregnancy, nonoral contraceptives in the form of transdermal, transvaginal, and injectable preparations are available and offer patients safe and effective alternatives to the pills for prevention of pregnancy. These formulations also do not require daily administration, making them more convenient than pill formulations.

Xulane and Twirla are transdermal patches that contain both an estrogen and a progestin. Xulane contains 35 mcg of EE and 150 mcg of norelgestromin, while Twirla contains 30 mcg of EE and 120 mcg of levonorgestrel. A new patch is applied to the abdomen, buttocks, back, or upper (outer) arm once weekly for 3 weeks, followed by 7 patch-free days. Although some women have noted irregular bleeding during the first two cycles of patch use, the patch has been demonstrated to provide similar menstrual cycle control and contraceptive efficacy to that of CHCs. It is important to note, however, that higher contraceptive failure rates are seen when the patch is used in women weighing more than 90 kg (about 198 lb).[7] Furthermore, manufacturer prescriber information indicates that women who take transdermal contraception are exposed to approximately 60% more estrogen than women who take CHCs with 35 mcg of estrogen.[31] Although the clinical significance of this is not well defined, studies have suggested a link between the use of the patch and an increased risk for VTE. It is not recommended to use Xulane in women with a body mass index of 30 kg/m^2 or more due to an increased risk for developing VTE.[32] A slightly higher reported incidence of breast discomfort and local skin irritation has also been reported with the patch.[7,33]

NuvaRing and EluRyng are both a transvaginal delivery system that provides 15 mcg of EE and 120 mcg of etonogestrel for the prevention of ovulation. Annovera is a newly approved transvaginal delivery system that contains 150 mcg of segesterone, instead of etonogestrel as the progestin, along with 13 mcg of EE. Transvaginal delivery systems are inserted into the vagina on or before day 5 of the menstrual cycle and removed from the vagina 3 weeks later.[7] Seven days after the ring is removed, a new ring should be inserted. In clinical trials, this transvaginal delivery system demonstrated comparable efficacy and cycle control to CHCs as well as a similar side-effect profile.[7,34] Transvaginal rings should not be removed during intercourse. In addition to the brand name products available for transvaginal delivery, there is also a generic product that also contains 15 mcg of EE and 120 mcg of etonogestrel.

Depo-Provera is a progestin-only, injectable contraceptive that contains depot medroxyprogesterone acetate. Depo-Provera is administered intramuscularly as a 150-mg injection once every 3 months. An advantage of Depo-Provera is that it provides an estrogen-free method of contraception either for women in whom estrogens are contraindicated or for women who cannot tolerate estrogen-containing preparations. Depo-Provera is extremely effective in preventing pregnancy. However, the incidence of menstrual irregularities (including amenorrhea) and weight gain appears to be much greater than that seen with CHCs.[35] Recent data has also shown when women gain 5% of their body weight during the first 3 to 6 months of treatment they are at increased risk for additional weight gain with continued use of the injectable contraceptive.[36] The use of Depo-Provera also has been demonstrated to result in significant loss of bone mineral density (BMD).[38] Although the effect is known to be reversible following product discontinuation, a black-box warning within the product labeling cautions against the risk of potentially irreversible BMD loss associated with long-term use (eg, > 2 years) of the injectable product. Although injectable contraceptives offer no protection against STIs, it is important to note the CDC finds that the risk of HIV acquisition does not outweigh the benefit of contraceptive use in a patient at high risk of HIV infection. Although the extended duration of activity of this product may offer women the advantage of less frequent administration, it is important to note that on discontinuation of Depo-Provera, the return of fertility can be delayed by approximately 10 to 12 months (range 4–31 months).[7]

Depo-SubQ Provera 104 is also an injectable contraceptive product that contains only progestin (depot medroxyprogesterone acetate). This product differs from Depo-Provera in that it is given subcutaneously rather than intramuscularly and contains only 104 mg of medroxyprogesterone acetate (~30% less hormone) administered every 3 months for the prevention of pregnancy. Clinical trials have demonstrated that the subcutaneous formulation of depot medroxyprogesterone acetate is as effective as the intramuscular formulation in the prevention of pregnancy.[37] This product carries the same warning in its package labeling regarding possible effects on BMD as Depo-Provera. It is also used for the management of endometriosis-associated pain along with its use for contraception.

Long-Acting Reversible Contraception

The currently available products for long-term reversible contraception (LARC) are listed in Table 49–6.[38] Surveys have shown that LARC has the highest satisfaction rate among patients using reversible contraceptives, and use within the United States is on the rise.[1]

The primary mechanism of action for IUDs is by preventing fertilization. It is believed that copper-containing IUDs may interfere with sperm transport and fertilization and prevent implantation by releasing toxic copper ions.[38] Progestin-containing

Table 49–6

Long-Acting Reversible Contraception[38]

Product	Ingredient	Dosage Form	Dose	Duration
Mirena	Levonorgestrel	Intrauterine device	52 mg	Up to 6 years
Skyla	Levonorgestrel	Intrauterine device	13.5 mg	Up to 3 years
Kyleena	Levonorgestrel	Intrauterine device	19.5 mg	Up to 5 years
Liletta	Levonorgestrel	Intrauterine device	52 mg	Up to 6 years
ParaGard	Copper	Intrauterine device	380 mm^2	Up to 10 years
Nexplanon	Etonorgestrel	Implantable device	68 mg	Up to 3 years

implantable contraceptives can have direct effects on the uterus, such as thickening of cervical mucus and alterations to the endometrial lining. If an implanted embryo is established, IUDs do not cause destruction of the embryo.[38]

It is important to evaluate a patient to determine whether she is an appropriate candidate for an implantable contraceptive. IUDs are recommended for women who are in a monogamous relationship, at low risk for acquiring STIs, and have no current pelvic inflammatory disease (PID). Contraindications to the use of progestin-containing LARC products include (a) known or suspected pregnancy, (b) hepatic tumors or active liver disease, (c) undiagnosed abnormal genital bleeding, (d) known or suspected carcinoma of the breast or personal history of breast cancer, (e) history of thrombosis or thromboembolic disorders, and (f) hypersensitivity to any components of the products. There are also multiple additional contraindications to IUD use. Evaluation of the patient is essential because IUDs cannot be used in the following situations: (a) anatomically abnormal or distorted uterine cavity, (b) acute PID, (c) postpartum endometritis or infected abortion in the past 3 months, (d) known or suspected uterine or cervical malignancy, (e) untreated acute cervicitis, (f) previously inserted IUD still in place, (g) increased susceptibility to pelvic infections, and (h) Wilson disease (Paragard only).

The most common adverse effects are abdominal/pelvic cramping, abnormal uterine bleeding, and expulsion of the device. Other side effects seen are ectopic pregnancy, sepsis, PID, embedment of the device, uterine or cervical perforation, and ovarian cysts.

Nonpharmacologic Contraceptive Methods

▶ *Barrier Contraceptives*

In addition to or as an alternative to hormonal contraceptives, several barrier contraceptive options are available for the prevention of pregnancy. Although barrier contraceptives are associated with far fewer adverse effects compared with hormonal contraceptives, their efficacy is highly user-dependent. Overall, compared with both hormonal contraceptives and IUDs, barrier contraceptives are associated with much higher unintended pregnancy rates[7] (see Table 49–1).

Diaphragms and Cervical Caps Diaphragms and cervical caps are dome-shaped rubber caps that are placed over the cervix to provide barrier protection during intercourse. Both diaphragms and cervical caps require fitting by a healthcare professional, and they must be refitted in the event of weight gain or weight loss. Diaphragms or cervical caps typically can be placed over the cervix as much as 6 hours prior to intercourse. FemCap should be placed 15 to 40 minutes before intercourse. Diaphragms and cervical caps must be left in place for at least 6 hours after intercourse before they can be removed. Diaphragms should not be left in place longer than 24 hours, and smaller cervical caps should not be left in place longer than 48 hours owing to the risk of toxic shock syndrome (TSS). Diaphragms and cervical caps are used along with spermicides to prevent pregnancy. When sexual intercourse is repeated with the diaphragm, reapplication of the spermicide is necessary. However, when sexual intercourse is repeated with a cervical cap, reapplication of the spermicide typically is not necessary.[7] Whether or not diaphragms or cervical caps provide adequate protection against STIs remains unclear.[39]

Spermicides Nonoxynol-9, a surfactant that destroys the cell membranes of sperm, is the only chemical spermicide in the United States.[4,7] Nonoxynol-9 is available in a variety of forms, including a cream, foam, film, gel, suppository, and tablet. Spermicides may be used alone, with a barrier method, or adjunctively with other forms of contraceptives to provide additional protection against unwanted pregnancy.[4] To be used most effectively, spermicides must be placed in the vagina not more than 1 hour prior to sexual intercourse, and they must come in contact with the cervix.[7] Additionally, film, suppositories, and tablets must dissolve to be effective. Although the efficacy of spermicides depends largely on how consistently and correctly they are used, their efficacy is enhanced when they are used in combination with a barrier contraceptive device.[39] Clinical trials assessing the ability of spermicides to protect against STIs have failed to produce positive results.[4] Furthermore, there exists some evidence to suggest that frequent use of spermicides actually may increase risk for acquisition of human immunodeficiency virus (HIV) secondary to vaginal mucosal tissue breakdown, which may allow a portal of entry for the virus.[7] The FDA requires manufacturers of nonoxynol-9 products to include a warning on the product label indicating that the spermicide does not provide protection against infection from HIV or other STIs. Patients should be encouraged not to use spermicides alone. They are recommended with a barrier method.

Condoms Condoms, which are available for both male and female use, act as physical barriers to prevent sperm from coming into contact with ova.[4] Condoms may be easy to use, are available without a prescription, and may be relatively inexpensive. Most condoms are made of latex. When used correctly, condoms can be very effective in prevention of unwanted pregnancy.[40] Condoms should be stored in a cool, dry place, away from exposure to direct sunlight. When stored improperly or when used with oil-based lubricants, however, latex condoms can break during intercourse, increasing the risk of pregnancy.[7] For latex-sensitive individuals, condoms made from lamb intestine ("natural membrane" condoms) and synthetic polyurethane condoms are available. Unlike latex condoms, condoms made from lamb intestine contain small pores that may permit the passage of viruses and therefore do not provide adequate protection against STIs.[4] As well, synthetic polyurethane condoms may be more likely to break than latex condoms. **KEY CONCEPT** Both latex and synthetic condoms can provide some protection against many STIs. Data from one meta-analysis suggested that HIV transmission can be reduced by as much as 90% when condoms are consistently used.[41] This is in contrast to hormonal contraceptives (oral, transdermal, or vaginal), IUDs, and most other barrier contraceptives, which do not protect against STIs. Relative to male condoms, female condoms may offer even better protection against STIs because they provide more extensive barrier coverage of external genitalia, including the labia and the base of the penis.[4] Female condoms are generally less effective than male condoms at preventing pregnancy, however. It is important to note that the male and female condoms are not recommended to be used together because they may adhere to one another, causing displacement of one or both condoms.[4]

Sponge The Today Sponge is a small, pillow-shaped polyurethane sponge impregnated with nonoxynol-9.[40] It is an over-the-counter barrier contraceptive that has been shown to be generally less effective at preventing pregnancy than diaphragms.[41] The sponge is moistened with water and then is inserted and placed over the cervix up to 6 hours prior to sexual intercourse. The sponge then is left in place for at least 6 hours following intercourse.[4] Although the sponge maintains efficacy for 24 hours (even if intercourse is repeated), as with diaphragms, the sponge should be removed after 24 hours owing to the risk of TSS.[7]

Table 49–7

Emergency Contraception

Product	Availability	Ingredient	Dose	When Recommended[a]
Levonorgestrel, Aftera, EContra EZ, EContra One-Step, Fallback Solo, My Choice, My Way, Opcicon One-Step, Option 2, Plan B One-Step, Preventeza, React, Take Action	All ages with no identification required	Levonorgestrel	1.5 mg	Within 72 hours of unprotected sex
ella	Only as a prescription	Ulipristal acetate	30 mg	Within 120 hours of unprotected sex

▶ *Fertility Awareness–Based Methods*

Fertility awareness–based methods (natural methods) represent another nonpharmacologic means of pregnancy prevention. Although failure rates of such methods can be high, some couples still prefer these types of approaches. Fertility awareness–based methods depend on the ability of the couple to identify the woman's "fertile window," or the period of time in which pregnancy is most likely to occur as a result of sexual intercourse.[4] During the fertile window, the couple practices abstinence, or avoidance of intercourse, to prevent pregnancy. In general, fertility awareness–based methods are not recommended for women who have irregular menstrual cycles or who have difficulty interpreting their fertility signs correctly.[4] More recently, the FDA has approved a fertility awareness mobile app that incorporates information about a woman's menstrual cycle and basal body temperature to provide a recommendation on whether to use a barrier contraceptive or abstinence based on predicted fertility windows.

Emergency Contraception

Emergency contraception (EC) is used to prevent pregnancy after known or suspected unprotected sexual intercourse. Ideally it should be used as soon as possible after unprotected sexual intercourse and within 72 hours (120 hours with ella), but it can still remain effective beyond this time frame. If a woman is already pregnant, EC cannot stop the pregnancy or harm the fetus. All oral EC products suppress LH and therefore delay or block ovulation. It is not proven, but evidence suggests EC will only work before ovulation, so it would not prevent implantation of a fertilized egg.[42] It is not recommended that EC be used as a regular form of birth control.

There are currently 14 FDA-approved oral agents available for use as EC. Thirteen of these agents have the active ingredient of levonorgestrel and are over the counter and available to all ages with no identification required. Common side effects of levonorgestrel containing EC are headache, nausea, abdominal pain, fatigue, dizziness, vomiting, and breast tenderness. Of note, there is some evidence that efficacy of levonorgestrel containing EC may be decreased in women weighing more than 75 kg or those with a BMI greater than 26 kg/m^2.[42]

The product known as ella (ulipristal acetate), a progesterone-receptor agonist/antagonist, is only available with a prescription. It can delay follicular rupture if taken just before ovulation and may cause endometrial changes to interfere with implantation. Common side effects include headache, nausea, abdominal pain, fatigue, dizziness, dysmenorrhea, upper abdominal pain, back pain, and can delay menses up to approximately 2 days. A pharmacokinetic study of ulipristal acetate showed similar serum levels in patients with a BMI greater than 30 kg/m^2 compared to those with a lower BMI, so it may be a preferred oral EC option in this population.[42]

The available products are listed in Table 49–7[43] along with information on availability and dosage. It is important to note that EC is more effective the earlier it is used after unprotected intercourse. If severe abdominal pain occurs, patients should be referred to their healthcare provider for evaluation of risk of an ectopic pregnancy. Patients should also contact their healthcare provider if their menstrual cycle is more than 1 week late after taking EC.

Patient Encounter Part 3: Missed Doses

The patient calls your clinic in a panic today because she forgot to take her oral contraceptive for the past 2 days, beginning the third week of active pills. Two days have elapsed since she took her last active pill, and she reports having had sexual intercourse last night. She states that her male partner used a condom. The patient is very concerned about her risk of pregnancy and interested to learn more about emergency contraception and her options.

Given this patient's reported imperfect use of her oral contraceptive, what information can you provide to the patient regarding her risk of pregnancy?

What additional education should be provided to the patient regarding her risk of STIs?

Provide appropriate patient education regarding the use of various forms of emergency contraception, in the event she decides to use EC.

OUTCOME EVALUATION

Schedule follow-up visits as needed and at the discretion of the provider. At each follow-up visit, assess blood pressure, headache frequency, and menstrual bleeding patterns, as well as compliance with the prescribed regimen. Strict adherence to the prescribed hormonal contraceptive regimen is essential for effective prevention of unintended pregnancy. **KEY CONCEPT** When a contraceptive dose is missed, the risk of accidental pregnancy may be increased. Depending on how many doses were missed, the contraceptive formulation being used, and the phase of the cycle during which doses were missed, counseling regarding the use of additional methods of contraception may be warranted. For further information, patients can be referred to https://www.cdc.gov/reproductivehealth/unintendedpregnancy/pdf/248124_fig_2_3_4_final_tag508.pdf.

Patient Care Process

Collect Information:

- Determine goals related to contraceptive use (pregnancy prevention, menstrual regulation, control of acne).
- Based on medical, social (ie, smoking), and family history, determine if patient qualifies for hormonal contraceptives. Rule out pregnancy and evaluate patient's risk for STIs.
- Conduct thorough medication history to identify potential for drug interactions.

Assess the Information:

- At follow-up visits, assess blood pressure, weight, and menstrual patterns for changes from baseline.
- Assess tolerability of and adherence to the prescribed contraceptive method.
- Assess safety of hormonal contraceptives by using the mnemonic "ACHES"[4]:

A = Abdominal pain
C = Chest pain
H = Headaches (especially if associated with focal neurologic symptoms)
E = Eye problems (blurred vision, ocular pain, visual changes)
S = Severe leg pain

- Also monitor for missed periods, signs of pregnancy, appearance of jaundice, and/or severe mood changes.
- Assess safety of IUDS by using the mnemonic "PAINS"[4]:

P = Period late
A = Abdominal pain, pain with intercourse
I = Infection, abnormal/odorous vaginal discharge
N = Not feeling well, fever, chills
S = String (missing, shorter, longer)

Develop a Care Plan:

- Select a contraceptive option that the patient is comfortable with, that is likely to achieve the patient's desired goal(s), and is not contraindicated.
- Educate regarding the potential for side effects, safety risks, drug interactions, and any noncontraceptive benefits that may result for the chosen method.
- Determine the patient's sexual behavior and evaluate whether the contraceptive method will impact the risk for STIs.
- Evaluate insurance coverage/cost factors.

Implement the Care Plan:

- Instruct the patient to consult a healthcare professional upon noticing or experiencing any warning signs.
- Stress the importance of adherence (especially if prevention of pregnancy is desired).
- Educate on what to do in the event of missed doses.

Follow-up: Monitor and Evaluate:

- Schedule a follow-up visit 3 to 6 months after initiating a new contraceptive.
- Assess blood pressure, headache frequency, and menstrual bleeding patterns.
- Assess patient tolerance and evaluate for the occurrence of side effects specific to the regimen prescribed.
- Assess adherence to the prescribed regimen.

Abbreviations Introduced in This Chapter

BMD	Bone mineral density
CHC	Combination hormonal contraceptive
CYP450	Cytochrome P450
EC	Emergency contraception
EE	Ethinyl estradiol
FSH	Follicle-stimulating hormone
GnRH	Gonadotropin-releasing hormone
HIV	Human immunodeficiency virus
HPV	Human papilloma virus
IUD	Intrauterine device
LARC	Long-acting reversible contraception
LH	Luteinizing hormone
MEC	Medical eligibility criteria
PID	Pelvic inflammatory disease
PMDD	Premenstrual dysphoric disorder
STI	Sexually transmitted infection
TSS	Toxic shock syndrome
WHO	World Health Organization

50 Menopause and Menstruation-Related Disorders

Nicole E. Cieri-Hutcherson and Kylie N. Barnes

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the underlying etiology of dysmenorrhea, amenorrhea, anovulatory bleeding, heavy menstrual bleeding, and menopause.
2. Explain the physiologic changes associated with dysmenorrhea, amenorrhea, anovulatory bleeding, heavy menstrual bleeding, and menopause.
3. Identify the signs and symptoms associated with dysmenorrhea, amenorrhea, anovulatory bleeding, heavy menstrual bleeding, and menopause.
4. Determine the desired therapeutic outcomes for patients with dysmenorrhea, amenorrhea, anovulatory bleeding, heavy menstrual bleeding, and patients taking menopausal hormone therapy (MHT).
5. Explain how to evaluate a patient for the appropriate use of MHT.
6. Recommend appropriate nonpharmacologic and pharmacologic interventions for dysmenorrhea, amenorrhea, anovulatory bleeding, heavy menstrual bleeding, and menopausal symptoms.
7. Design a monitoring plan to assess the safety and effectiveness of pharmacotherapy for dysmenorrhea, amenorrhea, anovulatory bleeding, heavy menstrual bleeding, and a patient taking MHT.

INTRODUCTION

Menstrual cycle disorders are common amongst women of reproductive age. The most common include dysmenorrhea, amenorrhea, anovulatory bleeding, and heavy menstrual bleeding. Menstruation-related disorders can negatively affect quality of life (QOL), reproductive health, and productivity and may also lead to long-term health consequences. As menstruation begins to cease, the perimenopause and menopause phases begin. During this time, irregular menses, vaginal dryness, dyspareunia, hot flashes, and mood swings may occur. This chapter explores the most common menstruation-related disorders women face and symptoms associated with menopause.

DYSMENORRHEA

Dysmenorrhea is pelvic pain, generally described as painful cramping, occurring during or just prior to menstruation. Primary dysmenorrhea occurs with normal pelvic anatomy and physiology, whereas secondary dysmenorrhea is associated with underlying pelvic pathology.[1]

Epidemiology and Etiology

Dysmenorrhea is the most commonly reported menstrual complaint, with over 50% of menstruating women reporting pain for at least 1 or 2 days each month.[2] Of adolescents with dysmenorrhea, up to 12% report missing work or school each month due to pain.[3] Risk factors include irregular or heavy menses, age less than 30, menarche prior to age 12, body mass index less than 20 kg/m^2, history of sterilization or sexual abuse, and smoking.[1,4] Causes of secondary dysmenorrhea may include endometriosis, pelvic inflammatory disease (PID), uterine or cervical polyps, and uterine fibroids.[3,4]

Pathophysiology

In primary dysmenorrhea, elevated arachidonic acid levels in the menstrual fluid lead to increased concentrations of prostaglandins and leukotrienes in the uterus. This induces uterine contractions, stimulates pain fibers, reduces uterine blood flow, and causes uterine hypoxia.[4]

Treatment

▶ *Desired Outcomes*

Desired treatment outcomes (Figure 50–1) are reduction of pelvic pain, improved QOL, and fewer missed days from school and work.

▶ *Nonpharmacologic Therapy*

Dysmenorrhea intensity has shown to be decreased by exercise, applying topical heat therapy, acupuncture, and consuming a low-fat vegetarian diet.[1,5,6] Exercise may reduce dysmenorrhea by increasing pelvic blood flow and stimulating the release of beta-endorphins which act as analgesics.[1,7] Heat applied as an abdominal patch has shown to be as effective as 400 mg of ibuprofen dosed three times daily.[5,6,8] In addition, a low-fat vegetarian diet may lessen the duration of dysmenorrhea. A variety of dietary supplements have been evaluated for dysmenorrhea, including fenugreek, fish oil, vitamin B1, ginger, valerian, and zinc oxide; however, none should be recommended at this time due to lack of quality evidence for efficacy.[9] Additionally, evidence supporting

acupuncture and acupressure is low and both are not currently recommended as standards of care.[6]

▶ *Pharmacologic Therapy*

Medication management options are summarized in Table 50–1.

Nonsteroidal Anti-inflammatory Drugs

KEY CONCEPT Nonsteroidal anti-inflammatory drugs (NSAIDs) are first-line therapy for dysmenorrhea and are effective in up to 80% of patients.[10] NSAIDs inhibit prostaglandin production, exert analgesic properties, decrease uterine contractions, and reduce menstrual blood flow. Choice of agent is based on effectiveness, tolerability, and patient preference, with the most commonly utilized agents being naproxen and ibuprofen.[1,4] Of note, aspirin is not recommended as it is not potent enough in usual dosages.

NSAID treatment should begin 1 to 2 days prior to menses, or at dysmenorrhea onset, and continued for 2 to 3 days or until pain resolves.[1,4] A loading dose (twice the usual single dose) is recommended, followed by the usual recommended dose.[1,3] For patients with limited response or with contraindications to NSAID therapy, combination hormonal contraceptives (CHCs) should be considered.[4]

Combination Hormonal Contraceptives

CHCs improve dysmenorrhea by decreasing endometrial lining and inhibiting ovulation, which decreases the formation of prostaglandins and leukotrienes contributing to menstrual pain.[3,4] Precisely, 2 to 3 months of therapy are often required to achieve full effects, and can take up to 6 months.[4] Both cyclic

Clinical Presentation and Diagnosis of Dysmenorrhea

General

- May be in acute distress depending on the severity of pain.

Symptoms

- Recurrent, crampy pelvic pain (lasting 2–3 days) beginning shortly before or during menses. Pain may radiate into lower back or thighs. Associated symptoms generally begin in adolescence and include nausea, vomiting, diarrhea, headache, dizziness, bloating, and fatigue.

Laboratory Tests

- Gonorrhea, chlamydia cultures, or polymerase chain reactions test, wet mount

Other Diagnostic Tests

- Pelvic examination for sexually active females, females reporting severe pain or limitation of activity, or who have not responded to first- and second-line treatments.
- Pelvic ultrasound may identify anatomic abnormalities (eg, masses/lesions), ovarian cysts, or endometriomas.

Patient Encounter 1, Part 1

A 14-year-old woman presents reporting crampy pelvic pain that radiates to her thighs during menses causing her to miss school a few days each month. Her last menses started 21 days ago, and her first menstrual cycle occurred at age 12. She has a history of sexual abuse when she was 6 to 8 years of age, which included penetration. She has been removed from the abuse situation, and reports she is not currently sexually active. She has been taking ibuprofen 800 mg three times a day for 4 days during menses for the last six cycles, which has provided some relief. She plays volleyball for her school, is 5′10″ (178 cm) tall, and weighs 146 pounds (66.2 kg).

What risk factors does the patient have for primary dysmenorrhea?

Table 50–1

Therapeutic Agents for Selected Menstrual Disorders

Specific Menstrual Disorder(s)	Agent(s)	Dose Recommended	Common Adverse Effects
Amenorrhea (primary or secondary)	CEE[a]	0.625–1.25 mg by mouth daily on cycle days 1–26[9]	Thromboembolism, breast enlargement, breast tenderness, bloating, nausea, GI upset, headache, peripheral edema
	Ethinyl estradiol patch[a]	50–100 mcg/24 hours[11]	
	Oral CHC[a]	30–40 mcg ethinyl estradiol formulations	
Amenorrhea (secondary)	Oral medroxyprogesterone acetate[a]	10 mg by mouth on cycle days 14–26[11]	Edema, anorexia, depression, insomnia, weight gain or loss, elevated total and LDL cholesterol may reduce HDL cholesterol
Amenorrhea (hyperprolactinemia)	Bromocriptine	2.5 mg by mouth two to three times daily[15]	Hypotension, nausea, constipation, anorexia, Raynaud phenomenon
	Cabergoline	0.25 mg by mouth twice weekly[15]	
Anovulatory bleeding	Oral CHC[a]	Optimal dose unknown[19] For acute or severe bleeding, product containing 35-mcg ethinyl estradiol; take one tablet by mouth three times daily × 1 week; then one tablet by mouth daily × 3 weeks.[19] Therapy continuation may be necessary to prevent future occurrences	As noted above for CEE, ethinyl estradiol, and oral CHC (progesterone side effects with the CHC depend on agent chosen)
	Oral medroxyprogesterone acetate[a]	For acute bleeding, 20 mg by mouth three times daily × 1 week; then 20 mg by mouth once daily × 3 weeks[19]	As noted above for oral medroxyprogesterone acetate
Dysmenorrhea	Oral CHC[38,a]	< 35-mcg ethinyl estradiol formulations + norgestrel or levonorgestrel[39]; use of extended-cycle formulations is beneficial for this indication	As noted above for CEE, ethinyl estradiol, and oral CHC (progesterone side effects with the CHC depend on agent chosen)
	Depot medroxyprogesterone acetate[a]	104 mg subcutaneously every 3 months (12–14 weeks) 150 mg intramuscularly every 3 months (13 weeks)	Irregular menses, amenorrhea
	Levonorgestrel IUD[10,a]	20 mcg released daily	Irregular menses, amenorrhea
	NSAIDs—any are acceptable except aspirin or salicylates; the most commonly studied/cited are included in this table.[1,3-5,38] Treatment should begin 1–2 days prior to the expected onset of menses	Ibuprofen 800 mg by mouth three times daily[a] Naproxen 550-mg loading dose by mouth started 1–2 days prior to menses, followed by 275 mg by mouth every 6–12 hours as needed[c] Mefenamic acid 500 mg by mouth as a loading dose, then 250 mg by mouth up to four times daily as needed[b] Diclofenac 50 mg by mouth three times daily[b]	GI upset, stomach ulcer, nausea, vomiting, heartburn, indigestion, rash, dizziness
Abnormal uterine bleeding	Oral CHC[a]	Optimal dose unknown	As noted above
	Levonorgestrel IUD[a]	20 mcg released daily	As noted above
	Medroxyprogesterone acetate (oral)[a]	5–10 mg by mouth on days 5–26 of the cycle *or* during the luteal phase[32]	As noted above
	NSAIDs	Doses as recommended for above; therapy should be initiated with the onset of menses[32]	As noted above
	Tranexamic acid	1300 mg (650 mg × 2) by mouth three times days × 5 days[35–37]	Fatigue, abdominal, back, or muscle pain

(Continued)

Table 50–1

Therapeutic Agents for Selected Menstrual Disorders (*Continued*)

Specific Menstrual Disorder(s)	Agent(s)	Dose Recommended	Common Adverse Effects
PCOS-related amenorrhea and/or anovulatory bleeding	If pregnancy is not an immediate goal:		
	Metformin	Metformin dosing: 1500-2000 mg by mouth daily in two to three divided doses.	Metformin: Anorexia, nausea, vomiting, diarrhea, flatulence, lactic acidosis
	Oral CHC	35 mcg or less ethinyl estradiol and progesterone with antiandrogenic effects (eg, drospirenone)	
	Levonorgestrel IUD	20 mcg released daily	
	Women with side effects or contraindications to estrogen:		
	Medroxyprogesterone acetate (oral)[a]	10 mg by mouth × 10 days[17]	As noted above
	Depot medroxyprogesterone acetate[a]	150 mg intramuscularly every 12 weeks	

[a] Use is contraindicated in patients with severe hepatic impairment.

[b] Not recommended in patients with severe renal impairment.

[c] Use is contraindicated with creatinine clearance < 30 mL/min (0.5 mL/s).

CEE, conjugated equine estrogen; CHC, combination hormonal contraceptive; GI, gastrointestinal; HDL, high-density lipoprotein; IUD, intrauterine device; LDL, low-density lipoprotein; NSAIDs, nonsteroidal anti-inflammatory drugs; PCOS, polycystic ovary syndrome.

(28-day) and extended cycle (91-day) therapies have been used effectively.[1,4] Continuous CHC may provide more rapid pain relief when compared to cyclic therapy; however, both effects are similar when evaluated at 6 months.[1,4] For dysmenorrhea secondary to endometriosis, CHCs, specifically extended cycle regimens, are considered first-line.[1,4] If no response with any agent occurs after 3 to 6 months, the patient should be reevaluated.[3]

Progestin-Only Hormonal Contraceptives

Long-acting progestins are often utilized for dysmenorrhea treatment and work by reducing or eliminating menses over 6 to 12 months of use, thus eliminating prostaglandin release. Three long-acting reversible contraceptive agents are available: depot medroxyprogesterone acetate (MPA), etonogestrel implant, and levonorgestrel-releasing intrauterine device (IUD). Observational data showed that women with active dysmenorrhea symptoms

Patient Encounter 1, Part 2

Additional workup reveals:

PMH: exercise-induced asthma

PSH: Tonsillectomy at age 7

FH: Mother and father alive and well; two siblings (ages 11 and 21), both alive and well

SH: (–) tobacco use; (–) illicit drug use; (–) alcohol use

Medication: albuterol inhaler 1 to 2 puffs prior to exercise as needed

Past Gynecologic History: Menarche at age 12; never pregnant; (–) sexual activity; (+) history of painful menses beginning at age 13; (–) heavy menstrual flow; menstrual cycle 27 to 28 days

ROS: (+) fatigue with menses; (–) headaches; (–) mild acne on face, chest, and upper back; (+) moderate-to-severe pelvic pain radiating to thighs with menses

PE:

General: Thin, athletic woman, in no acute distress

VS: BP 110/68, P 72, RR 14, Wt 146 lbs (66.2 kg), Ht 5′10″ (178 cm), Body mass index: 20.9 kg/m^2

HEENT: (–) hirsutism

Breasts: (–) galactorrhea

Pelvic examination: Normal appearance of external genitalia and vagina, cervix without lesions, uterus midposition without masses

Labs: (–) hCG

Given this information, what is your assessment of this patient's condition?

What nonpharmacologic therapies are recommended for this patient?

Is the patient's self-treatment with ibuprofen appropriate? Why or why not?

What pharmacologic therapies are recommended for this patient?

who used a levonorgestrel-releasing IUD saw a reduction in their symptoms from 60% to 29% after 3 years of therapy.[7]

Dysmenorrhea in Adolescents

Dysmenorrhea is the most common gynecologic complaint amongst female adolescents, reported in 60% to 90%, and the most common reason for missed school or work.[7] NSAIDs are the preferred initial treatment in adolescents, followed by hormonal treatment. **KEY CONCEPT** Adolescents with symptoms unresponsive to NSAID therapy for three menstrual periods should be offered CHC, which can also provide effective contraception if desired.[3] If symptoms do not improve within 3 to 6 months of NSAIDs and CHC, it is important to assess for medication adherence. If adherence is confirmed and patient still not experiencing symptom relief, further evaluation through laparoscopy is indicated. Since adolescence is a critical period for bone mineral density (BMD) accrual, and prolonged use of depot MPA may lead to significant loss of BMD that may not be completely reversible, other agents are considered first line.

AMENORRHEA

Amenorrhea is the absence of menses over a 90-day period and can be primary or secondary. **Primary amenorrhea** is the failure to reach menarche by age 15, in women who have never menstruated. **Secondary amenorrhea** is the cessation of menses for 3 months in a previously regular menstruating woman or 6 months in a previously irregular menstruating woman.[11]

Epidemiology and Etiology

KEY CONCEPT Unrecognized pregnancy can be a common cause of amenorrhea; therefore, a urine pregnancy test should be one of the first steps in evaluating amenorrhea. There are three main causes of amenorrhea: anatomical causes including pregnancy and uterine structural abnormalities, endocrine or hormone imbalances leading to chronic amenorrhea, and ovarian insufficiency or failure. Primary amenorrhea is often caused by chromosomal irregularities resulting in primary ovarian insufficiency or anatomic abnormalities.[11] Causes of secondary amenorrhea include **polycystic ovary syndrome** (PCOS), hypothalamic suppression, thyroid disorders, hyperprolactinemia, or primary ovarian insufficiency.[11] Additional causes include undernutrition, anorexia, and excessive exercise.

Pathophysiology

Normal menstrual cycle physiology depends on hormonal interactions involving the hypothalamus, anterior pituitary gland, ovary, and endometrium (Figure 50–2).[11] Table 50–2 shows causative condition(s) and the organ system(s) involved in the pathophysiology of amenorrhea. Amenorrhea is a potential side effect from using low-dose or extended oral CHCs, MPA, or levonorgestrel-releasing IUD.[11] Many women experience delayed return of menses after discontinuing hormonal contraception. If resolution of amenorrhea does not occur within 3 to 6 months after discontinuing contraception, evaluation for other conditions should be considered (eg, PCOS).

Treatment

▶ *Desired Outcomes*

Treatment goals include ensuring normal puberty is occurring, restoring the normal menstrual cycle, preserving bone density, preventing bone loss, improving QOL, reduction of associated symptoms, and restoring ovulation, thus improving fertility.[11]

▶ *Nonpharmacologic Therapy*

Nonpharmacologic therapy depends on the underlying cause. Amenorrhea secondary to undernutrition or anorexia may respond to weight gain and psychotherapy.[11] If excessive exercise is the cause, exercise reduction is recommended.[11] Women with functional hypothalamic amenorrhea should undergo a reasonable trial of psychological (such as cognitive behavior therapy), nutritional, and/or exercise intervention prior to starting pharmacologic therapy.

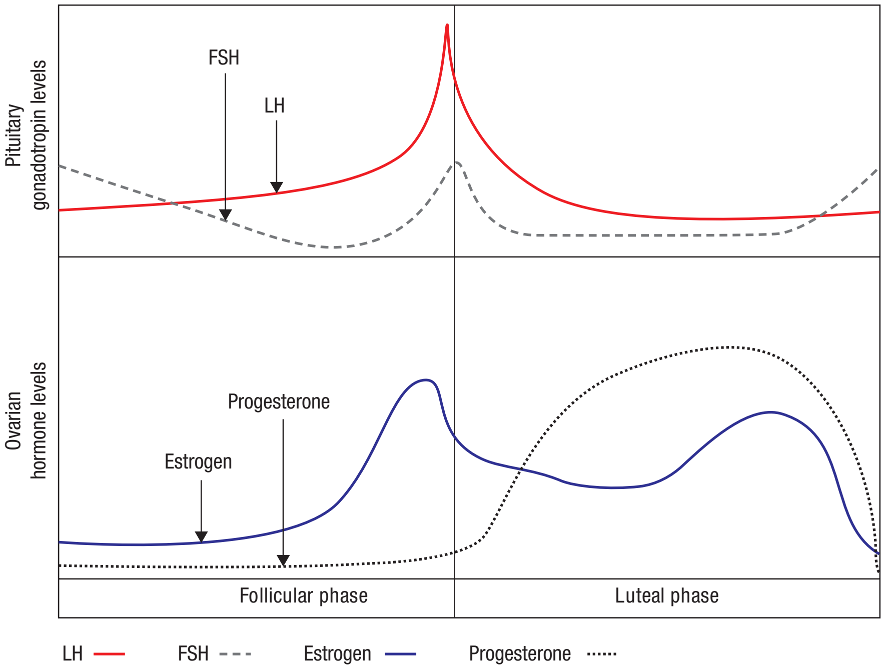

FIGURE 50–2. Hormonal fluctuations with the normal menstrual cycle. (FSH, follicle-stimulating hormone; GnRH, gonadotropin releasing hormone; LH, luteinizing hormone.) Table 50–2

Expected Outcome Measures for Selected Menstrual Bleeding Disorders[10,12,19,25,28]

Menstruation-Related Disorder	Expected Outcome Measures
Dysmenorrhea	*Efficacy:* Reduction in menses-related pelvic pain; reduction in time lost from work/school; improved quality of life. *Time to relief/effect:* Improvement in pain may be observed within hours of NSAID therapy; improvement with other options such as oral CHCs may be observed after a full 1–3 cycles of use.
Amenorrhea	*Efficacy:* Normal breast development (especially primary amenorrhea in adolescents); BMD preservation/ improvement; return of menses. *Time to relief/effect:* Menses should occur within 1–2 months of therapy.
Anovulatory Bleeding	*Efficacy:* Alleviation of acute bleeding when present; ovulation and subsequent pregnancy in women desiring this; reduced risk of developing the long-term complications of PCOS (eg, diabetes and cardiovascular disease); improved quality of life. *Time to relief/effect:* The acute treatment of heavy bleeding should reduce bleeding within 10 days of therapy onset; return of ovulation may require several months of therapy; when oral CHCs are used, abnormal bleeding control can be expected within one to two treatment cycles.
Heavy Menstrual Bleeding	*Efficacy:* Decline in amount of blood loss with menses (monitor a decline in the number of times feminine hygiene products such as pads and tampons require changing during menses); increase in hemoglobin/ hematocrit if anemia was present as because of abnormal uterine bleeding. *Time to relief/effect:* A decline in menstrual blood loss should be realized within one to two cycles of therapy initiation.

BMD, bone mineral density; CHCs, combination hormonal contraceptives; NSAID, nonsteroidal anti-inflammatory drug; PCOS, polycystic ovary syndrome

▶ *Pharmacologic Therapy*

Estrogen/Progestin Replacement Therapy For most conditions associated with primary or secondary amenorrhea, estrogen supplementation with either an oral contraceptive, conjugated equine estrogen (CEE), or estradiol patch has historically been recommended. However, CHC and synthetic estrogen are no longer recommended as first-line agents for patients with functional hypothalamic amenorrhea. The 2017 Endocrine Society Clinical Practice Guideline for functional hypothalamic amenorrhea recommends patients trial nonpharmacological therapy first (with psychological and nutritional interventions), and then start a short-term transdermal estrogen with cyclic oral progestins.[13] Table 50–1 lists the types and doses of estrogen and progestin therapy for amenorrhea.

Dopamine Agonists When hyperprolactinemia is the cause of amenorrhea, dopamine agonists are preferred. Dopamine agonists restore normal prolactin levels, resolve amenorrhea, and restore ovulation in 80% to 90% of women.[14] Bromocriptine and cabergoline are the most commonly studied agents, with cabergoline being more effective in resolving amenorrhea.[14,15]

Progestins Progestins induce withdrawal bleeding in women with secondary amenorrhea. Withdrawal bleeding occurs with intramuscularly injected progesterone and oral MPA in 70% and 95% of patients, respectively.[16] The usual dose of oral MPA is 10 mg orally once daily for 7 to 10 days.[11]

Insulin-Sensitizing Agents PCOS-induced amenorrhea may respond well to insulin sensitizing agents.[17] Using metformin for this purpose is discussed in the anovulatory bleeding section.

All patients experiencing amenorrhea should follow a diet rich in calcium and vitamin D to support bone health. Supplemental calcium and vitamin D (1200 mg/800 IU/day) should be recommended for patients with inadequate dietary consumption.[11] Figure 50–3 illustrates treatment recommendations for amenorrhea.[11]

Amenorrhea in Adolescents

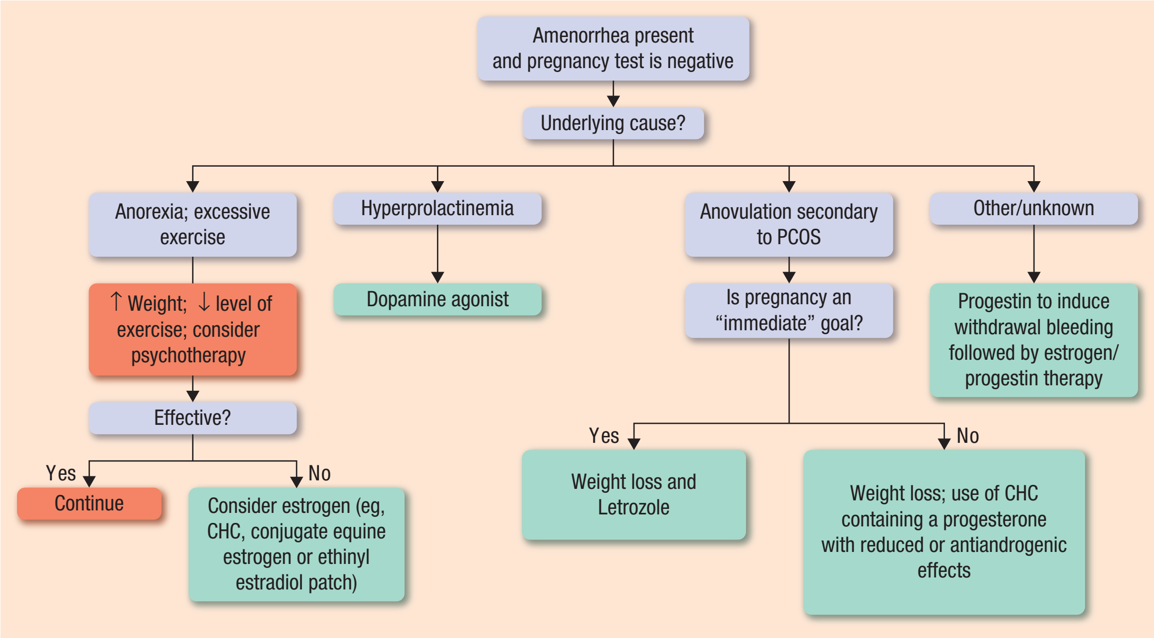
Optimal treatment of adolescents diagnosed with amenorrhea, especially primary ovarian insufficiency, includes careful consideration to both the physical and emotional needs of a young patient receiving this diagnosis. It may be difficult to process the emotions to understand the immediate and long-term impacts of amenorrhea diagnosis on long-term fertility. Patients may need higher doses of estrogen than menopausal women in order to ensure adequate replacement and optimal bone health. For patients with absent or incomplete breast development, estrogen therapy should be started and increased slowly before adding progesterone in order to allow for breast development and prevent tubular breast development. Once puberty is complete, the goal becomes maintaining normal ovarian functioning levels of estradiol. Estradiol 100 mcg daily is recommended, either by transdermal, oral, or occasionally transvaginal administration may be considered. Cyclic progesterone should be added for 10 to 12 days each month to help protect against endometrial hyperplasia and endometrial cancer. Oral contraceptives often contain higher doses of estrogen than what is needed and are no longer recommended as first-line therapy.[12]

ANOVULATORY BLEEDING

Anovulatory uterine bleeding is irregular menstrual bleeding from the endometrium ranging from light spotting to heavy blood flow.[18] It includes menstrual bleeding that occurs outside of the normal cyclic bleeding. This bleeding occurs due to the effects of unopposed estrogen. Of note, it does not include bleeding due to uterine anatomic lesions.[18] Many women pursue medical care to regulate menstrual cycles or improve fertility.

Epidemiology and Etiology

Anovulatory uterine bleeding is the most common form of noncyclic uterine bleeding. PCOS is the most common cause, occurring in 8% to 13% of women.[19] Anovulation results from dysfunction at any level of the hypothalamic–pituitary–ovarian axis which can be due to physiologic life stages such as adolescence, perimenopause, pregnancy, and lactation or pathologic causes (see Table 50–2).[18] Anovulation may also occur at any time during the reproductive years due to a pathologic cause. The most common causes of nonphysiologic ovulatory dysfunction are PCOS, hypothalamic amenorrhea, hyperprolactinemia, and premature ovarian failure.



Amenorrhea present and pregnancy test is negative
Underlying cause?
Anorexia; excessive exercise
Hyperprolactinemia
Anovulation secondary to PCOS
Other/unknown
↑ Weight; ↓ level of exercise; consider psychotherapy
Dopamine agonist
Is pregnancy an "immediate" goal?
Progestin to induce withdrawal bleeding followed by estrogen/progestin therapy
Effective?
Yes
No
Continue
Consider estrogen (eg, CHC, conjugate equine estrogen or ethinyl estradiol patch)
Yes
No
Weight loss and Letrozole
Weight loss; use of CHC containing a progesterone with reduced or antiandrogenic effects

FIGURE 50–3. Treatment algorithm for amenorrhea. (CHC, combination hormonal contraceptive; IUD, intrauterine device; PCOS, polycystic ovary syndrome.) Reproduced with permission from DiPiro JT, Yee GC, Posey IM, et al., eds. Pharmacotherapy: A Pathophysiologic Approach. 11th ed. New York City: McGraw-Hill; 2020.

Pathophysiology

In anovulation, a corpus luteum does not develop, and the ovary fails to secrete progesterone. This causes the endometrium to continue proliferation under the influence of unopposed estrogen, and eventually it becomes thick, vascular, and fragile. The clinical result is unpredictable, heavy, noncyclic bleeding, as sporadic sloughing of the endometrium begins to occur[18] (see Table 50–2).

Treatment

▶ *Desired Outcomes*

The desired outcomes are to stop acute bleeding, restore natural cycle of endometrial growth and shedding, decrease long-term complications of anovulation (eg, osteopenia and infertility), and improve QOL.[18]

▶ *Nonpharmacologic Therapy*

Nonpharmacologic treatment options depend on the underlying cause. For women with PCOS, weight loss of 5% to 10% may help improve menstrual regularity, decrease hirsutism, improve insulin sensitivity, and increase response to fertility treatments.[20] In women who have completed childbearing or who have failed medical management, endometrial ablation or resection, and hysterectomy are considered surgical options.

Clinical Presentation and Diagnosis of Amenorrhea

General

- Concerns about cessation of menses and fertility implications
- Generally no acute distress

Symptoms

- Cessation of menses
- Possible reports of infertility, vaginal dryness, decreased libido

Signs

- The absence of menses by age 15 in the presence of normal secondary sexual development or within 5 years of **thelarche** (if occurs before age 10)
- Recent significant weight loss or gain
- The presence of acne, hirsutism, hair loss, or **acanthosis nigricans** suggests androgen excess

Laboratory Tests

- Pregnancy test
- Thyroid-stimulating hormone (TSH)
- Prolactin
- If PCOS is suspected, consider free or total testosterone, 17-hydroxyprogesterone, fasting glucose, and fasting lipid panel.
- If premature ovarian failure is suspected, consider follicle-stimulating hormone (FSH) and luteinizing hormone (LH) measurements.

Other Diagnostic Tests

- Pelvic ultrasound to evaluate for polycystic ovaries
- May consider progesterone challenge, by administering either progesterone 100- to 200-mg intramuscular injection or oral MPA 10 mg daily for 5 to 10 days to see if it induces a menstrual period. If bleeding occurs beyond spotting within 2 weeks after progesterone is given, the amenorrhea is due to anovulation. If no withdrawal bleeding occurs, amenorrhea is due to other causes.

Patient Encounter 2

A 43-year-old woman presents for a gynecologic examination with complaints of galactorrhea and amenorrhea for the last year. All previous Pap smears have been normal, and she denies a history of sexually transmitted infections. She reports history of one sexual partner, her husband, of 10 years. Currently sexually active, she is not on any form of contraception and does not desire any more children. PMH significant for hypertension, type 2 diabetes mellitus, and hirsutism. Current medications include hydrochlorothiazide 25 mg once daily, lisinopril 20 mg once daily, and metformin 1000 mg twice daily. On examination, patient is overweight with mild acne and hirsutism.

Labs: (–) human chorionic gonadotropin (hCG); free testosterone 103 ng/dL (3.6 nmol/L; elevated); TSH 2.7 µIU/mL (mIU/L; WNL); fasting glucose 136 mg/dL (7.5 mmol/L); total cholesterol 198 mg/dL (5.12 mmol/L); LDL cholesterol 115 mg/dL (2.97 mmol/L), HDL cholesterol 60 mg/dL (1.55 mmol/L); triglycerides 68 mg/dL (0.77 mmol/L), prolactin 145 ng/mL (mcg/L; 6300 pmol/L)

Pelvic ultrasound: normal findings

What anovulatory disorder is this patient most likely experiencing?

What pharmacologic therapies are recommended for this patient?

▶ *Pharmacologic Therapy*

Estrogen Table 50–1 summarizes therapeutic agents and doses. Estrogen is the recommended treatment for managing acute bleeding episodes because it promotes endometrial growth and stabilization.[18] CHCs are useful for cycle regulation, helping to provide a more predictable menstrual cycle. For women with PCOS, CHCs also suppress ovarian hormones and adrenal androgen production, and oral agents also indirectly increase sex hormone-binding globulin. This, in turn, binds and reduces circulating androgen.[17,18] Women with high androgen levels or signs of hyperandrogenism (eg, hirsutism, acne) are recommended to start low-dose CHCs (35 mcg or less ethinyl estradiol) and a progesterone with minimal androgenic side effects (eg, norgestimate and desogestrel) or antiandrogenic effects (eg, drospirenone).[20]

Clinical Presentation and Diagnosis of Anovulatory Bleeding

General

- Acute distress may or may not be present.

Symptoms

- Irregular, heavy, or prolonged vaginal bleeding, perimenopausal symptoms (hot flashes, night sweats, vaginal dryness, dyspareunia)

Signs

- Acne, hirsutism, obesity

Laboratory Tests

- If suspect PCOS: free or total testosterone, fasting glucose, fasting lipid panel
- If suspect perimenopause: TSH and FSH

Other Diagnostic Tests

- Pelvic ultrasound to evaluate for polycystic ovaries

Progestins Women who experience side effects or have contraindication(s) to estrogen, or who have abnormal uterine bleeding due to anovulatory bleeding, should consider progesterone-only products. For women with PCOS, depot and intermittent oral MPA suppress pituitary gonadotropins and circulating androgens, leading to endometrial shedding.[19] If contraception is desired, placement of a levonorgestrel-releasing IUD is an option.

Estrogen Modulators Women with anovulatory bleeding from PCOS who are pursuing pregnancy should be seen by a fertility specialist. Women may be treated with letrozole or clomiphene citrate for ovulation induction under specialist care.

Insulin-Sensitizing Agents Metformin improves insulin sensitivity, reduces circulating androgen concentrations, and improves ovulation rates and should be considered for women with PCOS for management of metabolic features.[20] Notably, metformin may increase spontaneous ovulation, and contraception should be used in women with PCOS who do not desire pregnancy.

Anovulatory Bleeding in Adolescents

Anovulation is the most common cause of non-cyclic uterine bleeding in adolescents. Anovulatory bleeding in teenagers can become excessive, persistent, and require medications to treat. The differential diagnosis is similar to adults and should include evaluation for blood dyscrasias.[18,22] Patients should also be evaluated for PCOS by assessing for signs of hyperandrogenism, including acne and hirsutism.[18]

HEAVY MENSTRUAL BLEEDING

Heavy menstrual bleeding describes prolonged menstrual bleeding (lasting > 7 days) or cyclic, heavy menstrual bleeding (> 80 mL per cycle).[23] It can be difficult to quantify menstrual blood loss in clinical practice. Women will often seek medical attention with concerns of containment flow problems, unpredictable heavy flow, reduced QOL, anemia, and other dysmenorrhea symptoms. These women may have blood loss of less than 80 mL but still warrant treatment based on the heavy bleeding's impact on QOL, and social, professional, familial, and sexual aspects of life.

Epidemiology and Etiology

Heavy menstrual bleeding accounts for 18% to 30% of gynecological visits.[24] KEY CONCEPT Causes of heavy menstrual bleeding are divided into systemic disorders and reproductive tract abnormalities. KEY CONCEPT Women presenting with heavy menses should be examined to rule out intrauterine pregnancy, ectopic pregnancy, and miscarriage. Additionally, genital tract malignancies and infections may present with abnormal bleeding.[16] Systemic disorders include coagulation dysfunction such as von Willebrand disease, hemophilia, and platelet function disorders, in addition to hypothyroidism.[16,21,22] Specific reproductive tract causes of abnormal uterine bleeding are more common in older childbearing women, and include fibroids, adenomyosis, endometrial polyps, PID, and gynecologic malignancies.[25,26]

Clinical Presentation and Diagnosis of Heavy Menstrual Bleeding

General

- Acute distress may or may not be present.

Symptoms

- Reports of heavy/prolonged menstrual flow. Associated symptoms may include dysmenorrhea, fatigue, or lightheadedness in the case of severe blood loss.

Signs

- Orthostasis, tachycardia, and pallor may be noted, especially with significant acute blood loss.

Laboratory Tests

- Complete blood count (CBC) and ferritin levels; hemoglobin and hematocrit results may be low.
- TSH to rule out thyroid deficiencies
- If the history dictates, testing may be done to identify coagulation disorder(s) as a cause.

Other Diagnostic Tests

- Pelvic ultrasound
- Pelvic magnetic resonance imaging
- Papanicolaou smear
- Endometrial biopsy
- Hysteroscopy
- Sonohysterogram

Pathophysiology

Table 50–2 describes the pathophysiology of heavy menstrual bleeding and specific conditions resulting in abnormal uterine bleeding.

Treatment

▶ *Desired Outcomes*

Goals of therapy include reducing menstrual blood flow, preventing or correcting iron-deficiency anemia, improving QOL, and deferring the need for surgical intervention. Treatment recommendations are outlined in Table 50–1 and Figure 50–4.

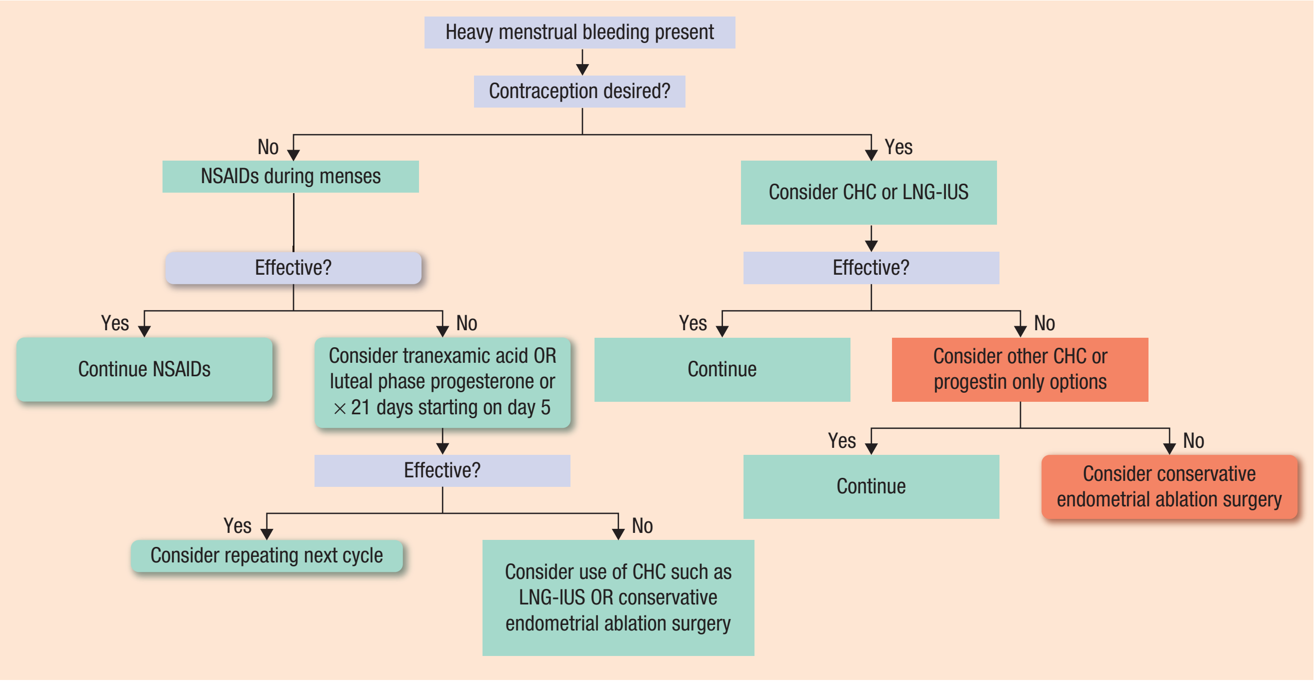
▶ *Nonpharmacologic Therapy*

Surgical interventions may be considered and are based on the clinical stability of the patient, severity of bleeding, contraindications to medical management, and patient response to medical management. Interventions range from endometrial ablation to hysterectomy and are often guided based on the patient's choice to maintain fertility.[16]

▶ *Pharmacologic Therapy*

NSAIDs are beneficial for patients desiring therapy only during menses, and without the need for contraception. They are associated with a 10% to 51% reduction in blood loss and are also beneficial for dysmenorrhea symptoms.[24]

Combination Hormonal Contraceptives CHCs are beneficial to women with heavy menstrual bleeding who do not desire pregnancy and are associated with a 30% to 60% reduction in blood loss.[24] Although many CHCs have been used for heavy menstrual bleeding and it is assumed all will lower menstrual blood loss,



Heavy menstrual bleeding present

Patient Encounter 3

An 18-year-old female presents for a follow-up for heavy menstrual bleeding. She reports she has been taking naproxen 550-mg loading dose 1 to 2 days prior to menses, followed by 275 mg every 6 to 12 hours during her period each month for the last 18 months. She notes the naproxen seems to have helped with the bleeding; however, her periods are heavy and require a change in supersize tampon every 3 to 4 hours despite continuing NSAID therapy. She reports issues with flow containment and associated embarrassment. She has noticed over the last few months, she feels tired and her hair has thinned. Her last menstrual cycle was 12 days ago, and she entered menarche at age 12. She is not sexually active and she does not take any medications. She is generally very active. Pelvic ultrasound completed and unremarkable.

What diagnostic tests should be considered for the patient?

What nonpharmacologic and pharmacologic therapies are recommended for this patient?

the only agent approved by the Food and Drug Administration (FDA) for heavy menstrual bleeding is the four-phasic formulation containing estradiol valerate and dienogest.[24]

Progestins Heavy menstrual bleeding may also be treated with progestin-only contraceptives. The levonorgestrel IUD reduces menstrual flow by up to 70% to 96% and is considered the most effective treatment to reduce menstrual flow.[24] In a small open-label study, the levonorgestrel 54-mg IUD resulted in a greater blood loss reduction and number of days missed at work or school when compared to oral CHCs.[28] When compared to endometrial ablation, the levonorgestrel IUD causes similar reductions in menstrual blood loss and improved QOL after up to 2 years following treatment. Its use may also help postpone or cancel the need for endometrial ablation or hysterectomy.

Cyclic progestin therapy as oral norethindrone acetate or MPA, either during the luteal phase only or for 21 days of the menstrual cycle, leads to regulation of the menstrual cycle in 50% of women.[26]

Progestin-related side effects are typically greater in women using the levonorgestrel IUD when compared with oral progestin and often include intermenstrual bleeding and breast tenderness.

Patient Care Process

Collect Information:

- Review medical history and physical assessment findings and complete physical examination and review of systems, including gynecological history (eg, start of menarche, presence of galactorrhea, symptoms of androgen excess, review of typical menstrual cycle including frequency, duration, and associated symptoms, sexual history, and history of gynecological infections). Additional workup may be necessary depending on a patient's presenting problem(s) (eg, amenorrhea, abnormal uterine bleeding, anovulatory bleeding, or PCOS), including a pregnancy test or pelvic examination.
- Perform medication history for the use of prescription, nonprescription, and dietary supplements. Determine if any treatments have previously helped with chief complaint(s). Identify allergies to medications or other substances.
- Review current and future desire for children and contraception beliefs and preferences with the patient.

Assess the Information:

- Based on medical history and presenting symptoms, determine which menstruation-related disorder the patient currently has.
- Review available diagnostic data to determine hormonal, reproductive, and pregnancy status.
- Document presenting symptoms and medical history, including pertinent family medical history.
- Based on physical examination, review of symptoms, and patient history, determine if patient is experiencing signs or symptoms of complications from menstruation-related disorder, such as symptoms of anemia in women presenting with abnormal uterine bleeding, or difficulty conceiving in women with amenorrhea or anovulatory bleeding.
- Assess the appropriateness, efficacy, safety, and adherence of current therapy.

Develop a Care Plan:

- Educate patient on lifestyle modifications and nonpharmacological therapy recommendations.
- Select pharmacotherapy, if indicated, that is effective and safe.
- Determine whether long-term maintenance treatment is necessary.
- Discuss the importance of adherence to medication management and lifestyle modifications.

Implement the Care Plan:

- Educate the patient about changes in drug therapy, medication administration, potential adverse effects, and how to manage and report adverse effects that occur.
- Address any patient concerns about their menstruation-related disorder and its management.
- Address any secondary concerns the patient may be experiencing (eg, infertility, anemia, decline in QOL).
- Determine whether the patient has insurance coverage or whether recommended agents are included on the patient's insurance formulary.

Follow-up: Monitor and Evaluate:

- Follow up in 3 to 6 month intervals, or more frequently if needed, to assess efficacy and safety of therapy until goals are met, or symptoms resolved.
- Assess improvement in QOL.
- Review medical history, physical examination findings, and laboratory and diagnostic tests to assess changes in clinical status and continued need for pharmacological therapy.
- Evaluate for adverse drug reactions, drug allergies, and drug interactions.

Tranexamic Acid Tranexamic acid works by preventing fibrin degradation and is effective for patients with chronic abnormal uterine bleeding.[16] Evidence shows it reduces bleeding in patients with chronic issues by 34% to 56%.[4]

Abnormal Uterine Bleeding in Adolescents

An estimated 50% of adolescents with heavy menstrual bleeding have a bleeding disorder, most commonly von Willebrand disease or platelet dysfunction.[22] The incidence of von Willebrand disease is 1% to 2% in the general population; however, an estimated 5% to 36% of adolescents presenting with heavy menses have von Willebrand disease.[22] It is important to assess adolescent women presenting with heavy menstrual bleeding for a potential bleeding disorder.

OUTCOME EVALUATION

Treatment success for menstruation-related disorders is measured by how well the treatment (a) relieves or reverses symptoms, (b) prevents or alleviates complications (eg, osteoporosis, anemia, and infertility), and (c) causes minimal adverse effects. A regular menstrual cycle should resume, with minimal premenstrual or dysmenorrhea symptoms. Depending on the desire for conception and related therapy, these cycles may be ovulatory or anovulatory.

Assess treatment effectiveness in restoring normal menstrual cycles with minimal adverse effects after an appropriate treatment interval (2–3 months). Assess improvement in well-being and QOL (eg, physical, psychological, and social functioning). Evaluate the patient for adverse drug reactions (see Table 50–1), drug allergies, and drug interactions. Table 50–3 lists the expected outcome measures for each discussed menstruation-related disorder.

MENOPAUSE

Epidemiology and Etiology

Menopause is marked by the final menstrual period (FMP) resulting from loss of follicular activity and confirmed by 12 months of amenorrhea.[27] The average age for women to experience menopause is 52 years; however, women who undergo a hysterectomy with bilateral salpingo-oophorectomy experience menopause earlier compared with women who experience natural menopause, due to the removal of the ovarian tissue. Other factors associated with early menopause include low body weight, increased menstrual cycle length, nulliparity, and smoking.

Perimenopause is the transitional period prior to menopause when hormonal and biologic changes begin. It begins with the onset of menstrual cycle irregularities, and/or other menopausal symptoms.[27] Women may still intermittently ovulate during this time.

Physiology

The physiologic changes that occur during the perimenopausal and menopausal periods are caused by the decrease and eventual loss of ovarian follicular activity.[28] As women age, the number of ovarian follicles decrease, and the remaining follicles require higher levels of follicle-stimulating hormone (FSH) for maturation and ovulation. During perimenopause, anovulatory cycles are more likely as the lack of progesterone production leads to irregular and unpredictable menses. During menopause, FSH concentrations may increase 10- to 15-fold, luteinizing hormone (LH) concentrations increase fivefold, and levels of circulating estradiol decrease more than 90%. Due to fluctuations in this increase, FSH and LH levels are not required for diagnosis.[28]

Clinical Presentation and Diagnosis of Menopause

Menopausal Symptoms

- Vasomotor symptoms (hot flashes, night sweats)
- Sleep disturbances
- Mood changes
- Genitourinary syndrome of menopause (genital symptoms such as dryness, burning, or irritation [sometimes described as vulvovaginal atrophy], urinary symptoms such as dysuria, urgency and recurrent urinary tract symptoms; and sexual symptoms of dryness and dyspareunia)
- New-onset depression
- Problems with concentration and memory

Diagnosis

- Amenorrhea for 12 months
- FSH greater than 40 IU/L (mIU/mL)
- Fivefold increase in LH *not required to make diagnosis

KEY CONCEPT Common symptoms of menopause include vasomotor symptoms, and genitourinary syndrome of menopause.[27,29] Additional symptoms may include mood changes, sleep disturbances, new-onset depression, problems with concentration memory, and arthralgias. Menopausal symptoms are often more severe in women with surgically induced menopause compared with natural menopause due to a more rapid decline in estrogen concentrations.[27] Women should undergo laboratory evaluation to rule out other causes, such as abnormal thyroid function or pituitary adenoma, before menopausal hormone therapy (MHT) may be considered.

Treatment

▶ *Desired Outcomes*

MHT is the most effective treatment for moderate-to-severe menopausal symptoms. Treatment goals include alleviating or reducing menopausal symptoms and improving QOL while minimizing adverse effects of therapy. Lowest effective dose, shortest

Patient Encounter 4

A 51-year-old African American woman with a history of hypothyroidism, obesity, and poorly controlled hypertension presents to the clinic complaining of hot flashes, vaginal dryness, dyspareunia, and insomnia. She states that she experiences approximately seven to eight hot flashes per day and is awakened from sleep at least three times per week requiring her to change her bed clothes. Her symptoms began about 6 months ago and have worsened to the point where they are significantly impacting her QOL. Upon questioning, she states she has no past surgical history.

Which of the patient's symptoms and past medical history are consistent with menopause?

What additional information do you need to know in order to make an appropriate therapeutic plan for this patient?

Table 50–3

Hormone Formulations and Dosages[11,15,16]

Product	Available Strengths	Common Dosages
Oral estrogens		
Conjugated estrogens (Premarin)	0.3–1.25 mg	0.3–0.625 mg/day
Esterified estrogens (Menest)	0.3–1.25 mg	0.3–1.25 mg/day
Estradiol (Estrace[a])	0.5–2 mg	1–2 mg/day
Estropipate[a]	0.75–3 mg	0.75–6 mg/day
Transdermal estrogens		
Estradiol patch (Alora, Minivelle, Vivelle-Dot)	0.025–0.1 mg/24 hour	0.025–0.1 mg, changed twice weekly
(Climara,	0.025–0.1 mg/24 hour	0.025–0.1 mg, changed weekly
(Menostar[b])	0.014 mg/24 hour	0.014 mg/ changed weekly
Topical estrogens		
Vaginal creams		
Conjugated estrogens (Premarin)	0.625 mg/g	0.5–2 g/day
Estradiol (Estrace)	0.01%	1 g one to three times/week
Gel		
Estradiol gel		
(Elestrin)	0.06%	1–2 actuations of pump once daily
(EstroGel)	0.06%	1 actuation of pump once daily
(Divigel)	0.1%	0.25 g/day packet once daily
Spray		
Estradiol spray (Evamist)	1.53 mg/actuation	1–3 sprays daily
Vaginal inserts		
Vaginal ring		
Estradiol (Estring)	2 mg	1 ring every 3 months
Estradiol acetate (Femring)	0.05–0.1 mg/24 hour	1 ring every 3 months
Vaginal tablet		
Estradiol (Vagifem)	10-mcg estradiol	One tablet twice weekly
(Yuvafem)	10-mcg estradiol	One tablet twice weekly
Vaginal insert		
Estradiol (Imvexxy)	4–10-mcg estradiol	One insert twice weekly
(Yuvafem)	10-mcg estradiol	One insert twice weekly
Progestogens[c,d]		
Medroxyprogesterone acetate (Provera)	2.5–10 mg	5–10 mg once daily for 12–14 days sequentially per 28-day cycle
Micronized progesterone (Prometrium)	100–200 mg	100 mg once daily for 12–14 days sequentially per 28-day cycle
Norethindrone acetate (Aygestin)	2.5–5 mg	5 mg once daily for 12–14 days sequentially per 28-day cycle
Combination products[d]		
Oral		
Conjugated estrogens + medroxyprogesterone (Prempro; Premphase)	0.3/1.5 mg–0.625/5 mg	One tablet daily
Conjugated estrogens + bazedoxifene (Duavee)	0.45 mg/20 mg	One tablet daily
Estradiol + norethindrone (Activella; Amabelz, Mimvey; Lopreeza)	0.5 mg/0.1 mg–1 mg/0.5 mg	One tablet daily
Estradiol + drospirenone (Angeliq)	0.5 mg/0.25 mg–1mg/0.5 mg	One tablet daily
Ethinyl estradiol + norethindrone acetate (Femhrt low dose, Fyavolv)	2.5 mcg/0.5 mg–5 mcg/1 mg	One tablet daily
Estradiol + norgestimate (Prefest)	1 mg/0.09 mg	One tablet daily
Estradiol + progesterone (Bijuva)	1 mg/100 mg	One capsule daily in evening
Transdermal		
Estradiol + norethindrone acetate (CombiPatch)	0.05/0.14–0.05/0.25 mg/24 hour	Apply one patch twice weekly
Estradiol + levonorgestrel (Climara Pro)	0.045/0.015 mg/24 hour	Apply one patch once weekly

[a] FDA-approved commercially available bioidentical product.

[b] Indicated for the prevention of postmenopausal osteoporosis only

[c] May be administered cyclically or continuously.

[d] Dose varies based on daily or cyclic administration.

CEE, conjugated equine estrogens; MPA, medroxyprogesterone acetate.

duration possible, and appropriate regimen and route of administration should be used to minimize risk.

▶ *General Approach to Treatment*

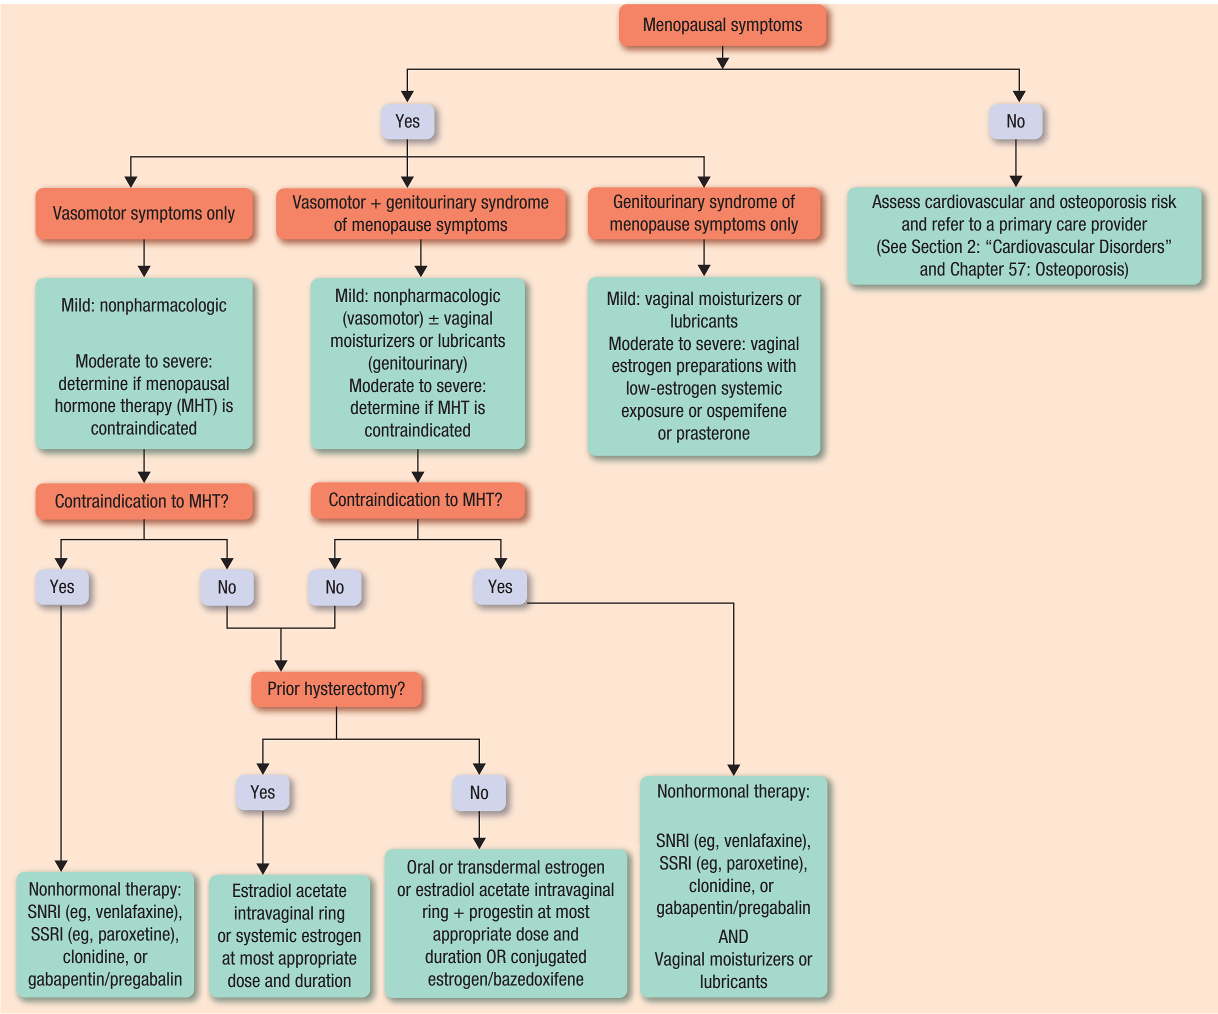
There are a number of national and international guidelines and consensus statements available on the management of menopause.[28-37] Women who seek medical treatment usually have symptoms that diminish their QOL. An assessment confirming that vasomotor symptoms (VMS) are adversely affecting sleep, daytime functioning, or QOL should be completed prior to initiating prescription hormone therapy.[34] **KEY CONCEPT** Women should undergo a risk factor assessment for absolute contraindications including breast or endometrial cancer; cardiovascular disease including coronary heart disease (CHD), stroke, or transient ischemic attack; active liver disease; and undiagnosed vaginal bleeding before MHT is considered and shared decision-making should be utilized to select appropriate therapy (Figure 50–5). Nonhormonal options are available for women who have contraindications or are unwilling to take MHT, but these options may have limited evidence for efficacy and safety.

▶ *Nonpharmacologic Therapy*

Evidence for efficacy and safety of nonpharmacologic therapy is limited. Group- and individual-based cognitive-behavioral therapy, clinical hypnosis, and yoga have limited evidence showing benefit for VMS.[27,28,38,39] Mindfulness-based stress reduction and weight loss may also be recommended. Due to the minimal adverse effects of these interventions, patients should try behavioral modifications prior and in addition to pharmacologic therapy. Cooling techniques, avoidance of triggers, exercise, and relaxation are not recommended for relief of VMS, as there are negative, insufficient, or inconclusive data supporting their use. First-line therapies to alleviate symptoms of mild genitourinary syndrome of menopause (GSM) include nonhormonal vaginal lubricants and moisturizers; however, evidence supporting the efficacy of these products is limited.[29]

▶ *Pharmacotherapy: Hormonal Therapy*

After assessment for appropriate indications and performance of a risk factor assessment, systemic MHT may be recommended for patients less than 60 years of age, with menopause onset within 10 years, and at a low risk of breast cancer or cardiovascular disease.[34] MHT can be considered with caution in those greater than 60, with menopause onset greater than 10 years prior; or with moderate risk of breast cancer or cardiovascular disease. MHT should be avoided in those with a high risk of breast cancer; or a high risk of cardiovascular disease; or those greater than 60, greater than 10 years since menopause onset, and at a moderate risk.



Menopausal symptoms
Yes
No
Vasomotor symptoms only
Vasomotor + genitourinary syndrome of menopause symptoms
Genitourinary syndrome of menopause symptoms only
Assess cardiovascular and osteoporosis risk and refer to a primary care provider (See Section 2: "Cardiovascular Disorders" and Chapter 57: Osteoporosis)
Mild: nonpharmacologic
Moderate to severe: determine if menopausal hormone therapy (MHT) is contraindicated
Mild: nonpharmacologic (vasomotor) ± vaginal moisturizers or lubricants (genitourinary)
Moderate to severe: determine if MHT is contraindicated
Mild: vaginal moisturizers or lubricants
Moderate to severe: vaginal estrogen preparations with low-estrogen systemic exposure or ospemifene or prasterone
Contraindication to MHT?
Contraindication to MHT?
Yes
No
No
Yes
Prior hysterectomy?
Yes
No
Nonhormonal therapy:
SNRI (eg, venlafaxine), SSRI (eg, paroxetine), clonidine, or gabapentin/pregabalin
AND
Vaginal moisturizers or lubricants
Nonhormonal therapy: SNRI (eg, venlafaxine), SSRI (eg, paroxetine), clonidine, or gabapentin/pregabalin
Estradiol acetate intravaginal ring or systemic estrogen at most appropriate dose and duration
Oral or transdermal estrogen or estradiol acetate intravaginal ring + progestin at most appropriate dose and duration OR conjugated estrogen/bazedoxifene

Patient Encounter 5: Medical History, Physical Examination, and Diagnostic Tests

The workup reveals the following additional information:

PMH: Hypertension since age 45, currently poorly controlled; hypothyroidism since age 25; obesity

FH: Father: Deceased due to MI at age 54. Mother: Alive with hypothyroidism, HTN, and diabetes. Siblings: Two, noncontributory history

SH: Occupation: civil engineer; nonsmoker; drinks one glass of red wine with dinner on the weekends; smokes marijuana two times per month

Meds: lisinopril 5 mg by mouth once daily; levothyroxine 0.1 mg by mouth once daily; takes all medications 30 minutes before breakfast. Occasionally forgets to take lisinopril.

ROS: (+) hot flashes (+) dyspareunia; (+) vaginal dryness; (+) insomnia, (–) bowel changes, 5-lb (2.3 kg) weight gain since last visit 6 months ago.

PE:

Gen: WDWN woman in NAD

VS: BP 140/78, P 78, RR 16, T 37.0°C (98.6°F), Ht 5′6″ (168 cm), Wt 83.4 kg (184 lbs)

HEENT: WNL

Neck: Supple; no bruits, no adenopathy, no thyromegaly

Breasts: Supple; no masses

CV: RRR, normal S_1 and S_2; no MRG

Abd: Soft, nontender, nondistended; (+) BS, no masses

Genitourinary: Pelvic examination normal except (+) mucosal atrophy; stool guaiac (–)

Ext: (–) CCE; pulses intact

Neuro: normal sensory and motor

Labs:

FSH: 105 mIU/mL (IU/L)

TSH: 2.46 μIU/mL (mIU/L)

Chem-7 (fasting): Na 136 mEq/L (mmol/L), K 4.2 mEq/L (mmol/L), Cl 104 mEq/L (mmol/L), CO_2 25 mEq/L (mmol/L), BUN 9 mg/dL (3.2 mmol/L), SCr 0.9 mg/dL (80 μmol/L), Glucose 90 mg/dL (5.0 mmol/L)

CBC: Hgb 13 g/dL (130 g/L or 8.07 mmol/L), Hct 39% (0.39 volume fraction), WBC 4.5 × 10^3/mm^3 (5.5 × 10^9/L), platelets 250 × 10^3/mm^3 (250 × 10^9/L)

Fasting lipid levels: Total cholesterol (TC) 200 mg/dL (5.17 mmol/L), low-density LDL 128 mg/dL (3.31 mmol/L), HDL 48 mg/dL (1.24 mmol/L), triglycerides 120 mg/dL (1.36 mmol/L)

Assess the patient's condition based on this additional information.

What are the goals of treatment for this patient?

Conduct a risk factor assessment for this patient.

Recommend nonpharmacologic and pharmacologic treatment for this patient. Justify your recommendations.

Estrogens Estrogen is indicated for moderate-to-severe VMS with or without GSM. It is also indicated for the prevention of postmenopausal osteoporosis in women with significant risk; however, it is recommended that nonestrogen medications be used first line if the sole indication is osteoporosis.[34] Appropriate dose, duration, regimen, and route of administration should be utilized at the lowest effective dose of MHT. Topical vaginal products in the form of creams, tablets, or certain rings should only be prescribed for women experiencing GSM without VMS.

The transdermal route of administration bypasses the liver and has shown to have less risk of venous thromboembolism (VTE) and gallbladder disease.[28,33,39] Transdermal estrogen preparations are usually prescribed for patients who experience adverse effects, elevated triglycerides, or liver function abnormalities while taking an oral product. Low-dose vaginal estrogens are available in several forms and comparative analysis have found similar efficacy in the alleviation of GSM.[29]

Progestogens KEY CONCEPT Women who have an intact uterus should be prescribed a progestogen in addition to estrogen due to the increased risk of endometrial hyperplasia and endometrial cancer with estrogen monotherapy (unopposed estrogen).[27] Women with an intact uterus and on estrogen therapy must always be prescribed a progestogen or selective estrogen receptor modulator (SERM), bazedoxifene, for endometrial protection. Progestogens should be prescribed for at least 12 to 14 days of the month and often are prescribed continuously. Table 50–3 lists estrogen and progestogen preparations and dosages.

Adverse Effects

Estrogen therapy with or without a progestogen should be initiated at the lowest dose in order to minimize adverse effects. Changing preparations, particularly the progestogen, or changing the method of administration may alleviate adverse effects. Table 50–4 lists the adverse effects that may be associated with estrogen and progestogen preparations. Adverse effects associated with the use of vaginal estrogen include vaginal discharge, vulvovaginal candidiasis, vaginal bleeding, and breast pain.[29] Trials have not demonstrated an increase in risk of endometrial or breast cancer, VTE, or cardiovascular outcomes with vaginal estrogen therapy.

Contraindications

Systemic MHT is contraindicated in women with unexplained vaginal bleeding, severe active liver disease, prior estrogen-sensitive breast or endometrial cancer, coronary heart disease (CHD), stroke, dementia, personal history or inherited high risk of thromboembolic disease, porphyria cutanea tarda, or hypertriglyceridemia.[28]

Methods of Administration

▶ *Continuous Estrogen and Cyclic Progestogen*

Estrogen is administered daily, and progestogen is administered for 12 to 14 days of the month. Menses returns in approximately 90% of women 1 to 2 days following the last progestogen dose. Women may view this scheduled bleeding as an advantage as it limits spotting.

Table 50–4

Adverse Effects of Systemic Estrogens and Progestogens[5,11,15,16]

Estrogens
Common adverse effects
- Nausea
- Headache
- Bloating
- Breast tenderness
- Breakthrough uterine bleeding

Serious adverse effects
- Coronary heart disease
- Stroke
- Venous thromboembolism
- Breast cancer
- Gallbladder disease

Progestogens
Common adverse effects
- Nausea
- Headache
- Weight gain
- Bleeding
- Irritability
- Depression

Serious adverse effects
- Venous thromboembolism (in combination with estrogen)
- Breast cancer (in combination with estrogen)
- Decreased bone mineral density (effect of injectable medroxyprogesterone acetate)

▶ *Continuous Combined Estrogen and Progestogen*

Estrogen and progestogen are administered daily and result in endometrial atrophy; therefore, women do not experience withdrawal bleeding but may experience unanticipated breakthrough bleeding or spotting. Continuous combined regimens offer the best protection against endometrial hyperplasia and cancer. If bleeding persists beyond 6 to 12 months, women should seek medical attention to rule out endometrial hyperplasia or cancer.

Benefits of HT

▶ *Vasomotor Symptoms*

If after VMS severity assessment and risk factor assessment is conducted, it is decided to initiate MHT, pharmacotherapy should be individualized and reassessed every 6 to 12 months. During reassessment visits, discontinuation of therapy should be considered if severity becomes mild or contraindications arise. Extended treatment duration may be warranted for relief of persistent VMS and prevention of bone loss when unable to tolerate therapy primarily indicated for osteoporosis.[28]

▶ *Genitourinary Symptoms of Menopause*

Topical vaginal preparations should be prescribed for women with moderate-to-severe GSM who do not respond to lubricants and moisturizers. If VMS are also present, systemic MHT is warranted. Vaginal estrogen does not require supplementation with a progestogen in women using low doses; however, women with an increased risk of endometrial cancer may warrant endometrial surveillance.[40] Intermittent progestogen therapy may be considered for women at high risk for endometrial cancer. A vaginal estrogen product may also be considered in women with VMS and GSM receiving systemic MHT with adequate VMS relief but lacking adequate GSM relief in an effort to reduce additional systemic exposure. Estradiol in the form of a vaginal tablet or ring is not significantly absorbed systemically, with the exception of the estradiol vaginal ring 0.05 to 0.1 mg/24 hour which is the only vaginal ring indicated for VMS.

Risks of MHT

The Women's Health Initiative (WHI) was a large, randomized, double-blind, placebo-controlled trial conducted to evaluate the effect of MHT on several outcomes including cardiovascular disease, osteoporosis/fracture risk, and certain cancers.[41,42] The two arms of the WHI included a CEE plus MPA in women with an intact uterus and CEE monotherapy in women without. Both arms were terminated early due to a significant increase in risk (stroke, VTE, and breast cancer in estrogen plus progestogen and stroke in the estrogen monotherapy).

▶ *Cardiovascular Disease*

There is an increased risk of CHD and stroke with daily MHT compared with placebo in women with an intact uterus without established CHD.[43,44] Women who initiate MHT greater than 10 years after menopause have an increased cardiovascular risk.[28,45] MHT should not be prescribed for the prevention of CHD or in patients with preexisting CHD.

▶ *Breast Cancer*

There may be an increased risk of breast cancer with the use of MHT in older women and in those who initiate therapy within 5 years of menopause.[41,46] A significant increased risk of breast cancer was not noted in women using CEE monotherapy in the WHI.[42] In a long-term follow-up study from the WHI, the use of CEE alone compared to placebo was associated with a significantly lower risk of breast cancer incidence and breast cancer mortality.[47] In contract, women in the CEE + MPA arm had a significantly higher risk of breast cancer incidence compared to placebo and no difference was found in breast cancer mortality. Whether MHT is associated with an increased risk for breast cancer recurrence is still questionable. Women with a history of breast cancer, and possibly even a strong family history of breast cancer, should avoid the use of MHT and consider nonhormonal therapies for the treatment of VMS. In the management of GSM for women with a high risk of breast cancer, the use of local MHT may be an option for some women who fail nonpharmacologic and nonhormone treatments. This decision should include a discussion of risks and benefits and review by the patient's oncologist. Increased risk of breast cancer with local MHT is highly unlikely.[29]

▶ *Venous Thromboembolism*

There is an increased risk for VTE with MHT, which may be dose related.[41] MHT administered orally is associated with a higher risk compared with the transdermal route.[39]

Discontinuation of MHT

KEY CONCEPT When treating moderate-to-severe postmenopausal symptoms, the benefit-to-risk ratio appears to be best when MHT is started close to the time of menopause. MHT therapy should be tapered at discontinuation to limit the recurrence of hot flashes. Although VMS subside for most women within 4 years, approximately 10% will continue to experience symptoms. Literature suggests that one of every four women needs to be reinitiated on MHT due to persistent and bothersome symptoms. There are few studies to guide the optimal method of discontinuation, but slowly discontinuing MHT over 3 to 6 months after 4 to 5 years of therapy is considered reasonable and associated with less risk of recurrent symptoms while mitigating the increase in breast cancer risk that occurs at this time.[28,40] Women experiencing menopause prior to age 45 should be encouraged to use MHT until the natural average age of menopause onset.

Alternative Hormonal Treatments

▶ *Selective Estrogen Receptor Modulators (SERMs)*

Although estrogen +/– progestogen remains first-line therapy for the relief of moderate-to-severe VMS with or without GSM, additional hormone options utilizing SERMs are available.

Ospemifene is approved for the treatment of vaginal dryness and moderate-to-severe dyspareunia. Ospemifene acts as an estrogen agonist in some tissues (vaginal and endometrial) and antagonist in other tissues. Ospemifene's action on the endometrium resulted in a black-boxed warning for caution in women with an intact uterus due to a potential for increased risk of endometrial cancer in a woman with an intact uterus who takes unopposed estrogen therapy. Although labeling states that ospemifene should not be used in patients with known or suspected breast cancer, some studies have found a decreased risk.[28,29]

CEEs 0.45 mg/bazedoxifene (BZA) 20 mg (Duavee), the first tissue-selective estrogen complex, is approved for the treatment of postmenopausal osteoporosis and moderate-to-severe VMS in women with an intact uterus.[28] CEE/BZA acts as an agonist in bone tissue and an antagonist in breast and uterine tissue. Adverse effects with CEE/BZA are minimal with musculoskeletal symptoms reported most commonly. Efficacy appears to be similar to CEE/MPA, with potentially less occurrence of estrogen-like adverse effects with CEE/BZA. An advantage of the formulation may be for women intolerant to progestogen adverse effects or when progestogen is contraindicated; however, because no long-term data are available, the same precautions and contraindications as estrogen products should be assumed.

▶ *Dehydroepiandrosterone (DHEA)*

Dehydroepiandrosterone (DHEA) is a precursor hormone for the synthesis of estrone, estradiol, and testosterone and was recently approved for intravaginal administration as prasterone for the treatment of moderate-to-severe dyspareunia.[48] Prasterone is not recommended in women with a history or suspected breast cancer and in women with abnormal uterine bleeding. The most common adverse effects are vaginal discharge and abnormal Pap smear. Unlike other estrogen products, prasterone is not contraindicated in women with a history of VTE or endometrial hyperplasia.

▶ *Bioidentical MHT*

The term bioidentical hormones refers to exogenous hormones that are identical to those produced in a woman's body (eg, estradiol, estrone, estriol, and progesterone) that are either commercially manufactured (such as micronized progesterone and estradiol) or custom-compounded into formulations such as topical creams, gels, and suppositories. Custom-compounded formulations utilizing bioidentical hormones may be subject to higher out-of-pocket costs and are not subject to the same US FDA regulations as commercially manufactured prescription products; therefore, the efficacy and safety data are lacking.[28,49-51] A recent publication from the National Academies of Sciences, Engineering, and Medicine makes the following recommendations regarding compounded bioidentical hormone therapy (cBHT): restrict use to allergy and not patient preference alone; review cBHT as candidates for the FDA Difficult to Compound List; improve education for prescribers and pharmacists marketing, prescribing, compounding, and dispensing cBHT preparations; additional federal- and state-level oversight to address safety and effectiveness concerns; collect and disclose conflicts of interest; and strengthen and expand on evidence base for safety and effectiveness of cBHT.[52]

Patient Encounter 6

The patient has been in good health for the past 9 years and is now 60. She reports adherence with her medications, a healthy diet and exercise routine, and her medical conditions are controlled. However, 2 months ago, she had a heart attack. She is concerned that her hormone therapy may have caused this.

Educate the patient regarding the risk of CHD and MHT.

▶ *Perimenopausal Contraception*

During the perimenopausal period, women may experience hot flashes despite continued menstrual cycles. CHCs can provide relief of VMS while also providing contraception and decreasing risk of ovarian and endometrial cancer. In perimenopausal women who may have contraindications for CHC, a progestin-only IUD may be used.

Nonhormonal and Alternative Treatments

Nonhormonal and alternative therapies (Table 50–5) have been studied for symptomatic management of VMS.[38] **KEY CONCEPT** The limited, and often conflicting, evidence demonstrates that these agents are only modestly effective compared to MHT and have adverse effects.

Selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) reduce the frequency of hot flashes by increasing serotonin in the central nervous system. Of the SSRIs, paroxetine mesylate is the only one approved to treat VMS and has the most published data demonstrating a reduction in hot flashes.[37] Other SSRIs and SNRIs such as escitalopram, citalopram, fluoxetine, sertraline, venlafaxine, and desvenlafaxine may also be effective. SSRIs and SNRIs should be considered for women who are unwilling or unable to take MHT, particularly those who suffer from depression or anxiety.

Gabapentin, pregabalin, and clonidine have also been studied for the management of menopausal symptoms and have demonstrated reductions in severity and frequency of hot flashes.[53] Clonidine has demonstrated reductions in hot flashes but to a lesser extent than gabapentin.[37]

Phytoestrogens are plant sterols that are structurally similar to human and animal estrogen. There are differences among classes

Patient Encounter 7

It has been 6 months since this patient discontinued taking MHT secondary to her heart attack. She presents to her PCP for follow-up with a chief complaint of occasional mild hot flashes and recurrent severe vaginal dryness and dyspareunia.

Recommend the most appropriate therapy for her recurrent mild hot flashes and GSM.

Table 50–5

Nonhormonal Therapies for Menopause[13,39,40,42]

Product	Initial Dose	Common Dosages	Potential Adverse Effects
Venlafaxine[a,b] (Effexor, Effexor XR	37.5 mg	37.5–150 mg/day	Nausea, HA, somnolence, dizziness, insomnia, hypertension, xerostomia constipation, diaphoresis, weakness
Desvenlafaxine[a,b] (Pristiq)	25–50 mg/day	100–150 mg/day	Nausea, xerostomia, constipation, vomiting, anorexia, dizziness, drowsiness, and insomnia
Paroxetine mesylate[c] (Brisdelle)	7.5 mg	7.5 mg/day	Nausea, somnolence, insomnia, HA, dizziness, xerostomia, constipation, diarrhea, weakness, diaphoresis
Paroxetine CR (Paxil CR)	12.5 mg CR	12.5 mg–25 mg CR/day	
Paroxetine HCl (Paxil)	10–20 mg	10–20 mg/day	
Citalopram (Celexa)	10 mg/day	10–20 mg/day	Xerostomia, nausea, drowsiness, and insomnia
Escitalopram (Lexapro)	10 mg/day	10–20 mg/day	Nausea, insomnia, drowsiness, and headache
Clonidine (Catapres, Catapres TTS)	0.1 mg/day	0.1–0.4 mg/day	Drowsiness, dizziness, hypotension, dry mouth
Gabapentin[a] (Neurontin)	300 mg at bedtime	900 mg/day, divided in three daily doses (up to 2400 mg/day)	Somnolence and dizziness (can decrease with gradual increase in dosing)
Pregabalin[a] (Lyrica)	75 mg twice daily	150–300 mg/day	Peripheral edema, dizziness, drowsiness, ataxia, headache, fatigue, weight gain, infection, diplopia, and tremor

[a] Dosage adjustments recommended in patients with renal impairment.

[b] Dosage adjustment recommended in patients with hepatic impairment.

[c] FDA approved for the treatment of moderate to severe hot flashes associated with menopause.

HA, headache.

of phytoestrogens and biologic potencies vary, making it difficult to recommend specific dosing. The most commonly studied phytoestrogen is the isoflavone class. These products should not be considered in women with a history of estrogen-dependent cancers due to unknown effects. Isoflavones are modestly effective in relieving menopausal symptoms.[37,54]

Black cohosh may be used as an alternative therapy for VMS.[37] The mechanism of action, safety profile, drug–drug interactions, and adverse effects of black cohosh remain unknown. However, there have been case reports of hepatotoxicity with its use. It is not recommended for more than a 6-month period of time. Other alternative treatments that have been utilized but are not effective include dong quai, red clover leaf, kava, and evening primrose oil.

OUTCOME EVALUATION

Evaluating the outcomes of any therapy for menopausal symptoms focuses primarily on the woman's report of symptom resolution. Monitor for breakthrough bleeding or spotting and refer to a primary care provider if abnormal or heavy bleeding occurs.[27] Monitor subjective parameters such as adverse effect occurrence, contraindication occurrence, and adherence. Objective parameters, including blood pressure, should also be monitored. Encourage yearly clinical breast examinations, mammograms, lipid panel, and thyroid-stimulating hormone (TSH) determination, particularly for women with hypothyroidism on thyroid therapy, and conduct a BMD test as indicated. Also perform endometrial studies, as necessary, in women with undiagnosed vaginal bleeding. Frequent follow up, proper monitoring, and education will help to ensure that the woman achieves optimal results from any therapy chosen to treat menopausal symptoms.

ACKNOWLEDGMENT

The authors and editors wish to acknowledge and thank Drs. Nicole S. Culhane and Regine Beliard, coauthors of the chapter Hormone Therapy in Menopause in the first through fifth editions of this book.

Patient Care Process

Collect Information:

- Obtain the chief complaint and history of present illness regarding symptomatology of VMS and GSM.
- Obtain patient health and functional goals for the treatment of VMS and GSM.
- Obtain a medical history that includes past medical history, social history, family history, surgical history, allergies, and information from a hot flash diary if the patient keeps one.
- Obtain a thorough medication history, including the use of over-the-counter and herbal products.

Assess the Information:

- Evaluate for the presence of VMS and GSM.
- Rule out other medical conditions that could be contributing to symptoms and manage those conditions prior to initiating therapy for symptoms.

(Continued)

Patient Care Process (*Continued*)

- If the patient is experiencing bothersome VMS with or without GSM, consider the use of MHT only after risk factor and contraindication assessment.
- If the patient has a contraindication or does not wish to use MHT, consider alternative, nonhormonal treatments for VMS.
- Consider appropriate nonpharmacologic interventions.

Develop a Care Plan:

- Create a patient-centered pharmacologic plan in conjunction with the health care provider.
- Create a patient-centered nonpharmacologic plan.

Implement the Care Plan:

- Recommend the appropriate dose of a pharmacologic agent and duration, regimen, and route of administration that are patient-specific and aim to utilize the lowest effective dose of MHT.
- Document findings and recommendations.
- Discuss the importance of adhering to the medication regimen.
- Discuss methods of administration, potential adverse effects, and expectations of therapy.
- Discuss lifestyle or behavioral interventions that may help to alleviate VMS and GSM.

Follow-up: Monitor and Evaluate:

- Efficacy: monitor for reduction in VMS, GSM, improvements in sleep, and QOL.
- Safety: monitor for breakthrough bleeding and spotting, adverse effects of MHT, blood pressure at every outpatient visit, yearly mammograms, yearly TSH, and endometrial studies in women with undiagnosed vaginal bleeding.
- Assess symptoms every 6 to 12 months, and consider tapering the MHT dose and discontinuing treatment after 4 to 5 years. If VMS return, determine whether a longer tapering schedule is warranted or if long-term treatment is necessary. If treatment beyond 5 years is necessary, consider switching to a nonhormonal product.

Abbreviations Introduced in This Chapter

BMD	Bone mineral density
cBHT	Compounded bioidentical hormone therapy
CEE	Conjugated equine estrogens
CHC	Combination hormonal contraceptive
CHD	Coronary heart disease
DHEA	Dehydroepiandrosterone
FMP	Final menstrual period
FSH	Follicle-stimulating hormone
GSM	Genitourinary syndrome of menopause
hCG	Human chorionic gonadotropin
IUD	Intrauterine device
LH	Luteinizing hormone
MHT	Menopausal hormone therapy
MPA	Medroxyprogesterone acetate
NSAID	Nonsteroidal anti-inflammatory drug
PCOS	Polycystic ovary syndrome
PID	Pelvic inflammatory disease
QOL	Quality of life
SERMs	Selective estrogen receptor modulators
SNRI	Serotonin-norepinephrine reuptake inhibitor
SSRI	Selective serotonin reuptake inhibitor
TSH	Thyroid-stimulating hormone
VMS	Vasomotor symptoms
VTE	Venous thromboembolism
WHI	Women's Health Initiative

Erectile Dysfunction

Cara Liday

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiology of erectile dysfunction (ED).
2. Recognize risk factors and medications associated with the development of ED.
3. List the goals of therapy when treating ED.
4. Describe current nonpharmacologic and pharmacologic options for treating ED, and determine appropriate first- and second-line therapies for a specific patient.
5. Identify patients with significant cardiovascular risk and recommend an appropriate treatment approach for their ED.
6. Identify contraindications for the use of phosphodiesterase type 5 (PDE5) inhibitors.
7. Compare and contrast the benefits and risks for current PDE5 inhibitors.
8. Assess reasons for PDE5 failure and determine an optimal approach to improve treatment efficacy.

INTRODUCTION

Erectile dysfunction (ED) is defined as the persistent inability to achieve or maintain an erection sufficient for sexual intercourse.[1] ED is the most prominent sexual disorder in men and can lead to lower quality of life and self-esteem.[2] Other male sexual complaints include libido and ejaculatory disorders, but these are not considered ED.

EPIDEMIOLOGY AND ETIOLOGY

The incidence of ED increases with age. Few men report erection problems before age 40, but one study reported rates as high as 61% in men aged 40 to 69 years and 77% in men older than 70 years.[3] The increase in incidence could be due to physiologic changes that occur with aging, the onset of chronic disease states associated with ED, increased medication use, lifestyle factors, or a combination of the above.

PATHOPHYSIOLOGY

The penis consists of three components, two dorsolateral corpora cavernosa and a ventral corpus spongiosum that surrounds the penile urethra and distally forms the glans penis. The corpora are composed of sinusoidal spaces that are encased in a fibrous sheath called the tunica albuginea.

In the flaccid state, a balance exists between blood flow into and out of the corpora cavernosa. Sexual stimulation triggers a reduction in sympathetic tone and an increase in parasympathetic activity. This stimulates the release of nitric oxide (NO), which in turn enhances the production of cyclic guanosine monophosphate (cGMP). The enzyme phosphodiesterase type 5 (PDE5) is responsible for the catabolism of cGMP within the cavernosal tissue. Prostaglandins, E_1 and E_2, stimulate increased production of cyclic adenosine monophosphate (cAMP). Increased cAMP and cGMP concentrations ultimately lead to smooth muscle relaxation and increased blood flow into the cavernosal spaces. As the spaces become engorged, pressure increases, subtunical venules (very small veins) are compressed by the tunica albuginea, and the penis becomes rigid and elongated (Figure 51–1).

Detumescence, or return of the penis to a flaccid state, occurs with an increase in norepinephrine. This results in smooth muscle contraction, a reduction in blood inflow, decompression of the sinusoidal spaces, and enhanced outflow.

Testosterone also plays a significant albeit complex role in erectile function. In addition to stabilization of intracavernosal levels of NO synthase, the enzyme responsible for triggering the NO cascade, testosterone, is responsible for much of a man's libido. While low testosterone has been associated with ED[5], normal or low serum testosterone levels are not a strong indicator of ED.

Normal penile erections are complex events that require the full function of the vascular, neurologic, hormonal, and psychological systems. Anything that affects the function of these systems may lead to ED. **KEY CONCEPT** ED can be classified as organic, psychogenic, or a mixture of these. Organic dysfunction includes abnormalities in the vascular, hormonal, or neurologic systems or may be medication-induced (Tables 51–1 and 51–2). It is estimated that 10% to 25% of ED cases are due to medications. Note that many of the risk factors for ED are the same as those for cardiovascular (CV) disease, including hypertension, diabetes, dyslipidemia, smoking, obesity, metabolic syndrome, and sedentary behavior. In many patients, ED is the first indication of the endothelial dysfunction associated with CV, with a time between onset of ED and a CV event of 2 to 5 years.[7] The presence of ED risk factors leads to the assumption that the patient has organic dysfunction. Most commonly, medical conditions that impair arterial flow into or out of the erectile tissue or affect the innervation will be strongly associated with ED. Patients with diabetes mellitus have exceptionally high rates of ED as a result

Inhibition

FIGURE 51–1. Molecular mechanism of penile smooth muscle relaxation. Cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) activate their specific protein kinases, which leads to sequestration of intracellular calcium by the endoplasmic reticulum. The resultant decrease in intracellular calcium leads to smooth muscle relaxation. Sildenafil inhibits the action of phosphodiesterase (PDE) type 5 and increases the intracellular concentration of cGMP. Papaverine is a nonspecific (PDE) inhibitor. (ATP, adenosine triphosphate; eNOS, endothelial nitric oxide synthase; GTP, guanosine triphosphate.) (Reproduced, with permission, from Shindel AW, Lue T. Physiology of penile erection and pathophysiology of erectile dysfunction. In: Partin AW, Dmochowski RR, Kavoussi LR, et al., eds. Campbell-Walsh-Wein Urology, 12th ed. Philadelphia, PA: Elsevier; 2021:1497.)

of vascular disease and neuropathy. Additionally, a relationship has been found between low testosterone levels and an increased incidence of metabolic syndrome and type 2 diabetes.[8]

Psychogenic dysfunction occurs if a patient does not respond to psychological arousal. Common causes include performance anxiety, strained relationships, lack of sexual arousability, and overt psychiatric disorders such as depression and schizophrenia. KEY CONCEPT Many patients may initially have organic dysfunction but develop a psychogenic component as they try to cope with their inability to achieve an erection.[2]

CLINICAL PRESENTATION AND DIAGNOSIS OF ED

The introduction of oral medications and direct-to-consumer advertising has made patients feel more comfortable approaching practitioners for treatment advice. Despite this, some patients may only discuss their dysfunction when questioned directly by their provider or if their partner initiates the interaction.

TREATMENT

Desired Outcomes

ED is not a life-threatening condition, but if left untreated, it can be associated with depression, loss of self-esteem, poor self-image, and marital discord.[10] The primary goal of therapy is achievement of erections suitable for intercourse and improvement in patient and partner quality of life. Additionally, the ideal therapy should have minimal side effects, be convenient to administer, have a quick onset of action, and have few or no drug interactions.

General Approach to Treatment

KEY CONCEPT Before initiating treatment for ED, a physical examination and thorough medical, social, and medication histories with

Table 51–1

Factors Associated with ED[1,4,6]

Chronic Medical Conditions
Hypertension
Diabetes mellitus
Benign prostatic hyperplasia
Coronary and peripheral vascular disease
Neurologic disorders (eg, Parkinson disease and multiple sclerosis)
Endocrine disorders (hypogonadism, pituitary, adrenal, and thyroid disorders)
Psychiatric disorders
Dyslipidemia
Renal failure
Liver disease
Penile disease (Peyronie's disease or anatomic abnormalities)
Surgical Procedures
Perineal or vascular surgeries
Radical prostatectomy
Lifestyle
Smoking
Excessive alcohol consumption
Obesity
Poor overall health and reduced physical activity
Trauma
Pelvic fractures or surgeries
Spinal cord or brain injuries

Table 51–2

Medication Classes Associated With ED[4,6]

Antihypertensives
β-Blockers (excluding nebivolol)
Thiazide diuretics
Centrally acting agents (clonidine, methyldopa, and reserpine)
Spironolactone
α-Blockers
CNS Depressants
Opioid analgesics
Benzodiazepines
Hypnotics
Lipid Medications
Gemfibrozil
HMG-CoA reductase inhibitors
Antidepressants/Antipsychotics
Tricyclic antidepressants
Monoamine oxidase inhibitors
Selective serotonin reuptake inhibitors/serotonin-norepinephrine reuptake inhibitors
Lithium
Anticonvulsants
Carbamazepine
Phenytoin
Gastrointestinal Agents
Histamine 2-receptor antagonists
Proton pump inhibitors
Antiandrogens and Hormones
5α-Reductase inhibitors
Progesterone and estrogen
Corticosteroids
Recreational Drugs
Ethanol
Cocaine
Marijuana
Opiates

Clinical Presentation and Diagnosis

Possible Signs and Symptoms

- Marital difficulties
- Low self-confidence or morale; depression
- Full or partial inability to achieve erections
- Erections sufficient for intercourse, but early detumescence
- The problem may have a slow or acute onset, or may wax and wane

Diagnosis

- ED may be the presenting symptom of other chronic disease states
- The following should be performed to determine factors that can cause or exacerbate ED and to assess the patient's ability to safely perform intercourse:
  - Medical history with emphasis on cardiovascular and psychiatric disorders, diabetes, trauma, and surgical procedures
  - Social history including nutrition and a history of smoking, recreational drug use, exercise, and alcohol consumption
  - Medication history including prescription, nonprescription, and herbal or dietary supplements

Physical Examination

- Review for **hypogonadism** (gynecomastia, testicular atrophy, reduced body hair, increase in body fat)
- Digital rectal examination to determine whether prostate is enlarged
- Vital signs
- Abnormalities of the penis; impaired vasculature or nerve function to the penis

Labs

- Fasting glucose or HbA_{1c}
- Serum testosterone if signs of hypogonadism
- Fasting lipid panel
- Further cardiac testing if warranted

Determine Severity

- Use an abridged, five-item version of the International Index of Erectile Function (IIEF-5) as a diagnostic tool.[9]
- How do you rate your confidence that you could get and keep an erection?
- When you had erections with sexual stimulation, how often were your erections hard enough for penetration?
- During sexual intercourse, how often were you able to maintain your erection after you had penetrated (entered) your partner?
- During sexual intercourse, how difficult was it to maintain your erection to completion of intercourse?
- When you attempted sexual intercourse, how often was it satisfactory for you?
- Questions scored 1 to 5, very low to very high, respectively. Score of 21 or less indicates ED likely.

Table 51–3

The Princeton III Consensus Recommendations for Cardiovascular Risk Assessment and the Management of Erectile Dysfunction[7,11]

Risk	Risk Description	Treatment Recommendation
Low	Able to perform exercise of moderate activity without symptoms Successful revascularization (CABG, stent, angioplasty) Asymptomatic, well-controlled hypertension Mild valvular heart disease Left ventricular dysfunction/heart failure (NYHA classes I and II) Uncomplicated previous MI	May initiate or resume sexual activity and begin ED treatment without further evaluation
Intermediate	Has three or more risk factors for CV disease Mild or moderate, stable angina Had a recent MI within the past 2–8 weeks Moderate heart failure (NYHA Class III) Noncardiac sequelae of atherosclerotic disease (PAD, stroke, TIA)	Further evaluation using exercise stress testing is required before resuming sexual activity. After completion, will be reassigned to low- or high-risk category
High	Moderately or severely symptomatic Unstable or refractory angina, despite treatment Uncontrolled hypertension Severe heart failure (NYHA Class IV) Recent MI without intervention (< 2 weeks) High-risk cardiac arrhythmia Obstructive hypertrophic cardiomyopathy with severe symptoms Moderate or severe valvular heart disease	Sexual activity should be deferred until cardiac condition stabilized

CABG, coronary artery bypass grafting; CV, cardiovascular; NYHA, New York Heart Association; PAD, peripheral arterial disease; PDE, phosphodiesterase; TIA, transient ischemic attack; MI, myocardial infarction.

emphasis on cardiac disease must be taken to assess for the ability to safely resume sexual activity and to assess for possible drug interactions. The Princeton Consensus was developed to estimate risk associated with sexual activity and determine the safety of ED treatment.[7,11] In patients with intermediate or high CV risk, additional testing should occur to determine whether sexual activity is safe (Table 51–3).

KEY CONCEPT Treatment options for ED include lifestyle modifications, medical devices, pharmacologic treatments, surgery, and psychotherapy. Reversible causes of ED should be identified first and treated appropriately. Additionally, combining different treatment modalities, that is, devices and pharmacologic options, may increase efficacy.

KEY CONCEPT When determining the best treatment for an individual, the role of the clinician is to inform the patient and their partner of all available options while understanding their medical history, desires, and goals. KEY CONCEPT After addressing risk factors and lifestyle modifications, oral PDE5 inhibitors are considered first line with vacuum erection devices (VEDs) as another noninvasive option, but the choice of treatment is primarily left up to the couple. Ultimately, the choice of therapy should be individualized, taking into account patient and partner preferences, concomitant disease states, response, administration route, cost, tolerability, and safety. Common drug treatment regimens for ED are listed in Table 51–4.

▸ *Nonpharmacologic Therapy*

Lifestyle Modifications Control of risk factors and general lifestyle modifications should always be addressed first in the management of ED. A healthy diet, increase in regular physical activity, and weight loss are associated with higher International Index of Erectile Function (IIEF) scores and an improvement in erectile function.[12] The clinician should also recommend smoking cessation, reduction in excessive alcohol intake, and the discontinuation of illicit drug use.

Psychotherapy Psychotherapy is an appropriate treatment approach for patients with psychogenic or mixed dysfunction. Counseling may include simple sex education and improved partner communication in addition to cognitive and behavioral therapy. Psychotherapy may help relieve anxiety and eliminate unrealistic expectations while enhancing pharmacologic efficacy.[10,13] Patients with psychogenic dysfunction may benefit from the addition of other therapies, whether nonpharmacologic or pharmacologic.

Vacuum Erection Devices VEDs induce erections by creating a vacuum around the penis; the negative pressure draws blood into the penis by passively dilating arteries and engorging the corpora. The erection is maintained with a constriction band placed at the base of the penis to reduce venous outflow (Figure 51–2). VEDs may be used as often as desired, but it is recommended that the constriction band not be left in place longer than 30 minutes at a time.

Onset of action can be slow until the user is experienced, which limits spontaneity. In addition, patients and partners may complain of a cold, lifeless, discolored penis that has a hinge-like feel. Painful ejaculation or the inability to ejaculate are additional adverse effects. VEDs are contraindicated in persons with sickle cell disease and a history of priapism. They should be used with caution in those on oral anticoagulants or who have bleeding disorders.

VEDs are highly effective treatment modalities for ED and are considered a first- or second-line therapy. They are generally more acceptable to older patients in stable relationships and with infrequent sexual encounters. Efficacy rates are as high as 90% in obtaining an erection sufficient for intercourse, and although satisfaction rates are as high as 94%, the discontinuation rate after 2 years is close to 40%.[14] A double pumping technique in which the vacuum is applied for 1 to 2 minutes, removed, then reapplied for another 3 to 4 minutes may improve comfort levels and rigidity. Higher efficacy rates can also be achieved by combining VEDs with other therapies.

Table 51–4

Common Drug Treatment Regimens for ED

Route of Administration	Generic Name	Brand Name	Typical Dosing Range[a]	Maximum Dosing Frequency
Oral	Sildenafil	Viagra	25–100 mg 1 hour prior to intercourse	Once daily
	Tadalafil	Cialis	5–20 mg 30 minutes prior to intercourse or daily dose of 5–20 mg	Once daily
	Vardenafil	Levitra, Staxyn	10 mg 1 hour prior to intercourse	Once daily
	Avanafil	Stendra	100–200 mg 15 minutes prior to intercourse	Once daily
	Testosterone undecanoate	Jatenzo[b]	158–396 mg twice daily	Twice daily
Intracavernosal	Alprostadil	Caverject, Caverject Impulse, Edex	1.25–60 mcg 5–20 minutes prior to intercourse[c]	Three times weekly, 24 hours between injections
Intraurethral	Alprostadil	MUSE	125–1000 mcg 5–10 minutes prior to intercourse[c]	Two times daily
Intramuscular	Testosterone cypionate	Depo-Testosterone	50–400 mg every 2–4 weeks	Once weekly
	Testosterone enanthate	Delatestryl, Xyosted	50–400 mg every 2–4 weeks	Once weekly
			50–100 mg once weekly by autoinjector	Once weekly
	Testosterone undecanoate	Aveed	750 mg on day 1 and week 4; then every 10 weeks	After titration once every 10 weeks
Topical	Testosterone patch	Androderm	2–6 mg/day applied at night to back, abdomen, upper arms, or thighs	Once daily
	Testosterone gel	AndroGel 1%, Testim, Vogelxo	5–10 g gel per day (50–100 mg testosterone) in morning to shoulders, upper arms, abdomen (AndroGel 1% only)	Once daily
		AndroGel 1.62%	40.5–81 mg/day in morning to shoulders or upper arms	Once daily
		Natesto	11 mg intranasally three times daily; 6–8 hours apart (2 pump actuations, 1 per nostril)	Three times daily
		Fortesta	10–70 mg/day in morning to thigh (1–7 pumps)	Once daily
	Testosterone solution	Axiron	30–120 mg/day in morning to axilla (1–4 pumps)	Once daily
Buccal	Testosterone	Striant	30 mg every 12 hours to gum region above incisor; rotate to alternate sides with each dose	Two times daily
Subcutaneous implantable pellet	Testosterone	Testopel	150–450 mg (150 mg for every 25 mg testosterone propionate required weekly)	Every 3–6 months

[a] Use the lowest effective dose to limit adverse effects.

[b] Oral testosterone undecanoate has warnings about increased blood pressure and CV events and is not indicated for age-related low testosterone.

[c] Initial dose, to achieve erection lasting 1 hour, must be titrated in physician's office.

MUSE, medicated urethral system for erection.

Prostheses Penile prostheses are semirigid malleable or inflatable rods, which are inserted surgically into the corpus cavernosa (see Figure 51–3). The malleable rods are rigid at all times but may be bent into position by the patient when desired. The inflatable prostheses are preferred due to a more "natural" erection as they remain flaccid until the pump within the scrotum moves fluid from a reservoir to the cylinders within the penis. Detumescence is achieved when the fluid is then transferred back to the reservoir by activating a release button.

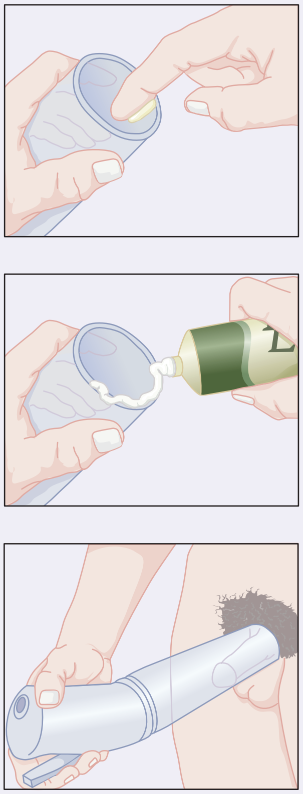
Patient satisfaction rates can be as high as 90%, with partner satisfaction rates slightly lower, but prostheses are costly and the most invasive treatment available so are considered last-line therapy.[15] Complications include mechanical failure and infection. Failure rates are less than 5% while infection occurs in 1% to 2% with primary implantation.[15]

▶ *Pharmacologic Therapy*

Phosphodiesterase Type 5 Inhibitors Avanafil, sildenafil, tadalafil, and vardenafil act by selectively inhibiting PDE5, which is responsible for degradation of cGMP. With prolonged cGMP activity, smooth muscle relaxation is induced, leading to an erection (see Figure 51–1). However, the PDE5 inhibitors are only effective in the presence of sexual stimulation to drive the NO/cGMP system, making them facilitators of an erection, not initiators.

KEY CONCEPT Effectiveness of the four available PDE5 inhibitors is essentially comparable, but differences exist in onset, duration of action, absorption with a fatty meal, and, to a small degree, incidence of side effects and drug interactions (Table 51–5). Review of available data for each individual agent shows a 60% to 75% response rate depending on the dose of agent used and the etiology of dysfunction.[2,6] Although efficacy rates appear to be similar between agents, there are some data to suggest that continuation rates are higher and patient preference greater with tadalafil due to its longer duration of efficacy (18 hours).[16] The PDE5 inhibitors are considered first-line therapies due to high efficacy rates, convenience of dosing, and minimal severe adverse effects.

All four PDE5 inhibitors are approved for as-needed dosing. Tadalafil has also been approved for use as a daily medication at a lower dose (2.5–5 mg) than the as-needed dose with similar



Assemble your system according to the two-step procedure.

Step 1

Apply Osbon Personal Lubricant to the following:

1. 2 in inside the open end of the cylinder;
2. the rim of the cylinder that meets the body to form the vacuum seal; and
3. the entire head of the penis.

Applying lubricant properly will help you achieve the best erection possible.

Tip: Trimming the pubic hair around the base of the penis with a pair of scissors may also prove helpful in creating an airtight seal.

Step 2

It is recommended that you stand for this step (the system can also be used when you are sitting or lying down).

Place the lubricated penis inside the cylinder with the label on the cylinder facing up. With one hand, hold the cylinder at a downward 45° angle with the open end snugly against the body.

Tip: Rotate cylinder slightly back and forth to make an airtight seal against the body, make sure the testicles are not drawn into the cylinder.

FIGURE 51–2. Technique for using a vacuum erection device. (From Lee M, Sharifi R. Erectile dysfunction. In: Dipiro JT, Yee GC, Posey LM, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill; 2020:1394.)

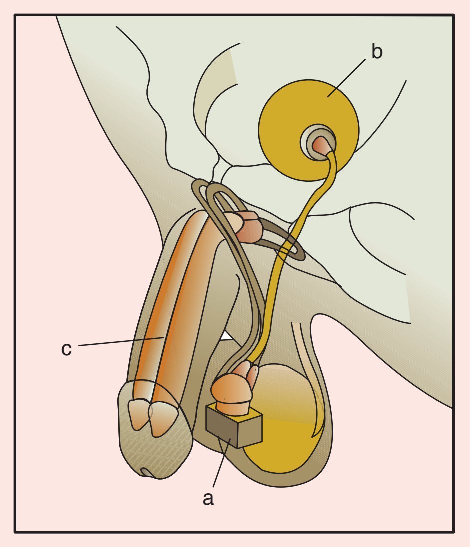


FIGURE 51–3. Example of a surgically implanted penile prosthesis. (a, activation mechanism; b, reservoir with fluid for inflating prosthesis; c, inflatable rods in corpora.) (From Lee M, Sharifi R. Erectile dysfunction. In: Dipiro JT, Yee GC, Posey LM, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill; 2020:1406.)

efficacy. It also has an indication for the treatment of lower urinary tract symptoms associated with benign prostatic hyperplasia.

PDE enzymes are also found in retinal, muscle, peripheral vascular, and tracheal smooth muscle tissue. Inhibition of PDE enzymes throughout the body leads to many of the most common adverse effects, including headache, facial flushing, nasal congestion, dyspepsia, myalgia, back pain, and, rarely, priapism. Vardenafil and sildenafil may also cause blurred vision, difficulty in discriminating blue from green, bluish tones in vision, or difficulty seeing in dim light due to cross-reactivity with PDE type 6 in the retina. Labeling for all PDE5 inhibitors includes a warning about rare nonarteritic ischemic optic neuropathy in which blood flow is blocked to the optic nerve. If patients experience sudden or decreased vision loss, they should call a health care provider immediately. PDE5 inhibitors have also been associated with acute hearing impairment although a causal relationship has not been established.[2]

Patient Encounter 1, Part 1

A 72-year-old man with type 2 diabetes, hypertension, dyslipidemia, BPH, and obesity comes into your clinic for routine follow-up with his spouse. When reviewing their history, they state they are only able to achieve partial erections that are insufficient for intercourse. They are quite emotional and state that the problem is distressing and has caused significant marital discord.

PMH: Type 2 diabetes for 20 years, uncontrolled. Hypertension for 8 years, currently controlled. Dyslipidemia for 15 years, controlled. BPH for 5 years uncontrolled.

SH: Retired; alcohol only occasionally; nonsmoker; No regular exercise; eats a healthy diet with orange or grapefruit juice daily.

Meds: Metformin 1000 mg orally twice daily; insulin glargine 60 U subcutaneously once daily; lisinopril/HCTZ 20/25 mg orally once daily; diltiazem ER 24 hour 120 mg orally once daily; rosuvastatin 40 mg orally once daily; tamsulosin 0.4 mg orally once daily.

ROS: (–) Morning, nocturnal, or spontaneous erections suitable for intercourse; (+) nocturia, urgency, dribbling; (–) symptoms of prostatitis; (–) chest pain, or anginal symptoms.

PE:

VS: BP 130/78, P 85, RR 18, Wt 249 lb (113 kg), Ht 70 in. (178 cm)

CV: Normal examination

Labs: Fasting glucose 189 mg/dL (10.5 mm/L); HbA_{1c} 9% (0.09; 74 mmol/mol Hgb), total testosterone 400 ng/dL (14 nmol/L); SCr 0.9 mg/dL (80 μmol/L), PSA 0.8 ng/mL (0.8 mcg/L)

What risk factors does this patient have for ED?

Identify treatment goals for this patient.

What pharmacologic and nonpharmacologic alternatives are available for this patient?

Based on the information available, which of the available options will be your treatments of choice based on concomitant disease states and medications, degree of invasiveness, side effects, ease of use, and side-effect profile?

What are the safety and efficacy monitoring parameters for the chosen treatment?

Table 51–5

Comparison of PDE Inhibitors

	Sildenafil (Viagra)	Tadalafil (Cialis)	Vardenafil (Levitra, Staxyn)	Avanafil (Stendra)
Available strengths	25-, 50-, 100-mg tabs	2.5-, 5-, 10-, 20-mg tabs	2.5-, 5-, 10-, 20-mg tabs	50-, 100-, 200-mg
Initial dosage in healthy adults	50 mg up to once daily taken 1 hour prior to sexual activity	10 mg up to once daily taken 30 minutes prior to sexual activity or 2.5 mg daily at the same time each day	10 mg up to once daily taken 1 hour prior to sexual activity	100 mg up to once daily taken 15 minutes prior to sexual activity
Dosing range for healthy adults	25–100 mg	5–20 mg	5- to 20-mg Levitra 10-mg Staxyn	50–200 mg
Dosage in the elderly	25 mg	10–20 mg	5 mg	50–200 mg
Dosage in renal impairment	25 mg (severe[b])	5–10 mg (moderate[a]) 5 mg (severe[b]) Daily use NR (severe[b])	5–20 mg	50–200 mg[c]
Dosage in hepatic impairment	25 mg	10 mg[c]	5 mg[c]	50–200 mg[c]
Time to onset	60 minutes	30–60 minutes	60 minutes	15 minutes
Onset delayed by high-fat meal?	Yes	No	Yes No—ODT	No
Duration of effect	Up to 4 hours	Up to 36 hours	Up to 6 hours	Up to 6 hours
Half-life	3–4 hours	18 hours	4–6 hours	5 hours
Metabolism	CYP3A4 (major) CYP2C9 (minor)	CYP3A4	CYP3A4 (major) CYP3A5 (minor) CYP2C (minor)	CYP3A4 (major) CYP2C9 (minor)
Clinically relevant drug interactions	Nitrates,[d] α_1-blockers,[e] protease inhibitors, azole antifungals, erythromycin, grapefruit	Nitrates,[d] α_1-blockers,[e] protease inhibitors, azole antifungals, erythromycin	Nitrates,[d] α_1-blockers,[e] antiarrhythmic agents,[f] grapefruit, erythromycin	Nitrates,[d] α_1-blockers,[e] protease inhibitors, azole antifungals, erythromycin, grapefruit

[a] Moderate renal impairment = creatinine clearance (CrCl) 31–50 mL/min (0.51–0.83 mL/s).

[b] Severe renal impairment = CrCl < 30 mL/min (0.50 mL/s).

[c] Mild to moderate only—contraindicated in severe disease.

[d] Oral, topical, sublingual, and injectable nitroglycerine products are all contraindicated.

[e] Selective α_1-blockers (such as alfuzosin, silodosin, and tamsulosin) are appropriate in combination. If nonselective, initiate with lowest dose possible.

[f] Vardenafil can cause QT-interval prolongation; this effect in combination with certain antiarrhythmic agents can lead to life-threatening arrhythmias.

CYP, cytochrome P-450 isoenzyme; NR, not recommended; ODT, oral disintegrating tablet

In addition to the inherent risk of renewing sexual activity, PDE5 inhibitors can lead to significant hypotension. Patients taking organic nitrates are at highest risk, as these drugs potentiate the drop in blood pressure. All four PDE5 inhibitors are absolutely contraindicated in patients taking any form of nitrate, whether scheduled or as needed for acute situations. Additionally, caution should be used when combining a PDE5 inhibitor with α-blockers. Vardenafil contains a precautionary statement about the possibility of QT prolongation. Drug interactions and cautions vary slightly between agents and are described in Table 51–5.

Up to a third of patients will not respond to therapy with PDE5 inhibitors. To achieve the greatest effect, patients must be fully informed of the onset and duration of effect, impact of high-fat meals, the need for sexual stimulation, and explanation that a single trial is not adequate. It is estimated that six to eight attempts with a medication and specific dose may be needed before successful intercourse.[6]

Alprostadil Alprostadil is a prostaglandin E_1 analog that induces an erection by stimulating adenyl cyclase, leading to increased cAMP, smooth muscle relaxation, rapid arterial inflow, and increased penile rigidity (see Figure 51–1). Alprostadil is available as an intracavernosal injection (Caverject or Edex) or an intraurethral suppository (MUSE, medicated urethral system for erection), with the injectable dose showing greater efficacy.[6,14] Both forms of alprostadil are considered more invasive than oral medications or VEDs and are, therefore, second-line therapies.

MUSE consists of a urethral pellet of alprostadil with an applicator (Figure 51–4). Onset of action is within 5 to 10 minutes and it is effective for 30 to 60 minutes. Success rates are between 30% and 66%, with higher doses showing the most consistent response.[15] The patient should void to moisten the urethra, insert the pellet, and then massage to distribute the medication. Aching in the penis, testicles, legs, and perineum; warmth or burning sensation in the urethra, minor urethral bleeding or spotting, priapism; and light-headedness are all possible adverse effects. In addition, partners may experience burning or itching, and use is contraindicated with a pregnant partner unless using a condom.

Intracavernous alprostadil injection is the more effective route and is the only Food and Drug Administration (FDA)-approved injection for ED. The onset of action is similar to intraurethral alprostadil, but duration varies with dose and must be titrated by a health care professional in a medical setting to achieve an

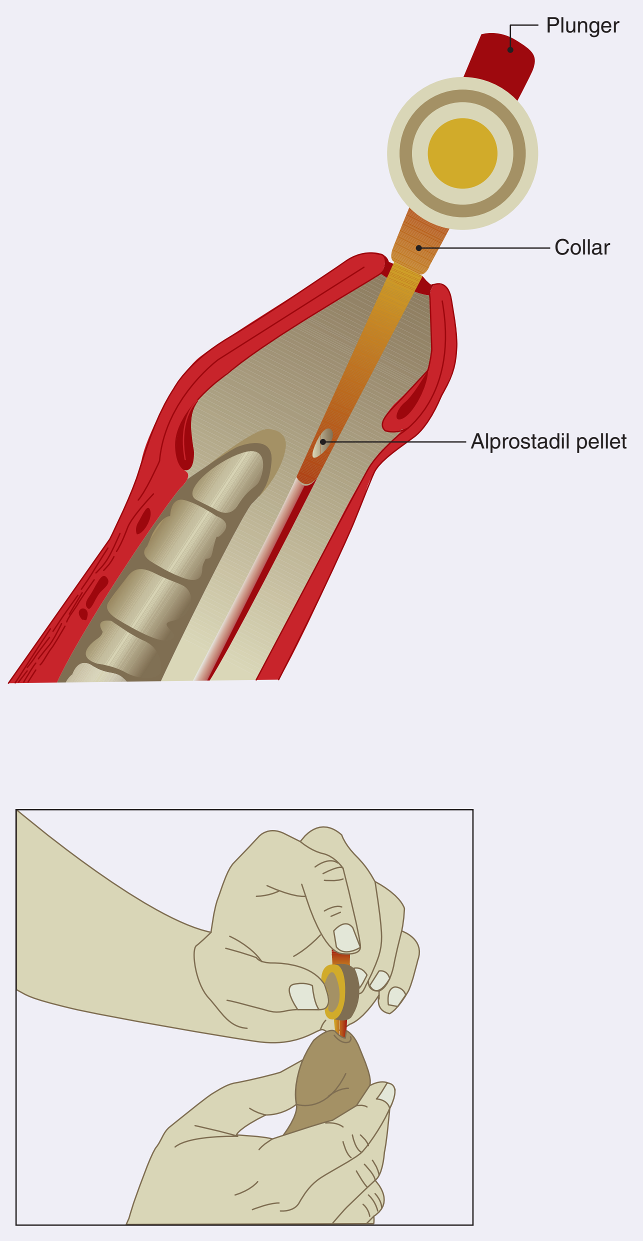

FIGURE 51–4. Technique for administration of intraurethral alprostadil with a mediated urethral system for erection applicator. (From Lee M, Sharifi R. Erectile dysfunction. In: Dipiro JT, Yee GC, Posey LM, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill; 2020:1405.)

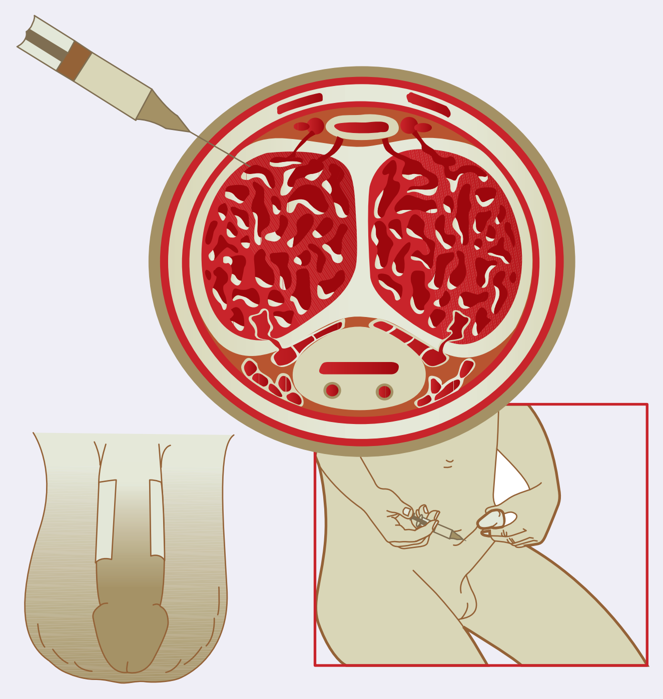

FIGURE 51–5. Technique for administration of intracavernosal injections. (From Lee M, Sharifi R. Erectile dysfunction. In: Dipiro JT, Yee GC, Posey LM, et al., eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill; 2020:1404.)

erection lasting no more than 1 hour. Papaverine and phentolamine are nonapproved intracavernosal agents that are only used in combination. Injections should be performed into one side directly into the corpus cavernosum, and then the penis should be massaged to distribute the drug to both corpora (Figure 51–5). Education is extremely important with intracavernosal injections. Patients must be adequately informed of technique, expectations, side effects, and when to seek help. Intracavernosal injections are effective in 60% to 80% of patients, but side effects, lack of spontaneity, and fear of needles limit their widespread use and, therefore, this therapy is most appropriate for patients in long-term stable relationships.[2,6] Adverse effects include pain with injection, bleeding or bruising at the injection site, fibrosis, or priapism. Use with caution in patients with sickle cell disease, those on anticoagulants, or those who have bleeding disorders, due to an increased risk of priapism and bleeding.

Testosterone Supplementation KEY CONCEPT Androgens are important for general sexual function and libido, but testosterone supplementation is only indicated in patients with documented low serum testosterone levels. In patients with hypogonadism, testosterone replacement is the initial treatment of choice, as it corrects decreased libido, fatigue, muscle loss, sleep disturbances, and depressed mood. However, testosterone is contraindicated in patients with prostate cancer, erythrocytosis, uncontrolled heart failure, or sleep apnea.

Testosterone supplementation may improve ED symptoms but is not universally effective. Initial supplementation should occur for 3 months with reevaluation and the addition of another ED therapy if needed at that time. Dosage forms include intramuscular, an implanted pellet, topical patches or gel, nasal spray, and a buccal tablet.

Injectable testosterone, cypionate and enanthate, offer the most inexpensive replacement option. There are several drawbacks associated with parenteral testosterone, including the need to administer deep intramuscular injections every 2 to 4 weeks. Testosterone undecanoate offers the benefit of an extended dosing interval of 10 weeks but is a more expensive injectable option. Concentrations of hormone are well above physiologic values within the first few days, and then decline and eventually dip below physiologic levels prior to the next dose. These changes in concentration may lead to mood swings and a reduced sense of well-being.[17] Implantable subcutaneous testosterone pellets are a longer acting and convenient alternative that are placed every 3 to 6 months.

Patient Encounter 1, Part 2

The patient returns to the clinic a year later after having undergone a radical prostatectomy due to a new diagnosis of prostate cancer. Current medication list includes: metformin, glargine, lisinopril/HCTZ, amlodipine, rosuvastatin, and tadalafil. They describe continued distress with no erections suitable for intercourse. After his prostatectomy, they switched from daily tadalafil to an as-needed dose of 20 mg prior to sexual activity. They have attempted more than 10 times with this dose and are waiting 60 minutes after dosing to attempt intercourse.

What treatment options should be considered for this patient?

Patient Encounter 2

A 62-year-old man presents with a history of hypertension and dyslipidemia. They have had ED for the past year, but now complains of being tired all the time. The patient does not have much of a libido anymore, is struggling to sleep, and is gaining weight.

Meds: Losartan 50 mg orally once daily, atorvastatin 40 mg orally once daily, vardenafil 10 mg orally as needed.

Labs: Lipid panel and complete metabolic panel within normal limits; total testosterone 125 ng/dL (4 nmol/L)

Based on the information provided, what is your assessment of the patient?

What should be recommended as the next step in treatment of ED?

Treatment with topical products is attractive to patients due to convenience, but they tend to be more expensive than the injections. Testosterone patches and gels are administered daily and result in serum levels within the physiologic range during the 24-hour dosing period.[17] Care must be taken with the use of the gel to prevent transfer of testosterone to children and females by washing hands thoroughly, allowing the site to dry, and covering immediately. Newer formulations for the axilla, thigh, and nasal mucosa may reduce this risk. It is recommended to avoid swimming or showering for 2 to 3 hours after patch or gel application. The most common side effects of topical testosterone are dermatologic reactions.

Oral testosterone products are also available for supplementation but have poor oral bioavailability and undergo extensive first-pass metabolism. Alkylated derivatives such as methyltestosterone and fluoxymesterone have been formulated, but this modification makes them considerably more hepatotoxic and, therefore, undesirable. Oral testosterone undecanoate contains

Patient Care Process

Collect Information:

- Assess the patient's specific symptoms to determine the type of dysfunction.
- Ask specific questions related to onset and frequency of dysfunction and status of sexual relationships. Assess severity with the IIEF-5 questionnaire.
- Perform complete histories, physical examination, and laboratory tests (see Clinical Presentation and Diagnosis, Tables 51–1 and 51–2).
- Assess cardiovascular risk (see Table 51–3).
- Speak with the patient regarding available options of therapy and preference.

Assess the Information:

- Evaluate medications, concomitant disease states, and lifestyle factors that could exacerbate ED or indicate a need to defer sexual activity.
- Based on histories, determine whether the patient has either compelling indications for or contraindications to specific therapies.
- Review relevant laboratory and cardiac tests (eg, testosterone, HbA1c, complete metabolic panel, treadmill).
- Assess the efficacy, safety, and adverse effects of current treatment.

Develop a Care Plan:

- Treat underlying diseases, discontinue medications, and eliminate risk factors which can exacerbate ED.
- PDE5 inhibitors are first-line treatment unless contraindicated, not tolerated, or ineffective, but treatment should be individualized.
- Give supplementation if patient has low testosterone.

Implement the Care Plan:

- Initiate PDE5 inhibitor or patient treatment of choice and provide education regarding:
  - ED
  - Nonpharmacologic therapy: lifestyle changes such as weight loss, healthy diet, regular exercise, smoking cessation, and psychotherapy when warranted
  - Treatment of associated disease states
  - Drug therapy—mechanisms of action and adverse effects
  - Device technique

Follow-up: Monitor and Evaluate:

- Follow up in 4 to 6 weeks or more frequently to assess effectiveness and safety of therapy including specific warning signs for PDE5 inhibitors (eg, vision changes, fibrosis, pain, priapism, or hypotension).
- Reeducate on lifestyle, associated disease states, expectations, and methods for increasing efficacy with therapy.
- Increase dosage, switch to alternate therapy, or add alternate therapy if needed.

warnings for increased blood pressure and CV events and is not indicated for age-related low testosterone.

An alternative to the oral route is the buccal mucoadhesive system. This system adheres to the inside of the mouth and testosterone is absorbed through the oral mucosa and delivered to the systemic circulation with no first-pass effect. Side effects unique to this dosage form include oral irritation, bitter taste, and gum edema.

General side effects of testosterone include gynecomastia, dyslipidemia, polycythemia, and acne. Weight gain, hypertension, edema, and exacerbations of heart failure also occur due to sodium retention. The undecanoate formulation also carries a risk of serious pulmonary oil microembolism reactions and anaphylaxis after any dose; therefore, patients must be monitored for 30 minutes after the injection. Before initiating testosterone, the patient should undergo evaluation for benign prostatic hypertrophy and prostate cancer due to worsening of urinary symptoms and elevations in serum prostate specific antigen (PSA) with supplementation. Routine follow-up includes yearly PSA, digital rectal examination, hemoglobin, and liver function, in addition to assessment of response.

OUTCOME EVALUATION

Successful therapy for ED results in an increase in erections suitable for intercourse and, most importantly, in an improvement in the patient's quality of life. Ideally, the therapy chosen is free of significant adverse effects, discomfort, and inconvenience. Laboratory evaluation and a physical examination are not necessary for evaluation of effectiveness but may be necessary for adverse event monitoring.

Evaluate satisfaction and effectiveness after a 4-week trial. Some therapies will require multiple visits over the long term to determine the correct dose and to detect adverse effects. If the initial therapy is not effective, the patient must be further evaluated to determine whether the initial assessment of comorbid disease states, type of dysfunction, and patient goals were appropriate. After providing further education and determination of realistic goals, providers may then increase the dose of medication, switch to another therapy, or add a therapy if indicated.

Abbreviations Introduced in This Chapter

cAMP	cyclic adenosine monophosphate
cGMP	Cyclic guanosine monophosphate
FDA	Food and Drug Administration
IIEF	International Index of Erectile Function
MUSE	Medicated urethral system for erection
NO	Nitric oxide
PDE5	Phosphodiesterase type 5
VED	Vacuum erection device

52 Benign Prostatic Hyperplasia

Mary Lee and Roohollah Sharifi

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiology of benign prostatic hypertrophy (BPH).
2. Recognize the symptoms and signs of BPH.
3. List the desired treatment outcomes for BPH.
4. Identify factors that guide selection of a particular α_1-adrenergic antagonist for an individual patient.
5. Compare and contrast α_1-adrenergic antagonists, 5α-reductase inhibitors, anticholinergic agents, tadalafil, and mirabegron in terms of mechanism of action, treatment outcomes, adverse effects, and interactions.
6. Describe the indications, advantages, and disadvantages of a combination drug regimen that includes an α_1-adrenergic antagonist and 5α-reductase inhibitor.
7. Describe the indications for surgical intervention.
8. Apply the patient care process to develop an individualized treatment plan.

INTRODUCTION

The prostate is an organ, which is the shape and size of a horse chestnut. It encircles the portion of the proximal posterior urethra that is located at the base of the urinary bladder. The prostate produces secretions, which are part of the ejaculate.

Benign prostatic hypertrophy (BPH) is the most common benign neoplasm in men who are at least 40 years of age. BPH can produce lower urinary tract symptoms (LUTS), a collection of obstructive and irritative voiding symptoms that are consistent with impaired emptying of urine from and defective storage of urine in the bladder, respectively. Medications are first-line treatment to reduce symptoms and/or delay complications of BPH.[1]

EPIDEMIOLOGY AND ETIOLOGY

BPH first presents as benign prostatic hyperplasia, a histologic disease in many elderly men which increases in prevalence with advancing patient age. Benign prostatic hyperplasia may progress to BPH, which is clinically evident, and then to benign prostatic obstruction, which produces LUTS. Of patients with histologic disease, only about 50% of patients develop an enlarged prostate on digital palpation and 25% of patients exhibit clinical voiding symptoms.[2,3] It is estimated that 8% of men 40 years of age, increasing to 35% of men 60 to 69 years of age, have voiding symptoms consistent with BPH, and 20% to 30% of all male patients who live to the age of 80 years will require a prostatectomy for severe voiding symptoms of BPH.[3]

Two chief etiologic factors for BPH include advanced patient age and the stimulatory effect of androgens.

- Prior to 40 years of age, the prostate in men is approximately 15 g (0.5 oz) to 20 g (0.7 oz). However, in men who have reached 40 years of age, the prostate undergoes a growth spurt, which continues as men advance in age. BPH can result in clinically symptomatic LUTS.[3,4]
- The testes and adrenal glands produce 90% and 10%, respectively, of circulating testosterone. Testosterone enters prostate cells, where predominantly Type II 5α-reductase converts testosterone to dihydrotestosterone, which combines with a cytoplasmic receptor. The complex enters the nucleus and induces changes in protein synthesis that promote glandular tissue growth of the prostate.

The prostate is composed of two types of tissue: (a) glandular or epithelial tissue, which produces prostatic secretions, including prostate-specific antigen (PSA), and (b) muscle or stromal tissue, which can contract around the urethra and bladder outlet when stimulated. In an enlarged prostate, the epithelial to stromal tissue ratio is 1:5.[5] Whereas androgens stimulate glandular tissue growth, they have no direct effect on stromal tissue. Stromal tissue growth may be stimulated by estrogen, which is derived from peripheral tissue conversion of testosterone. Stromal tissue is innervated by α_{1A}-adrenergic receptors. When stimulated, prostatic stroma contracts around the urethra, narrowing the urethra and causing obstructive voiding symptoms.

PATHOPHYSIOLOGY

KEY CONCEPT LUTS and signs of BPH are due to static, dynamic, and/or detrusor factors. The static factor refers to anatomic obstruction of the bladder neck caused by an enlarged prostate gland. As the gland grows around the urethra, the prostate occludes the urethral lumen. The dynamic factor refers to excessive stimulation of α_{1A}-adrenergic receptors in the smooth muscle of the prostate, urethra, and bladder neck, which results in smooth muscle contraction. This reduces the caliber of the urethral lumen and causes obstructive voiding symptoms. Stromal tissue is the

Clinical Presentation and Diagnosis of BPH

General

In early stages of disease, the patient may complain of obstructive voiding symptoms. If untreated, the disease may progress and the patient may complain of irritative voiding symptoms or acute urinary retention, which can be painful due to maximal distention of the urinary bladder. Also, the patient may be symptomatic of disease complications.

Symptoms

Patients may complain of any combination of three types of voiding symptoms:

- obstructive: urinary hesitancy, decreased force of urinary stream, straining to void, and intermittency
- irritative: urinary frequency, nocturia, and urgency with or without incontinence
- postmicturition: dribbling, incomplete bladder emptying

A patient with LUTS will seek medical care once voiding symptoms curb daily activities, are bothersome to the patient or his significant other, or cause embarrassment. Symptom severity is assessed by the patient using a standardized instrument (eg, the AUA Symptom Scoring Index; Table 52–1). However, a patient's perception of the bothersomeness of his voiding symptoms may not match with the AUA Symptom Score. In this case, after thorough evaluation of the signs and complications of BPH disease, the physician and patient should discuss the bothersomeness of the symptoms and decide together on the most appropriate course of treatment.[2,12,13]

It should be noted that LUTS is not specific for BPH. LUTS may be due to other urologic disorders including prostate cancer, prostatitis, or neurogenic bladder.

Signs

- Enlarged prostate on digital rectal exam (DRE); check for prostate nodules or induration, which suggests prostate cancer instead of BPH as the cause of the patient's voiding symptoms.
- Distended urinary bladder
- Rule out **meatal stenosis** or **urethral stricture**, which could cause voiding symptoms similar to LUTS.
- Check anal sphincter tone as an indirect assessment of peripheral innervation to the detrusor muscle of the bladder.

Complications of Untreated BPH

Upper and lower urinary tract infection, urosepsis, urinary incontinence, urinary retention, renal impairment, bladder diverticula, bladder stones, or recurrent gross hematuria.

Medical History

- Check the patient's general health, including previous surgery, presence of diabetes mellitus, or medications that may cause or worsen voiding symptoms.
- Have the patient provide a diary of his voiding pattern for the past week: date and time of each voiding, volume voided, and whether or not the patient had urinary leakage during the day.

Laboratory Tests

- Serum PSA: The combination of PSA and DRE of the prostate can be used to screen for prostate cancer, which could also cause an enlarged prostate. Also, PSA is a surrogate marker for an enlarged prostate due to BPH.[12]
- Urinalysis to rule out infection as a cause of the patient's voiding symptoms; also check urinalysis for microscopic hematuria, which typically accompanies BPH.
- Plasma BUN and serum creatinine may be increased as a result of long-standing bladder outlet obstruction. These tests are not routinely performed but rather are reserved for those patients in whom renal dysfunction is suspected.

Other Diagnostic Tests[12]

- Decreased peak and mean urinary flow rate (< 10–15 mL/s). A decreased urinary flow rate is not specific for BPH; it can also be due to other urologic disorders (eg, urethral stricture, meatal stenosis, or **bladder hypotonicity**).
- PVR measures urine left in the bladder after the patient voids. A normal PVR is 0 mL. A PVR greater than 50 mL is associated with recurrent urinary tract infection.
- DRE to check for an enlarged prostate (> 15–20 g [0.5–0.7 oz]). Nodules, induration, or asymmetry may be due to prostate cancer or some other disease.
- A focused neurological examination to check the integrity of innervation to the urinary bladder (that is responsible for bladder emptying).
- Transurethral cystoscopy reveals an enlarged prostate, which decreases urethral lumen caliber; information from this procedure helps the surgeon decide on the best surgical approach.
- Transrectal ultrasound of the prostate; a transrectal probe is inserted to evaluate prostate size and best surgical approach.
- Transrectal prostate needle biopsy is done if the patient has areas of nodularity or induration on DRE; tissue biopsy can document the presence of prostate cancer.
- Computerized tomography of the urinary tract (CT urogram) with contrast will show a thickened bladder wall, hydronephrosis, and retention of contrast in the bladder if the patient has chronic bladder outlet obstruction; this is only indicated in patients with recurrent hematuria, recurrent urinary tract infection, and urolithiasis.
- Filling cytometry provides information on bladder capacity, detrusor contractility, and the presence of uninhibited bladder contractions, which could also cause LUTS.

primary locus of α_1-adrenergic receptors in the prostate. An estimated 98% of α-adrenergic receptors in the prostate are found in prostatic stromal tissue. Of the α_1-receptors found in the prostate, 70% of them are of the α_{1A}-subtype and the remainder are of the α_{1B} and α_{1D} subtypes.[6] In some patients, excessive α_1-adrenergic stimulation of stromal tissue may cause significant LUTS even though the prostate is only slightly enlarged. The detrusor factor refers to bladder detrusor muscle hypertrophy in response to prolonged bladder outlet obstruction. To further explain, detrusor muscle fibers undergo hypertrophy so that the bladder can

Patient Encounter 1

A 75-year-old man with a BPH and an AUA Symptom Score of 7, urinary hesitancy, and a slow urinary stream presents to the clinic. He wakes up three times every night to void. A DRE reveals a prostate of 30 g (1.1 oz). His PSA is 3 ng/mL (3 mcg/L). A urinary flow rate is 10 mL/s and PVR is 0 mL. A serum creatinine is 1.5 mg/dL (132.6 mmol/L). The patient weighs 80 kg. He is otherwise healthy, takes no medications, and reports that he feels fine and really doesn't like to take any medications that are not necessary.

What stage of BPH does this patient have?

How should the patient be managed?

Table 52–1

Questions to Determine the AUA Symptom Score and Interpretation of Scores

Directions for the patient: The patient should be asked to respond to each question based on the absence or presence of symptoms over the past month. For each question, the patient can respond using a 1–5 scale, where 0 = not at all or none; 1 = less than 1 time in 5; 2 = less than half of the time; 3 = about half of the time; 4 = more than half of the time; and 5 = almost always

Directions for the clinician: After the patient completes the questionnaire, the scores for individual items should be tallied for a final score. Scores of 0–7 = mild symptoms; scores of 8–19 = moderate symptoms; scores more than 20 = severe symptoms. Score range 0-35.

Questions to Assess Obstructive Voiding Symptoms

1. How often have you had a sensation of not emptying your bladder completely after you finished urinating?
2. How often have you found you stopped and started again several times when you urinated?
3. How often have you had a weak urinary stream?
4. How often have you had to push or strain to begin urinating?

Questions to Assess Irritative Voiding Symptoms

5. How often have you found it difficult to postpone urination?
6. How often have you had to urinate again < 2 hours after you finished urinating?
7. How many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?

AUA, American Urological Association.

Data from AUA Practice Guidelines Committee. AUA guideline on the management of benign prostatic hyperplasia (2010, reaffirmed 2014). www.auanet.org/content/guidelines-and-quality care/clinical-guidelines.cfm?sub=bph. Last accessed August 31, 2020.

generate higher pressure to overcome bladder outlet obstruction. The hypertrophic detrusor muscle becomes irritable, contracting abnormally in response to small amounts of urine in the bladder. This causes storage voiding symptoms (urinary frequency, nocturia, urgency, or urinary incontinence). If obstruction is not treated, the bladder muscle will decompensate and be unable to empty completely; postvoid residual urine volume (PVR) will increase.

More recently, atherosclerosis of the pelvic vascular supply to the prostate and bladder has been linked to BPH. Specifically, atherosclerosis leads to hypoxia, which stimulates prostate stromal tissue to increase release of growth factors.[7] Also, in experimental models, chronic inflammation may also stimulate prostate gland growth.[7] Finally, many patients with BPH also have metabolic syndrome, which is characterized with insulin resistance and increased alpha-adrenergic tone.[4]

The natural history of untreated BPH is unclear in patients with mild symptoms. It is estimated that up to 38% of untreated men with mild symptoms will have symptom improvement over a 2.5- to 5-year period.[8] It may be that such patients attribute their symptoms to aging, grow tolerant of their symptoms, or adopt behavioral changes in their lifestyle that minimize their voiding symptoms. However, the majority of patients with mild symptoms will experience disease progression. Patients with moderate-to-severe symptoms can experience decreased quality of life as daily activities are reduced because of LUTS. Also, such patients may develop complications of BPH, which include urinary retention, recurrent urinary tract infection, renal impairment, urolithiasis, or persistent prostate bleeding.[1,9] Predictors of disease progression include an enlarged prostate of at least 40 g (1.4 oz) or PSA of 1.6 ng/mL (1.6 mcg/L) or greater.[10] Finally, erectile dysfunction commonly develops in patients with BPH. Effective treatment of BPH symptoms often improves sexual function without initiating specific treatment for erectile dysfunction.[11]

TREATMENT

Desired Outcomes[1,12,13]

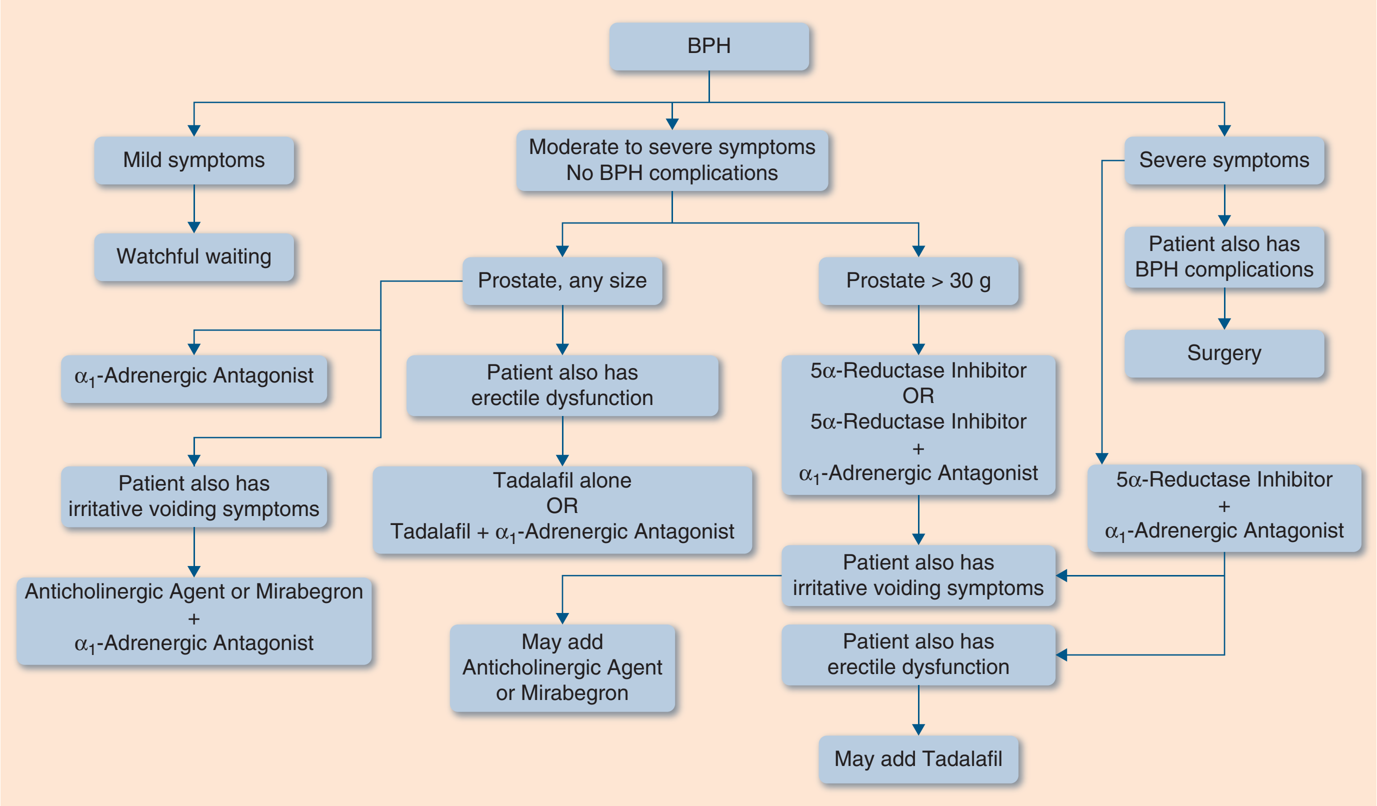
KEY CONCEPT Drug treatment is expected to decrease the American Urological Association (AUA) Symptom Score (Table 52–1) by 30% to 50% (or at least by three or more points),[1,12] improve peak and mean urinary flow rate by at least 1 to 3 mL/s, and decrease PVR to normal (< 50 mL total) when compared with pretreatment baseline values.

- Slowing disease progression. When compared with baseline, symptoms and signs of BPH, serum blood urea nitrogen (BUN), and creatinine should improve, stabilize, or decrease to the normal range with treatment.
- Preventing disease complications and reducing the need for surgical intervention.
- Avoiding or minimizing adverse treatment effects.
- Providing economical therapy.
- Maintaining or improving quality of life.

General Approach to Treatment

Until recently, the principal approach to treatment focused on reducing BPH symptoms (Figure 52–1). However, treatment should also slow disease progression and decrease complications of BPH, particularly in patients at high risk.[9,11-14]

KEY CONCEPT For patients with mild symptoms (AUA Symptom Score of 7 or less) that the patient does not consider to be bothersome, watchful waiting is a reasonable approach to treatment. The patient is instructed to schedule return visits to the clinician every 6 to 12 months. At each visit, the patient's symptoms are reassessed using the AUA Symptom Scoring Index, and results are compared against the baseline (see Table 52–1). In addition, the patient is educated about implementing nonpharmacologic measures to reduce voiding symptoms (see section on Nonpharmacologic Therapy) and avoiding factors that



BPH
Mild symptoms
Moderate to severe symptoms No BPH complications
Severe symptoms
Watchful waiting
Prostate, any size
Prostate > 30 g
Patient also has BPH complications
Surgery
α_1-Adrenergic Antagonist
Patient also has erectile dysfunction
5α-Reductase Inhibitor OR 5α-Reductase Inhibitor + α_1-Adrenergic Antagonist
Patient also has irritative voiding symptoms
Tadalafil alone OR Tadalafil + α_1-Adrenergic Antagonist
5α-Reductase Inhibitor + α_1-Adrenergic Antagonist
Patient also has irritative voiding symptoms
Anticholinergic Agent or Mirabegron + α_1-Adrenergic Antagonist
May add Anticholinergic Agent or Mirabegron
Patient also has erectile dysfunction
May add Tadalafil

FIGURE 52–1. Algorithm for selection of treatment for BPH based on symptom severity and presence of disease complications.

worsen LUTS (Table 52–2). A digital rectal examination (DRE) is repeated annually. If the patient's symptoms are unchanged, watchful waiting is continued. If the patient's symptoms worsen, specific treatment is initiated.[12] Watchful waiting is effective in approximately 33% to 65% of patients with mild LUTS after 5 years.[1,12,13,17]

KEY CONCEPT For patients with moderate-to-severe symptoms and no complications of BPH, the patient is usually offered drug treatment first. α_1-Adrenergic antagonists are preferred over 5α-reductase inhibitors because the former have a faster onset of action (days to a few weeks) and improve symptoms independent of prostate size. 5α-reductase inhibitors have a delayed onset of peak clinical effect of 6 months and are most effective in patients with moderate-to-severe LUTS and larger size prostate glands (larger than 30 g or 1.1 oz). Because of the delay in clinical effect, a 5α-reductase inhibitor is often taken with an α_1-adrenergic antagonist. With either medication, treatment must be continued as long as the patient responds (Table 52–3).[1,12]

KEY CONCEPT Combinations of medications to treat moderate or severe symptoms of BPH are more expensive and can cause more adverse effects than single drug treatment. Therefore, combination medication regimens are reserved for patients who have voiding symptoms that do not respond to an adequate trial of single drug treatment or patients who are at high risk of developing complications of BPH. Refer to the section on Combination Therapy for a detailed description of various regimens and their advantages and disadvantages.

KEY CONCEPT Surgery is indicated for patients who are at risk of disease progression (ie, those with large prostates [larger than 40 g or 1.4 oz]) and PSA higher than 1.6 ng/mL (1.6 mcg/L), have moderate-to-severe symptoms and who are unresponsive to or intolerant of drug treatment, or have complications of BPH disease.[1,9,10] Although potentially curative, surgery can result in significant morbidity, including erectile dysfunction, retrograde ejaculation, urethral stricture, urinary incontinence, bleeding, or urinary tract infection. The gold standard is prostatectomy, which can be performed transurethrally using electrocautery or as an open surgical procedure. A transurethral prostatectomy is typically reserved for prostates of intermediate size (30 g [1.1 oz] to 80 g [2.8 oz]), whereas an open prostatectomy is used for very large prostates (larger than 80 g [2.8 oz]) or when the patient has additional urologic disorders, for example, large bladder stones or bladder diverticula, that can be surgically treated at the same time.[9] The newer bipolar technique for performing a TURP, which uses saline irrigating solution, has reduced the incidence of dilutional hyponatremia, a common adverse effect of the older monopolar technique, which uses glycine or sterile water irrigating solution.[9] The outcomes of prostatectomy include an almost immediate improvement of LUTS, an increase of peak urinary flow rate by 6 to 15 mL/s, and a PVR decrease of 30 to 80 mL. The need for reoperation is 5% to 10% at 10 years.[9]

To minimize complications of prostatectomy,[9,18] or in patients who are taking anticoagulants, minimally invasive surgical procedures, such as transurethral incision of the prostate, transurethral vaporization, transurethral microwave thermotherapy, transurethral laser ablation, or prostatic urethral lift are options.[9,18] A variety of laser energy sources are used to vaporize tissue: holmium, thulium, potassium-titanyl-phosphate (KTP or green light), or diode.[9,18] The choice of energy source is largely determined by the surgeon's level of training, the patient's anatomy, and potential risks for the patient. Prostatic urethral lift refers to transurethral implantation of a mechanical device that pins up the lateral lobes and reduces urethral obstruction.[1,9,18] The potential advantages of minimally invasive surgical procedures include less blood loss

Table 52–2

Drugs and Diseases That Can Cause Irritative or Obstructive Voiding Symptoms[15,16]

Pharmacologic Class	Example Drugs	Mechanism of Effect
Androgens	Testosterone	Stimulate prostate enlargement to cause obstructive voiding symptoms
α-Adrenergic agonists	Phenylephrine, pseudoephedrine	Stimulate contraction of prostatic and bladder neck smooth muscle to cause obstructive voiding symptoms
Anticholinergic agents	Antihistamines, phenothiazines, tricyclic antidepressants, antiparkinsonian agents Antiarrhythmics: disopyramide, procainamide, quinidine	Block detrusor muscle contraction, thereby impair bladder emptying and cause acute urinary retention
Caffeine	Caffeine	Acts like a diuretic to increase urine output
	Calcium Channel Blocker, Nifedipine, diltiazem	Block detrusor muscle contraction and thereby impairs bladder emptying
Anticonvulsants	Valproic acid	Causes sleepiness, which leads to functional incontinence
Diuretics	Thiazides diuretics, loop diuretics	Produce polyuria
Antidepressants, selective serotonin reuptake inhibitors	Escitalopram	Suppresses acetylcholine-mediated contraction of detrusor muscle; acute urinary retention may result
Opiates	Morphine, hydromorphone, meperidine	Decrease bladder motility
Sedatives	Benzodiazepines, ethanol	Can cause functional incontinence
Disease	**Example Diseases**	**Mechanism of Effect**
Diabetes mellitus		Results in glucosuria, which can cause urinary frequency; also can be associated with a neuropathy of the bladder which can produce irritative symptoms
Neurologic disorder	Parkinson disease, multiple sclerosis, brain tumors, spinal cord injury	Associated with neurogenic bladder which can produce irritative symptoms
Urethral stricture		Reduces urethral caliber which can cause obstructive symptoms
Meatal stenosis		Blocks urethral opening which can cause obstructive symptoms
Obesity		Causes stress urinary incontinence
Cigarette smoking		Unknown

and retrograde ejaculation, shorter periods of catheterization postoperatively, and no need for hospitalization. However, minimally invasive surgical procedures are associated with a shorter duration of effectiveness and higher reoperation rates than prostatectomy.[9]

Nonpharmacologic Therapy

To reduce nocturia, patients should be instructed to stop drinking fluids 3 or 4 hours before going to bed and then void before going to sleep. During the day, timed voiding every 2 to 3 hours, double voiding, toilet mapping (knowing the location of toilets on the way to and from various destinations), or voiding before a long trip may be helpful. Patients should avoid excessive intake of caffeine-containing beverages, sugar-sweetened drinks, and alcohol, which can cause urinary frequency. Patients should avoid taking nonprescription medications that can worsen obstructive voiding symptoms (eg, antihistamines or decongestants). Patients who take a diuretic should avoid taking it in the evening. Patients are also advised to stop smoking and lose excessive weight. An alteration in the testosterone: estrogen ratio occurs in overweight men because of testosterone conversion to estrogen in adipose tissue, which may contribute to the development of BPH. For patients with diseases known to worsen LUTS, optimal management of such disorders is key (see Table 52–2).[12,19]

Although a variety of herbal agents are used for symptomatic management, including pygeum (African plum), *Cucurbita pepo* (pumpkin seed), *Secale cereale* (rye pollen), *Serenoa repens*, and *Hypoxis rooperi* (South African star grass), objective evidence of efficacy is lacking.[20,21]

Pharmacologic Therapy

Table 52-3 compares five pharmacologic treatment approaches for BPH management.

▶ α_1-Adrenergic Antagonist Monotherapy[22]

KEY CONCEPT α_1-Adrenergic antagonists reduce the dynamic factor causing BPH symptoms. These drugs competitively antagonize α_1-adrenergic receptors, thereby causing relaxation of the bladder neck, prostatic urethra, and prostate smooth muscle.[12,22] A secondary mechanism of action may be that α_1-adrenergic antagonists induce prostatic apoptosis.[23]

All α_1-adrenergic antagonists are considered equally effective in relieving symptoms.[12,22] See Table 52–4. In various clinical trials, 30% to 80% of patients experience improvement in the AUA Symptom Score by 4 to 6 points, and 20% to 40% of patients experience urinary flow rate increases of 2 to 3 mL/s.[1] The onset of action is days to weeks, with peak clinical effects observed in several weeks. An adequate clinical trial is at least 2 to 4 weeks of continuous treatment at a full maintenance dose with any of these agents.[12,22] Durable responses have been demonstrated for many years with continued use. However, some patients will develop disease progression despite treatment. α_1-Adrenergic antagonists are hepatically metabolized. Therefore, in patients with significant hepatic dysfunction, these drugs should be used in the lowest possible dose. With the exception of silodosin, these drugs do not require dosage modification in patients with renal dysfunction.

Table 52–3

Comparison of α-Adrenergic Antagonists, 5α-Reductase Inhibitors, Anticholinergic Agents, Tadalafil, and Mirabegron for Treatment of BPH

Characteristic	α-Adrenergic Antagonists	5α-Reductase Inhibitors	Anticholinergic Agents	Tadalafil	Mirabegron
Relaxes prostatic smooth muscle	Yes	No	No	Yes	No
Reduces size of enlarged prostate	No	Yes	No	No	No
Useful in patients with enlarged prostates	Yes (works independent of the size of the prostate)	Yes	Yes	Yes	No[a]
Efficacy in relieving voiding symptoms and improving flow rate	++	+	+, irritative symptoms	+	+, irritative symptoms
Reduces the frequency of BPH-related complications	No	Yes	No	No	No
Reduces the frequency of BPH-related surgery	No	Yes	No	No	No
Frequency of daily dosing	Once or twice daily, depending on the agent and the dosage formulation	Once daily	Once or twice daily, depending on the agent	Once daily	Once daily
Requirement for up-titration of dose	Yes (for terazosin and doxazosin immediate-release); no (for alfuzosin or silodosin; possibly for doxazosin extended-release and tamsulosin)	No	Yes, depending on the agent	No	Yes, but minimal
Peak onset of action	Days to 6 weeks, depending on need for dose titration	6 months	Days	Days	2–8 weeks
Decreases PSA	No	Yes	No	No	No
Cardiovascular adverse effects	Yes, hypotension	No	Yes, tachycardia	Yes, hypotension	Yes, hypertension, tachycardia
Drug-induced sexual dysfunction	Ejaculation disorders	Decreased libido, erectile dysfunction, ejaculation disorders	Yes, erectile dysfunction	No	No
Significant drug interactions	Antihypertensives Calcium channel blockers β-adrenergic antagonists CYP 3A4 inhibitors CYP 3A4 inducers	CYP 3A4 inhibitors (dutasteride only)	Drugs with anticholinergic effects/side effects Drugs that prolong QT interval CYP 3A4 inhibitors CYP 3A4 inducers	Nitrates Drugs that prolong QT interval CYP 3A4 inhibitors CYP 3A4 inducers α-Adrenergic antagonists	CYP2D6 substrates Drugs that prolong the QT interval

[a] Mirabegron is not FDA-approved for BPH.

BPH, benign prostatic hyperplasia; CYP, cytochrome P-450; PSA, prostate-specific antigen.

α_1-Adrenergic antagonists are distinguished by several characteristics:

- *Uroselectivity*. Pharmacologic uroselectivity refers to preferential inhibition of α_{1A}-receptors, which comprise 70% of α_1 receptors in the prostatic stroma, prostatic urethra, and bladder neck.[22] Pharmacologically uroselective α_{1A}-adrenergic antagonists, tamsulosin and silodosin, have the potential to produce less hypotension than other α_1-adrenergic antagonists, because the former have a lower propensity to antagonize α_{1B}-adrenergic receptors in the peripheral vasculature. Silodosin has significantly greater α_{1A}-adrenergic selectivity than tamsulosin and is preferred when a patient has minimal tolerance for any blood pressure–lowering adverse effects.[6]

Although not a pharmacologically uroselective α_{1A}-adrenergic antagonist, alfuzosin is only available in an extended-release formulation and is prescribed as a fixed dose with no up-titration. As a result, alfuzosin is considered functionally uroselective.[22]

Uroselectivity is a dose-related phenomena. Large daily doses of tamsulosin, silodosin, or alfuzosin may cause loss of uroselectivity, with resultant hypotension and dizziness in some patients.[22,24]

Table 52–4

Comparison of Pharmacologic Properties of α1-Adrenergic Antagonists

	Terazosin	Doxazosin	Alfuzosin	Tamsulosin	Silodosin
Brand name	*	Cardura Cardura-XL	Uroxatral	Flomax	Rapaflo
Generation	Second	Second	Second	Third	Third
Uroselective	No	No	Functionally (Clinically)	Pharmacologically	Pharmacologically
Need for up-titration	Yes	Yes (with immediate-release); possibly (with extended-release)	No	Minimal	No
Daily oral dose (mg)	5–20	2–8, immediate-release; 4–8, extended-release	10	0.4–0.8; (0.8 mg/day dose has not consistently produced clinical improvement over 0.4 mg/day)	8
Recommended dose reduction in patients with renal dysfunction	None needed	None needed	Manufacturer recommends caution in patients with severe renal insufficiency. No specific dosing recommendations provided	If creatinine clearance > 10 mL/min (0.17 mL/s), no dose reduction needed. Tamsulosin has not been studied in patients with creatinine clearance < 10 mL/min (0.17 mL/s)	If creatinine clearance > 50 mL/min (>0.83 mL/s), no dosage adjustment is needed. If creatinine clearance 30–50 mL/min (0.50–0.83 mL/s), use 4 mg/day.Contraindicated in patients with creatinine clearance < 30 mL/min (0.50 mL/s)
Recommended dose reduction in patients with hepatic dysfunction	Manufacturer provides no specific recommendation. Terazosin should be used cautiously as it undergoes extensive hepatic metabolism	Manufacturer provides no specific recommendation in patients with mild/moderate impairment. Avoid use in patients with severe hepatic impairment	Contraindicated in patients with moderate/severe hepatic impairment. Alfuzosin should be used cautiously in patients with mild hepatic impairment	Patients with mild/moderate hepatic impairment require no dosage adjustment. Manufacturer provides no specific recommendation in patients with severe hepatic impairment	Patients with mild/moderate hepatic impairment require no dosage adjustment. Contraindicated in patients with severe hepatic impairment
Best time to take doses	At bedtime	Immediate-release: anytime during the day; however, it is typically given at bedtime Extended-release: anytime during the day	After meals for best oral absorption	On an empty stomach for best oral absorption. If taken 30 minutes after a meal, as recommended by the manufacturer, extent of absorption is reduced, thereby further reducing the potential for hypotensive adverse effects	Take with a meal, which decreases extent of absorption. Theoretically, this would help decrease hypotensive adverse effects
Special administration instructions	None	Do not crush, cut, or chew extended release tablet	Do not crush or chew tablet	Do not crush, chew, or open capsule	May open capsule and sprinkle on applesauce. Must swallow (not chew) applesauce within 5 minutes of preparation. Follow with a full cup of water.
Half-life (hours)	12	22	5	10	13
Formulation	Immediate-release	Immediate-release and extended-release	Extended-release	Modified-release	Modified-release
Cardiovascular adverse effects	++	++	+	0 to +	0 to +
Ejaculation disorders	+	+	+	++	++
Rhinitis	+	+	+	+	+
Malaise	+	+	+	+	+
Major substrate for CYP 3A4	No	Yes	Yes	Yes	Yes

+ minimal; ++ moderate; * terazosin is only available as a generic formulation.

Despite the blood pressure–lowering property of some α_1-adrenergic antagonists, they are not recommended to be used alone to treat patients with both BPH and essential hypertension. In the ALLHAT study,[25] doxazosin was associated with a higher incidence of congestive heart failure when compared to other antihypertensives. Therefore, in patients with both hypertension and moderate-to-severe LUTS, it is recommended that an appropriate antihypertensive be added to the α_1-adrenergic antagonist.

- *Need for up-titration of daily dose*. Up-titration is required for immediate-release terazosin and doxazosin. It is minimally required for extended-release doxazosin and tamsulosin. It is not required for extended-release alfuzosin or silodosin. The need for up-titration with a particular α_1-adrenergic antagonist delays its onset of peak action.[26]
- *Plasma half-life*. α_1-Adrenergic antagonists with short plasma half-lives (eg, prazosin, which is a first generation α_1-adrenergic antagonist) require multiple doses during the day. This is challenging for most patients, and thus, prazosin is not recommended for BPH.[12]
- *Dosage formulation*. Immediate-release formulations of terazosin and doxazosin are quickly absorbed and produce high peak plasma levels, which contributes to hypotensive adverse effects. Modified- or extended-release formulations of doxazosin, alfuzosin, tamsulosin, and silodosin produce lower peak levels, but more sustained therapeutic plasma levels, than immediate-release formulations. Modified- or extended-release formulations have less potential for producing hypotensive episodes, which allows for initiation of treatment with a therapeutic dose, a faster onset of peak clinical effects, and once daily dosing.[22,26]
- *Adverse effects*. Hypotensive adverse effects of α_1-adrenergic antagonists can range from asymptomatic blood pressure reductions to dizziness and syncope. This adverse effect occurs in approximately 2% to 14% of treated patients and is most commonly associated with immediate-release terazosin and doxazosin; is less commonly associated with extended-release alfuzosin and extended-release doxazosin; and least commonly associated with tamsulosin and silodosin.[22,26] To minimize first-dose syncope from terazosin and doxazosin immediate-release, a slow up-titration from a subtherapeutic dose of 1 mg/day to a therapeutic dose is essential. The first dose should be given at bedtime so that the patient can sleep through the peak serum concentration of the drug when the adverse effect is most likely to occur. A 3- to 7-day interval between each dosage increase should be allowed, and the patient should be maintained on the lowest effective dose of the α_1-adrenergic antagonist. If the patient is noncompliant with his regimen or he skips or interrupts treatment, the α_1-adrenergic antagonist should be restarted using the usual starting dose and then retitrated up. The patient should not be instructed to simply double up on missed doses or resume treatment with the currently prescribed daily dose, as this can lead to significant hypotension or syncope.

  Reversible delayed or absent ejaculation occur with all α_1-adrenergic antagonists. This is due to pharmacologic blockade of peripheral α_{1A}-adrenergic receptors in the vas deferens and seminal vesicles, which results in decreased antegrade flow of semen to the ejaculatory ducts, or at the bladder neck.[27] The incidence appears to be dose-related and highest with daily doses of tamsulosin 0.8 mg and silodosin 8 mg, occurring in up to 26% and 28% of treated patients, respectively.[27-29] Ejaculation disorders generally do not necessitate discontinuation of treatment as some elderly patients may not be sexually active. Although this adverse effect may decrease a patient's satisfaction with the quality of sexual intercourse, ejaculation disorders are not harmful to the patient.

  Nasal congestion and malaise occur more commonly with nonuroselective α_1-adrenergic antagonists and are an extension of the pharmacologic blockade of α_{1B}-adrenergic receptors in the vasculature of the nasal mucosa and in the central nervous system, respectively. Tolerance often develops to these adverse effects and they rarely require discontinuation of treatment. Avoid use of topical or oral decongestants, as these may exacerbate obstructive voiding symptoms. Cautious use of antihistamines with anticholinergic adverse effects is also recommended in patients with severe BPH and large PVRs, as these drugs may precipitate acute urinary retention.[15,16]

  Floppy iris or small pupil syndrome has been reported with α_1-adrenergic antagonists, most often with selective α_{1A} adrenergic antagonists.[30] In response to tamsulosin, the iris dilator muscle relaxes and the pupil constricts. Pupillary constriction interferes with the surgical procedure and increases the risk of intraoperative and postoperative complications. That is, the α_1-adrenergic antagonist can cause the iris to become flaccid, floppy, or billow out, and it can prolapse into the incision.[30] Individuals undergoing cataract surgery should discuss α_1-adrenergic antagonist use with the provider performing the surgery. Although the drug will not need to be held or discontinued, the provider can use certain surgical techniques to deal with the drug's effect on the iris dilator muscle.[30] Likewise, when initiating an α_1-adrenergic antagonist, an individual who needs cataract surgery should have this ophthalmologic procedure performed prior to starting the medication, if possible.[30]
- *Potential for drug interactions*. Hypotensive adverse effects of terazosin and doxazosin can be additive with those of diuretics, antihypertensives, and phosphodiesterase type 5 inhibitors (eg, sildenafil). In patients at greatest risk for hypotension, or in those patients who tolerate hypotension poorly, including those with poorly controlled coronary artery disease or severe orthostatic hypotension, tamsulosin, or silodosin may be safer options.[31] In patients who cannot tolerate adverse effects of any α_1-adrenergic antagonist, a 5α-reductase inhibitor or surgery could be considered, particularly if the prostate is enlarged and greater than 30 g (1.1 oz). When initiating a phosphodiesterase type 5 inhibitor, patients who are taking α_1-adrenergic antagonists should be stabilized first on a fixed dose of the α_1-adrenergic antagonist, and then patients should be started on the lowest effective dose of phosphodiesterase type 5 inhibitor to minimize the likelihood of hypotensive effects.[31]

▶ *5α-Reductase Inhibitor Monotherapy*

KEY CONCEPT 5α-reductase inhibitors reduce the static factor, which results in shrinkage of an enlarged prostate by approximately 15% to 25% after 6 months of continuous treatment. They inhibit 5α-reductase, which is responsible for intraprostatic conversion of testosterone to dihydrotestosterone (DHT), the active androgen that stimulates prostate tissue growth. Two subtypes

Table 52–5

Comparison of Pharmacologic Properties of 5α-Reductase Inhibitors

	Finasteride	Dutasteride
Brand name	Proscar	Avodart
Subtype inhibition of the 5α-reductase enzyme	Type II	Types I and II
Percentage decrease of serum dihydrotestosterone level	70–76	90–95
Time to peak onset of reduction in serum dihydrotestosterone level	6 months	1 month
Percentage decrease of intraprostatic dihydrotestosterone	85–90	> 95
Half-life	6.2 hours	5 weeks
Daily dosage (mg)	5	0.5
Dosage formulation	Tablet	Capsule
Instructions for drug administration	Take with or without meals	Take with or without food. Do not open or chew capsules. Swallow capsule whole
Recommended dose reduction in patients with renal dysfunction	None needed	None needed
Recommended dose reduction in patients with hepatic dysfunction	Manufacturer provides no specific recommendation. Finasteride should be used cautiously as it undergoes extensive hepatic metabolism	Manufacturer provides no specific recommendation. Dutasteride should be used cautiously as it undergoes extensive hepatic metabolism

of 5α-reductase, Type I and II, are present in the prostate; the majority is the Type II isoenzyme.[12,32] Finasteride is a selective Type II isoenzyme inhibitor, whereas dutasteride is a nonselective inhibitor of both isoenzymes. When compared with finasteride, dutasteride produces a faster and more complete inhibition of 5α-reductase in prostate cells. However, no difference in clinical efficacy has been demonstrated between these two agents.[12,33] Thus, finasteride and dutasteride are considered therapeutically equivalent (Table 52–5). It should be noted that 5α-reductase inhibitors may also cause apoptosis of prostate cells, which could contribute to a reduction in prostate gland size.[34]

Finasteride and dutasteride are considered equally effective in decreasing the AUA symptom score by 2.7 to 4.5 points in 30% to 70% of patients, increasing the urinary flow rate by 1.6 to 2.2 mL/s, and decreasing PVR by 18% to 28%, which is less improvement than that seen with α_1-adrenergic antagonists.[12,32] A minimum of 6 months is required to evaluate the full clinical effectiveness of treatment, which may be a disadvantage in patients with moderate-to-severe symptoms. Durable responses have been demonstrated in responding patients treated continuously for years. Unique to 5α-reductase inhibitors is that they prevent BPH-related complications and prevent disease progression. 5-α-reductase inhibitors have been shown to reduce both the incidence of acute urinary retention by 57% and the need for prostate surgery by 55% in patients with significantly enlarged prostate glands (larger than 40 g [1.4 oz]) when used continuously for at least 4 consecutive years.[35]

These agents are hepatically metabolized; however, no specific recommendations for dosage modification are available in patients with significant hepatic dysfunction. No dosage adjustment is needed in patients with renal impairment.

Sexual dysfunction, including decreased libido, erectile dysfunction, ejaculation disorders, and gynecomastia, occurs in 5% to 15% of treated patients.[36,37] The frequency of sexual dysfunction peaks generally 1 year after the start of treatment,[37] and the incidence of such adverse effects tends to be higher for dutasteride than for finasteride.[33] Proposed mechanisms for these adverse effects include: (a) by decreasing DHT, this decreases nitric oxide in the corpora cavernosa, which leads to erectile dysfunction; (b) by crossing the blood–brain barrier, they inhibit neurotransmitters responsible for sexual drive; (c) they inhibit blood flow to the genitalia, which results in ejaculatory disorders; and (d) unused testosterone is converted to estrogen peripherally, which contributes to gynecomastia.[37,38]

Recently, a syndrome of chronic fatigue, penile and scrotal shrinkage, persistent sexual dysfunction, and gynecomastia after discontinuation of finasteride has been described.[38] Some have suggested that these symptoms are simply related to the aging of the patient who coincidentally is taking finasteride. In addition, there have been reports of dementia, depression, and suicidal ideation.[38] Further study is needed to establish cause–effect relationships for these possible adverse effects.

These agents reduce the incidence of prostate cancer by 25% but are suspected to increase the risk of developing moderate-to-high grade cancer, if prostate cancer does develop, and are not recommended for the prevention of prostate cancer.[39]

Patient Encounter 2

A 60-year-old man is diagnosed with moderate LUTS secondary to BPH. After a urologic work up, the patient has an AUA symptom score of 16, a urinary flow rate of 8 mL/s, PVR 60 mL, and prostate size of 50 g (1.8 oz) on transrectal ultrasound, and a PSA of 8 ng/mL (8 mcg/L). He has essential hypertension, which is well controlled on hydrohlorothiazide, valsartan, and amlodipine. The patient is a house painter and uses ladders all the time. He is started on dutasteride for BPH. The patient is sexually active.

Why should an α_1-adrenergic antagonist be used cautiously in this patient?

To enhance adherence to dutasteride, what education should be provided to this patient?

Exposure to 5α-reductase inhibitors is contraindicated in pregnant women, as the drugs may cause feminization of a male fetus. Pregnant women should not handle these drugs unless they are wearing gloves.

During continuing treatment of BPH, the patient should undergo an annual repeat PSA and DRE. These agents decrease PSA by a mean of 50% after 6 months of continuous use. A rising PSA level suggests that the patient has worsening BPH, new-onset prostate cancer, or that the patient is noncompliant with his regimen of 5α-reductase inhibitor. An abnormal DRE suggestive of prostate cancer would reveal a nodule or area of induration on the prostate. In this case, a prostate biopsy is required to rule out prostate cancer.

▶ Tadalafil

Tadalafil is expensive and should be reserved for patients with both BPH and erectile dysfunction, or those patients with LUTS that is not responsive to α-adrenergic antagonists. Tadalafil may be prescribed alone, or along with an α_1-adrenergic antagonist or 5α-reductase inhibitor. Proposed mechanisms of action for tadalafil include: (a) relaxation of smooth muscle of the urethra, prostate, and bladder neck, mediated by increased production of cyclic guanosine monophosphate, relieves obstructive voiding symptoms; (b) relaxation of detrusor smooth muscle which reduces irritative bladder symptoms; and (c) relaxation of vascular smooth muscle, which increases blood flow and decreases inflammation of the prostate.[40] Tadalafil is comparable to α_1-adrenergic antagonists in relieving obstructive voiding symptoms, but also reduces irritative voiding symptoms.[41] However, tadalafil does not increase urinary flow rate or reduce PVR.[42] Although patients will experience symptom improvement in a week, full clinical effects may take 2 to 3 months.[12,43] The usual recommended dose is 5 mg by mouth daily; the dose should be reduced to 2.5 mg daily if the creatinine clearance is 30 to 50 mL/min (0.50–0.83 mL/s). Daily doses greater than 5 mg have not been shown to be beneficial for BPH. Tadalafil should be avoided if the creatinine clearance is less than 30 mL/min (0.50 mL/s). Tadalafil is contraindicated in patients on nitrates by any route of administration. If added to treatment with an α_1-adrenergic antagonist, the patient's blood pressure should be stabilized first. If the patient is sexually active, tadalafil should not be used in patients with unstable angina, uncontrolled or high-risk arrhythmias, persistent hypotension, poorly controlled hypertension, or New York Heart Association Classification IV congestive heart failure; or patients who have had a myocardial infarction or stroke within the past 2 weeks.[31]

Common adverse effects include headache, dizziness, flushing, dyspepsia, back pain, myalgia, and cyanopsia (Table 52–6).

Tadalafil should be used cautiously in patients who are at high risk for priapism. This includes patients with sickle cell disease, multiple myeloma, leukemia; or those taking other erectogenic agents.

Although other phosphodiesterase type 5 inhibitors share the same mechanism of action as tadalafil and can improve the AUA Symptom Score, tadalafil is preferred because of its longer plasma half-life, which is theoretically beneficial in the management of BPH, a chronic disease.

▶ Anticholinergic Agents

Approximately 45% to 50% of men with BPH have symptoms of overactive bladder.[40,44,45] These irritative voiding symptoms are due to involuntary detrusor muscle contraction in response to small volumes of urine in the bladder. The detrusor muscle is innervated with muscarinic receptors. M_2 receptors comprise 75% of all muscarinic receptors; however, their physiologic function, along with that of M_4 and M_5 receptors, is not well understood. M_3 receptor stimulation is associated with abnormal detrusor contractions, which can cause irritative voiding symptoms.[44]

Anticholinergic agents are indicated when a patient has bothersome irritative voiding symptoms despite treatment with an α_1-adrenergic antagonist. Typically, an anticholinergic agent is added sequentially to an established α_1-adrenergic antagonist regimen. The ideal patient for the combination has a urinary flow rate of at least 10 mL/s and a PVR less than 50 mL. A recent meta-analysis showed that the addition of an anticholinergic agent to an α_1-adrenergic antagonist improved irritative symptoms more than what was observed with the α_1-adrenergic antagonist alone.[12,45] No cases of urinary retention were reported.

Many anticholinergic agents are available. Darifenacin is the only M_3 uroselective anticholinergic agent. Because M_3 receptors are present in the gastrointestinal tract, and eye, darifenacin can cause constipation, xerostomia, and mydriasis. Refer to Chapter 53, Urinary Incontinence and Pediatric Enuresis, for a discussion of the properties of anticholinergic agents.

If irritative symptoms do not improve after starting an anticholinergic agent, up-titrating the dose or switching to another anticholinergic agent may be helpful. Patients at the highest risk of anticholinergic agent-induced acute urinary retention include those with a PVR of 200 mL or more, low urinary flow rate, or previous history of acute urinary retention.[12,44,45] Also, the medication profile of patients should be checked for overall anticholinergic burden, which increases the likelihood of anticholinergic adverse effects, including dry mouth, tachycardia, constipation, confusion, drowsiness, and acute urinary retention. Finally, elderly patients have a high risk of cognitive impairment from anticholinergic agents, especially those with a history of stroke, head trauma, Parkinson disease, and Alzheimer disease.[43-45]

▶ Mirabegron

In the urinary bladder, 95% of all β-adrenergic receptors are of the β_3 type. Receptor stimulation relaxes the detrusor muscle, decreases detrusor overactivity, and increases bladder capacity, but does not interfere with the bladder's contractility.[40]

Mirabegron is a β_3-adrenergic agonist. It causes release of norepinephrine which stimulates β_3-adrenergic receptors, thereby reducing irritative voiding symptoms.[46,47] Although not Food and Drug Administration (FDA)-approved for BPH, mirabegron is an alternative to an anticholinergic agent in patients who poorly tolerate or are at high risk of anticholinergic adverse effects, or when irritative voiding symptoms do not respond to an anticholinergic agent. Mirabegron is typically added to an α_1-adrenergic antagonist.[47] The usual dose is 50 mg by mouth daily. Larger daily doses have shown no greater efficacy than 50 mg.[46] If the creatinine clearance is 15 to 29 mL/min (0.25–0.48 mL/s), the dose should be reduced to 25 mg daily. Mirabegron should be avoided if the creatinine clearance is less than 15 mL/min (0.25 mL/s) or in patients with poorly controlled hypertension. Common adverse effects of mirabegron include headache, hypertension, tachycardia, constipation, and nasopharyngitis.

▶ Combination Therapy

KEY CONCEPT A combination of an α_1-adrenergic antagonist and 5α-reductase inhibitor may be considered in symptomatic patients who do not respond to an adequate trial of monotherapy or in symptomatic patients at high risk of BPH complications.[12] In such patients, combination therapy will relieve voiding symptoms

Table 52–6

Summary of Adverse Effects of α-Anticholinergic Agents, Tadalafil, and Mirabegron and Management Suggestions

Drug Class	Adverse Reaction	Management Suggestion
α-Adrenergic antagonist	Hypotension	Start with lowest effective dose, give doses at bedtime, and slowly up-titrate at 0.5- to 1-week intervals to a full therapeutic dose, if using immediate-release terazosin or doxazosin Use tamsulosin, silodosin, extended-release doxazosin, or alfuzosin, as alternatives to immediate-release products, particularly in patients with low blood pressure at baseline or in those taking other antihypertensives
	Malaise	Educate the patient that this is a common adverse effect; tolerance may develop to malaise. Usually does not require discontinuation of treatment
	Nasal congestion	Educate the patient that this is a common adverse effect; tolerance may develop to rhinitis. Usually does not require discontinuation of treatment. Avoid decongestants.
	Ejaculation disorders	Educate the patient that this is a common adverse effect and is not harmful.
	QT interval prolongation	This is a rare but potentially serious adverse effect of alfuzosin only. The patient will most likely have chest pain, dizziness, loss of energy, and pass out. The patient should discontinue the medication and seek immediate attention of the prescriber. At high risk are patients taking other medications that prolong QT interval.
5α-Reductase inhibitor	Gynecomastia	Educate the patient that this may be painful or bothersome but not harmful
	Decreased libido	If the patient is sexually active, sexual counseling may be helpful. May be reversible despite continued use of the 5α-reductase inhibitor.
	Erectile dysfunction	The addition of sildenafil or another erectogenic drug may be helpful. May be reversible despite continued use of the 5α-reductase inhibitor.
	Ejaculation disorders	Educate the patient that this may occur but it is not harmful. May be reversible despite continued use of the 5α-reductase inhibitor
Anticholinergic agent	Dry mouth	Educate the patient that this is a common adverse effect. If drinking fluids and sucking on sugarless hard candy are not effective, the healthcare provider may switch to another agent in the same class or possibly reduce the daily dose.
	Constipation	This is a common adverse effect. Educate the patient to drink plenty of fluids and eat a high-fiber diet.
	Confusion, drowsiness	If this occurs, consider switching to another agent in the same class with less potential to cross the blood–brain barrier, eg, trospium
	Acute urinary retention	Do not use anticholinergic agents in patients with a PVR > 200 mL as they are high risk of developing this adverse effect, which is a urologic emergency
	Increased risk of heat stroke	By decreasing perspiration, patients who are in hot climates and who do not have access to air conditioning, are at risk of heat stroke. Use of anticholinergic agents in elderly who are exposed to these conditions should be avoided
Tadalafil	Headache	Educate the patient that this is a common adverse effect. It is usually mild, temporary, and does not require treatment discontinuation. If necessary, acetaminophen is usually effective
	Dizziness	Educate the patient that this is a common adverse effect and does not require treatment. If the patient is taking other blood pressure–lowering medications, stabilize blood pressure on these medications before starting tadalafil
	Flushing	This is a reversible, dose-related adverse effect that does not require treatment discontinuation
	Nasal congestion	This is an extension of the vasodilatory effects of tadalafil. It is reversible, dose-related, and does not require treatment discontinuation
	Visual loss	This can occur any time after tadalafil is started. It is usually painless. The patient should discontinue tadalafil and seek immediate medical attention
	Back pain	If severe, the patient should report this to the clinician. It may require discontinuation of tadalafil
	Dyspepsia	Heartburn-like symptoms may occur. Usually, it is mild and does not require treatment
	Back pain or myalgia	This occurs more often with tadalafil than with the other phosphodiesterase inhibitors. It usually resolves once the drug is stopped. If not severe, tadalafil may be continued as the adverse effect may resolve with continued tadalafil use.
Mirabegron	Hypertension	May need to initiate or adjust existing antihypertensive medications. Educate patient to monitor blood pressure while taking this medication.
	Tachycardia	Educate the patient that this is a common adverse effect. However, if increased pulse rate or palpitations are associated with low blood pressure, chest pain, or difficulty breathing, the patient should seek medical attention.
	Headache	Educate the patient that this is a common adverse effect. It is usually mild, temporary, and does not require treatment discontinuation. If necessary, a low dose of acetaminophen is usually effective.
	Constipation	This is a common adverse effect. Educate the patient to drink plenty of fluids and eat a high-fiber diet.
	Dizziness	Educate the patient that this is a common adverse effect. The patient should monitor blood pressure and seek medical attention if dizziness is moderate or severe.
	Angioedema	In addition to swelling of the face, lips, tongue, and throat, the patient may have shortness of breath and wheezing. This is an allergic reaction that requires immediate discontinuation of the drug and notification of the prescriber. The patient should not continue taking mirabegron unless the prescriber approves doing so.
	QT interval prolongation	This is a rare but potentially serious adverse effect. The patient will most likely have chest pain, dizziness, loss of energy, and pass out. The patient should discontinue the medication and seek immediate attention of the prescriber.

and also may reduce the risk of developing BPH-related complications by 64% and reduce the need for prostatectomy by 67% after continued use for a minimum of 4 years.[40,48-50]

The benefit of combination therapy with any α_1-adrenergic antagonist and any 5α-reductase inhibitor is well established. A recent study suggests that initiating a combination regimen in patients with moderate LUTS due to BPH is more likely to produce persistent improvements in AUA Symptom Score and urinary flow rate and may reduce the risk of clinical progression after 1 year than treatment with an α_1-adrenergic antagonist alone.[50] Because combination therapy is also associated with low adherence, a commercially available combination formulation of dutasteride 0.5 mg and tamsulosin 0.4 mg is available. In summary, combination therapy generally requires long-term use of an α_1-adrenergic antagonist and 5α-reductase inhibitor, which is more expensive, and is associated with lower adherence and more adverse effects than a single drug regimen. Therefore, clinicians should discuss the advantages and disadvantages of such a combination regimen with the patient before a final decision is made (see Table 52–4).[12,49]

Several other combination therapy regimens have also been used for moderate-to-severe LUTS due to BPH. Unlike that of the previously described combination, the published evidence to support newer combinations is limited. One rationale for combined use is that drugs working by different mechanisms to reduce LUTS may provide additional benefit. Tadalafil has been combined with an α_1-adrenergic antagonist[47,45] or with a 5α-reductase inhibitor. To minimize an additive blood pressure–lowering effect, tamsulosin or silodosin are preferred α_{1A}-adrenergic antagonists when combined with tadalafil. Similarly, tadalafil can offset erectile dysfunction that commonly occurs with finasteride or dutasteride. As tadalafil is expensive, combination therapy with tadalafil is reserved for patients with both moderate or severe BPH and erectile dysfunction.

For patients with moderate or severe irritative voiding symptoms due to BPH that are not responsive to an α_1-adrenergic antagonist alone, an anticholinergic agent may be added. The combination increases urine storage in the bladder and decreases voiding frequency and urgency.[12] Patients at low risk of acute urinary retention should be carefully selected for such combination therapy. These include patients with PVRs less than 50 mL and those with a urinary flow rate of at least 10 mL/s.

For patients who poorly tolerate anticholinergic adverse effects, an alternative is mirabegron, which may be added to an α_1-adrenergic antagonist. A combination of tamsulosin and mirabegron has reduced urinary urgency and frequency and increased urine storage in the bladder when compared to tamsulosin alone.[40,46]

Patient Encounter 3

A 69-year-old man LUTS secondary to BPH presents to clinic. He complains of moderate to severe urinary urgency and nocturia, which has necessitated his use of adult diapers during the day, and interrupted sleep during the night. His AUA symptom score is 20, PVR is 150 mL. He is started on tamsulosin 0.4 mg by mouth daily. After 4 weeks, a repeat AUA symptom score is 18 and he patient still complains of urinary urgency and nocturia.

What additional treatment options could be considered?

If an anticholinergic agent is selected, would an M2 selective agent be recommended?

Let us presume that the prescriber is concerned that the patient may develop confusion during treatment with an anticholinergic. What measures could be taken to minimize this adverse effect?

OUTCOME EVALUATION

KEY CONCEPT Once the peak effects of drug treatment are expected to occur, monitor the drug for effectiveness. This is approximately 2 to 4 weeks after the start of an α_1-adrenergic antagonist, anticholinergic agent, tadalafil, or mirabegron; and 3 and 6 months after the start of a 5α-reductase inhibitor. Assess symptom improvement using the AUA Symptom Scoring Index. A reduction in symptom score by a minimum of three points is anticipated. However, it should be noted that the AUA Symptom Score may not match the patient's perception of the bothersomeness of his voiding symptoms. If the patient perceives his symptoms as bothersome, independent of the AUA Symptom Score, consideration should be given to modifying the patient's treatment regimen. Similarly, a patient may regard his symptoms as not bothersome even though the AUA Symptom Score is high. At baseline and during treatment, the clinician should objectively assess symptoms and check urinary flow rate, PVR, and the absence of complications of BPH. If the patient shows a response to treatment, instruct the patient to continue the drug regimen and have the patient return at 6-month intervals for monitoring. If the patient shows an inadequate response to treatment, the dose of α_1-adrenergic antagonist can be increased (except for alfuzosin and silodosin) or another drug can be added to reduce the patient's symptoms or until the patient experiences adverse drug effects.

For the α_1-adrenergic antagonists, the severity of hypotensive-related adverse effects, which may manifest as dizziness or syncope, may require a dosage reduction, slower up-titration of the dose, or drug discontinuation. Other adverse effects of α_1-adrenergic antagonists are nasal congestion, malaise, headache, and ejaculation disorders. None of these generally require discontinuation of treatment, and these often improve as treatment continues. For the 5α-reductase inhibitors, the most bothersome adverse effects are decreased libido, erectile dysfunction, ejaculation disorders, and gynecomastia. In sexually active men, erectile dysfunction may be improved with erectogenic drugs; however, this adverse effect may necessitate discontinuation of treatment. The adverse effects of anticholinergics are dose-related and may be poorly tolerated and require drug discontinuation. Whereas tadalafil is well tolerated, mirabegron may increase blood pressure, necessitating the initiation or modification of an existing antihypertensive regimen.

Initial failure to respond to α_1-adrenergic antagonists occurs in 20% to 70% of treated patients. It is likely in these patients that the static factor may predominate as the cause of symptoms in these patients. In these patients, adding a 5α-reductase inhibitor may be helpful to shrink the prostate. Initial failure to respond to 5α-reductase inhibitors occurs in 30% to 70% of treated patients. It is likely that the dynamic factor may predominate as the cause of symptoms in these patients. Switching to or adding an α_1-adrenergic antagonist may be helpful. In contrast, drug treatment failures after an initial good response to drug therapy will likely be an indication of progressive BPH disease. In such patients, modifying the drug regimen or surgical intervention may be indicated. Finally, nonadherence to prescribed medication regimens, particularly combination therapy regimens for BPH, occurs in up to 40% of patients.[26]

Table 52–6 summarizes the adverse effects of the agents used to treat BPH and includes management suggestions for these situations.

Patient Care Process

Collect Information:

- Review the medical history and physical examination.
- Conduct a medication history for medications or dietary supplements that could be contributing to his voiding symptoms (Table 52–2). Identify allergies to medications and other substances. List current medications that the patient may be taking for LUTS and identify dose, start date, response to treatment, and adverse effects of treatment (Tables 52–3 to 52–6).
- Speak with the patient to identify lifestyle habits, preferences and health beliefs, health goals, and socioeconomic factors that affect medication access and other aspects of care.

Assess the Information:

- Based on the medical history, determine whether the patient has compelling indications for specific medications for BPH, (eg, does the patient also have erectile dysfunction?).
- Based on medical history, signs and symptoms, AUA Symptom Score (Table 52–1), and presence of complications of BPH disease, classify BPH as mild, moderate, or severe.
- Review available laboratory tests, especially serum electrolytes, renal function, and urinalysis.
- Assess the patient's adherence to lifestyle modification measures.
- Assess the efficacy and safety of, and patient adherence to current pharmacotherapy.
- Identify any significant adverse drug effects or interactions from current pharmacotherapy.

Develop a Care Plan:

- If the patient's AUA Symptom Score is in the range of 8 to 35 despite existing pharmacotherapy for BPH, modify the existing regimen. Consider increasing the dose of the drug, if feasible, or adding a drug to the existing regimen.
- If the patient is not on current pharmacotherapy for BPH but has mild LUTS, initiate lifestyle modifications. If LUTS is moderate to severe, drug therapy is also indicated. Choose medications and doses that are optimal for the patient.

Implement the Care Plan:

- Review lifestyle modification measures that reduce LUTS and reinforce adherence.
- Educate the patient about new or changes to drug therapy, best time to take daily doses, potential adverse effects, and how to self-manage and report adverse effects that might occur.
- Address any patient concerns about BPH and its management.
- Determine whether the patient has insurance coverage or whether recommended agents are included on this patient's insurance formulary.
- Educate the patient on the importance of adherence to the prescribed drug regimen.

Follow-up: Monitor and Evaluate:

- After starting an α_1-adrenergic antagonist, tadalafil, an anticholinergic agent, or mirabegron, assess effectiveness and safety of therapy in 1 month, and then at 6 months. At each visit, repeat the AUA Symptom Scoring Index, check for disease progression, repeat urinary flow rate and PVR, and assess adverse effects of treatment. As long as the patient continues to respond and tolerates the medication well, repeat all assessments at yearly intervals thereafter.
- After starting a 5α-reductase inhibitor, assess effectiveness and safety of therapy at the end of the third and sixth month.

Abbreviations Introduced in This Chapter

AUA	American Urological Association
BPH	Benign prostatic hyperplasia
BUN	Blood urea nitrogen
DRE	Digital rectal examination
FDA	Food and Drug Administration
LUTS	Lower urinary tract symptoms
PSA	Prostate-specific antigen
PVR	Postvoid volume
TURP	Transurethral resection of the prostate

Urinary Incontinence and Pediatric Enuresis

Sum Lam and Gladys El-Chaar

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiology of the major types of urinary incontinence (UI): urgency, stress, overflow, and functional.
2. Recognize the signs and symptoms of the major types of UI in individual patients.
3. List the treatment goals for a patient with UI.
4. Compare and contrast available therapeutic agents for UI; identify factors that guide drug selection for an individual patient.
5. Formulate a monitoring plan and provide patient counseling for a patient on a given treatment regimen based on patient-specific information.
6. Explain the pathophysiology of pediatric enuresis.
7. List treatment goals; compare and contrast available management strategies for managing pediatric enuresis.
8. Formulate a patient-specific monitoring plan and implement patient counseling for a patient on a given treatment regimen.
9. Describe nonpharmacologic treatment approaches for pediatric enuresis.

INTRODUCTION

Urinary incontinence (UI) is defined as the complaint of involuntary leakage of urine.[1] It is often associated with other bothersome lower urinary tract symptoms such as **urgency**, increased daytime **frequency**, and **nocturia**. Despite its prevalence in both genders, UI remains an underreported health problem that can negatively impact an individual's quality of life. Patients with UI may sense a loss of self-control, independence, and self-esteem, and often modify their activities for fear of an "accident." Patients with UI may also suffer from other consequences, including perineal dermatitis and infections, pressure ulcers, urinary tract infections (UTIs), and falls. In the United States, the estimated national cost of urgency urinary incontinence (UUI) in 2007 was $66 billion, with projected costs of $83 billion in 2020.[2]

EPIDEMIOLOGY AND ETIOLOGY

The true prevalence of UI is unclear because of varying definitions of UI and reporting bias.[3]

- About 44% of noninstitutionalized persons aged 65 and older report UI[4]
- 7% to 37% of women aged 20 to 39 report some degree of UI
- 9% to 39% of women aged 60 and older report daily UI
- 11% to 34% of older men report some degree of UI
- 2% to 11% of older men report daily UI
- In the noninstitutionalized setting, more than 50% of elderly women and more than 25% of elderly men report UI
- 46% of short-term and 76% of long-term nursing home residents report UI[4]

UI can result from abnormalities within (intrinsic to) and outside of (extrinsic to) the urinary tract. Within the urinary tract, abnormalities may occur in the urethra (including the bladder outlet and urinary sphincters), the bladder, or a combination of both structures. Focusing on abnormalities in these two structures, a simple classification scheme emerges for all but the rarest intrinsic causes of UI. **KEY CONCEPT** Accurate diagnosis and classification of UI type is critical to the selection of appropriate drug therapy.

PATHOPHYSIOLOGY

Stress Urinary Incontinence[5]

Stress urinary incontinence (SUI) occurs most frequently in women and is related to the underactivity of urethra and/or urethral sphincters, leading to inadequate resistance to impede urine flow from the bladder. SUI occurs when intra-abdominal pressure is elevated by exertional activities like exercise, running, lifting, coughing, and sneezing. SUI is usually episodic, associated with small volume leakage and rarely causes nocturia or **enuresis**. The etiology for urethral underactivity is not completely understood, although it is thought be related to the loss of the trophic effects of estrogen on the uroepithelium at menopause. The peak of SUI prevalence in the perimenopausal years supports this hypothesis. Clearly established risk factors for SUI include the following:

- Pregnancy (increased risk with increased parity)
- Childbirth (vaginal delivery)

Patient Encounter 1, Part 1

A 60-year-old woman presents to the clinic complaining of urinary symptoms that are mentioned by "the lady on a television commercial for a drug for overactive bladder." She often experiences a strong, sudden urge to urinate during the daytime. She has not leaked urine during the last 3 months. She is afraid "it might happen someday when she could not get to the toilet fast enough." On average she takes about 10 trips per day to bathroom during the daytime and gets up at least once at night to urinate. She is especially bothered by her urinary symptoms when she needs to attend consecutive sessions of work meetings that last more than 90 minutes. Occasionally she excuses herself from the meetings before they end, so she can get to the toilet fast enough. In the past 3 months, she has avoided six outdoor events planned by her family and friends. She used to love spending time with her grandkids and close friends. She denies any urinary leaks when she coughs, laughs, or exercises. She is diagnosed with overactive bladder without urinary incontinence. She is willing to try drug therapy in addition to nonpharmacologic interventions. She wants to avoid side effects as much as possible. She has a good employer-sponsored insurance plan for prescription drugs.

What information is suggestive of overactive bladder?

What additional information is necessary to differentiate overactive bladder from stress, overflow, and functional urinary incontinence? Are there any exacerbating factors?

What additional information do you need to know before creating a treatment plan for this patient?

- Menopause
- Cognitive impairment
- Obesity
- Increasing age

SUI is exceedingly rare in males unless the sphincter mechanism is compromised by surgery or trauma. The most common surgeries predisposing to SUI in men are radical prostatectomy for prostate cancer and transurethral resection of the prostate for benign prostatic hyperplasia (BPH).

Urgency Urinary Incontinence[5]

UUI is related to the overactivity of detrusor muscle in the bladder, which contracts inappropriately during the filling (urinary storage) phase and generates urgency. The bladder contractions are due to the stimulation of muscarinic cholinergic receptors, especially M2 and M3 subtypes. UUI is associated with large volume leakage (sometimes complete bladder emptying), nocturia and enuresis (may disrupt sleep). Overactive bladder (OAB) is a symptom syndrome with or without associated UUI.[6]

Most women with UUI or OAB have no identifiable causes (idiopathic), while in men similar symptoms are associated with BPH (see Chapter 52). Overactivity may be myogenic and/or neurogenic. Clearly established risk factors for UUI include:

- Older age
- Neurologic disorders (e.g., stroke, Parkinson disease, multiple sclerosis, and spinal cord injury)
- Bladder outlet obstruction (e.g., benign or malignant prostatic enlargement or hyperplasia)
- Hysterectomy
- Recurrent UTIs

Overflow Urinary Incontinence[5]

Overflow urinary incontinence (OUI) is a less common form of UI in men or women. It is related to urethral overactivity and/or bladder underactivity. In short, the bladder is filled to capacity at all times but cannot empty, causing urine to leak out episodically. If caused by bladder underactivity, the progressively weakened detrusor muscle eventually loses the ability to voluntarily contract, which leads to incomplete voiding and large residual urinary volume after micturition. Both myogenic and neurogenic factors have been associated with impaired bladder contractility that leads to OUI. Common neurogenic factors are diabetes, lower spinal cord injury, multiple sclerosis, or radical pelvic surgery.

If OUI is due to urethral overactivity, incomplete bladder emptying occurs because the resistance of the urethra and/or sphincters cannot be overcome by detrusor contractility. In men, this most frequently occurs in cases of long-term chronic bladder outlet obstruction due to BPH, prostate cancer, or abdominal-pelvic surgeries. In women, urethral overactivity is rare but may result from cystocele formation or surgical overcorrection for SUI. In both genders, systemic neurologic diseases such as multiple sclerosis or spinal cord injury may be the etiology.

Functional UI[5]

Functional UI is generally caused by extrinsic factors to the urinary tract, such as:

- Immobility (due to pain, physical limitations)
- Inadequate or delayed access to toileting facilities
- Neurologic impairment (Parkinson disease, multiple sclerosis, spinal cord injury, stroke, apathy due to depression)
- UTIs
- Postmenopausal atrophic urethritis and/or vaginitis

Clinical Presentation of Stress Urinary Incontinence (SUI) Related to Urethral Underactivity[5]

General

Usually occurs during activities like exercise, running, lifting, coughing, or sneezing; much more common in women.

Symptoms

Urine leakage volume is proportional to activity level; not associated with nocturia. No SUI with physical inactivity, especially when supine. May develop urgency and frequency as a compensatory mechanism (or independently as a separate component of bladder overactivity).

Diagnostic Tests

Observation of urethral meatus (opening) while patient coughs or strains.

Clinical Presentation of Urgency Urinary Incontinence (UUI) Related to Bladder Overactivity[5]

General

If sensory input from the lower urinary tract is absent, may have bladder overactivity and urine leakage without urgency. Patient with OAB may not have UUI.

Symptoms

Patients with OAB typically present with symptoms of urgency, frequency, nocturia with or without associated UUI.

Diagnostic Tests

Urodynamic studies are the gold standard for diagnosis. UTI must be ruled out by urinalysis and urine culture.

- Diabetes mellitus (glucosuria leading to polyuria)
- Diabetes insipidus (polyuria due to decreased antidiuretic hormone [ADH])
- Pelvic malignancy (extrinsic pressure on urinary tract structures causing obstruction)
- Constipation or fecal impaction
- Congenital malformations of the urinary tract system

Mixed and Drug-Induced UI[5]

Mixed urinary incontinence (MUI) occurs when two or more types of UI coexist in a given patient, which may lead to diagnostic and therapeutic difficulties. Patients may experience worsening of symptom due to the opposing effects of treatments indicated for specific and different types of UI.

KEY CONCEPT Many medications can influence the lower urinary tract system and precipitate or aggravate existing voiding dysfunction that leads to UI (Table 53–1).

Clinical Presentation of Overflow Urinary Incontinence (OUI) Related to Urethral Overactivity and/or Bladder Underactivity[5]

General

Rare type of UI in both genders. Urethral overactivity is usually due to prostatic enlargement in men or cystocele formation or surgical overcorrection for SUI in women. Bladder underactivity is usually due to a weakened detrusor muscle.

Symptoms

Lower abdominal fullness, **hesitancy**, straining to void, decreased force of stream, interrupted stream, sense of incomplete bladder emptying. May have urinary frequency and urgency, as well as abdominal pain if acute urinary retention occurs.

Signs

Increased postvoid residual urine volume.

CLINICAL PRESENTATION AND DIAGNOSIS

Guidelines are available for the assessment, diagnosis, and management of UI or OAB.[6-10] In general, obtaining a complete medical history and performing a targeted physical examination are essential to correctly classify the type(s) of UI. The degree of annoyance perceived by the patient due to urinary symptoms must also be assessed. However, it may not correlate well with quantitative tests such as symptom frequency/severity, use of absorbent products, and postvoid residual (PVR) urine volume (Table 53–2). Major components of the physical examination include:[5,11]

- Abdominal examination for distended bladder, organomegaly, and masses
- Neurologic evaluation of perineum and lower extremities to evaluate lumbosacral nerve function (includes digital rectal

Table 53–1

Medications Influencing Lower Urinary Tract Function

Medication	Effect
Diuretics	Polyuria, frequency, urgency
α-Adrenoceptor antagonists	Urethral relaxation: may relieve obstruction in males, induces/worsens SUI in females
α-Adrenoceptor agonists	Urethral constriction: aggravates obstruction in males (may cause urinary retention), potential SUI treatment in females
Calcium channel blockers (dihydropyridines)	Reduced bladder contractility (may cause urinary retention)
Opioid analgesics	Impaired bladder contractility (may cause urinary retention)
Sedative-hypnotics	Functional UI due to immobility, delirium, sedation
Psychotherapeutics with anticholinergic properties; anticholinergics	Urinary retention due to impaired bladder contractility or potential UUI treatment
TCAs	Combination of anticholinergic and α-adrenoceptor blocking activities can lead to unpredictable effects on UI
Ethanol	Polyuria and frequency (via effects on ADH), functional UI (delirium, sedation), urgency
ACEIs	Cough leading to SUI (ARBs do not induce cough)
Cyclophosphamide	Hemorrhagic cystitis due to acrolein metabolite (preventable with MESNA)

ACEIs, angiotensin-converting enzyme inhibitors; ADH, antidiuretic hormone (or vasopressin); ARB, angiotensin II receptor blocker; MESNA, sodium 2-mercaptoethanesulfonate; SUI, stress urinary incontinence; TCA, tricyclic antidepressant; UI, urinary incontinence; UUI, urge urinary incontinence.

Table 53–2

Items to Address during Diagnostic Evaluation of UI

Item	Comments
Urine Leakage	
Use of absorbent products	Type(s), quantity, times of day worn
Urine leakage per episode	Dribbling, small or large volumes, intermittently; consistent or varied quantities
Precipitants	Physical activity, excessive fluid intake, drug(s)
Times of day	Daytime/nighttime/both
Symptoms	
Urgency	Frequency, severity, duration from urge onset to micturition
Frequency	Daytime/nighttime/both, how often
Nocturia	How often, proportion associated with UI
Obstructive symptoms	Type(s) (hesitancy, strain to void, decreased force of stream, start and stop stream, sense of incomplete emptying), severity
Lower abdominal fullness	Frequency, severity
Comorbidities	
Current medication use	See Table 53–1. Remember CAMs, OTCs
Evidence of preexisting or new-onset:	
Diabetes mellitus	
Metastatic or genitourinary malignancy	
Multiple sclerosis or other neurologic disease	
CNS disease above the pons	Usually UUI
Spinal cord injury	UUI or OUI, depending on level and degree of completeness of injury
Recent nongenitourinary surgery	Functional UI
Previous local surgery/radiation	Prostate surgery, lower abdominal cavity surgery (direct injury versus denervation), radiation (direct injury)
Gynecologic history	Childbirth (vaginal versus cesarean section), prior gynecologic surgery, hormonal status (pre- versus peri- versus postmenopausal)
Pelvic floor disease	Constipation, diarrhea, fecal incontinence, dyspareunia, sexual dysfunction, pelvic pain
UTI	Dysuria, CVA tenderness, frequency
Gross Hematuria	Possible bladder or other genitourinary cancer

CAM, complementary and alternative medications; CVA, costovertebral angle; OTC, over-the-counter; OUI, overflow urinary incontinence; UTI, urinary tract infection; UUI, urge urinary incontinence.

examination to check rectal tone, reflexes, ability to perform a voluntary pelvic muscle contraction in women; size and surface quality of prostate in men)

- Pelvic examination in women for evidence of prolapse of bladder, small bowel, rectum, or uterus, or signs of estrogen deficiency
- Genital/prostate examination in men
- Urinalysis, PVR urine volume
- Direct observation of urethral meatus (opening) when patient coughs/strains (urine spurt consistent with SUI)
- Perineal examination for skin maceration, redness, breakdown, ulceration, and evidence of fungal skin infection

Clinicians could inquire about UI and OAB with open- and closed-ended questions.[12]

- Do you leak urine when you cough, sneeze, laugh, etc?
- Do you have to get up more than once at night to urinate?
- Do you feel the urge to urinate frequently?
- How many times do you typically urinate from waking in the morning until going to bed in the evening?
- How many times do you typically wake up to urinate from going to sleep at night until waking in the morning?
- How often do you have a sudden compelling desire to urinate, which is difficult to postpone?
- How often do you leak urine because you cannot postpone the sudden desire to urinate?

A validated three-item questionnaire helps clinicians discern the common incontinence subtypes by asking participants whether they experienced UI during the past 3 months, whether they experienced involuntary urinary leaking, and when they experienced it most often.[11]

TREATMENT

Desired and realistic treatment outcomes should be individualized and discussed with each patient. KEY CONCEPT The treatment goals for UI may change with time, and often require reaching a compromise between efficacy and tolerability of drug therapy.

Desired Outcomes

- Restoration of continence
- Reduction of the number of UI episodes (daytime and nighttime) and nocturia
- Prevention or delaying of complications associated with UI (e.g., pressure ulcers, skin conditions)
- Minimization of adverse effects and costs related to treatment
- Improvement in quality of life

Nonpharmacologic Treatment

At the primary care level, nonsurgical, nonpharmacologic intervention constitutes the chief approach to the management of UI.

It has no adverse reactions, is minimally invasive, and can be utilized adjunctively with other treatment modalities. KEY CONCEPT Nonpharmacologic treatment gives at least an additive effect in efficacy when combined with drug therapy. It can allow the use of lower doses of drug therapy. It is ideal for patients who fit the following scenarios:

- Being medically unfit for surgery
- Planning for pregnancies/childbirths, which can compromise the long-term results of certain types of continence surgery
- Having OUI whose condition is not amenable to surgical or drug treatment
- Avoiding drug therapy or surgery due to safety concern or patient preference

These approaches include lifestyle or behavioral modifications, fluid management, scheduled voiding regimens, pelvic floor muscle rehabilitation (PFMR; common term "Kegel exercises"), external neuromodulation, anti-incontinence devices, acupuncture, and supportive interventions.[5,11,13,14] Many of these are best utilized through attendance at multidisciplinary UI clinics staffed by specialized healthcare providers. Weight loss and exercise are recommended for all types of UI in women who are overweight or obese. Weight loss of 5% to 10% gives similar efficacy as other nonpharmacologic treatments for SUI.[8,10] Smoking cessation should be considered in patients with all types of UI. Other lifestyle modification strategies include management of constipation, avoidance of excessive fluids, reduced intake of caffeine, carbonated beverages, diet beverages, and alcohol. Frequent intake of small amounts of fluid (e.g., 4 to 5 oz per hour) up to 2 L/day in lieu of large, episodic fluid intake (e.g., 36 oz in one drink) can be helpful.[11]

Time voided measures or voiding at intervals that are tailored to each patient (e.g., every 2 to 3 hours) during the day can reduce UI episodes.[11] Bladder training and prompted voiding improve symptoms of UUI and MUI. PFMR is an effective treatment for adult women with SUI and MUI.[8] Combination therapy with PFMR plus behavioral training achieved better outcomes than drug therapy in women with UUI. However, these methods require motivation from patients. Medical conditions, such as cognitive dysfunction, may interfere with active participation and thus compromise efficacy. Regular follow-ups are important for monitoring outcomes and for providing reassurance and support. Lifestyle or behavioral interventions should be continued during drug therapy in patients with UI, even if the results have not fully achieved the desired outcomes. PFMT is strongly recommended for SUI; bladder training may be recommended for UUI; and the combination of both is strongly recommended for MUI.[8,10]

External neuromodulation may include nonimplantable electrical stimulation, percutaneous tibial nerve stimulation, or extracorporeal magnetic stimulation. This treatment option is typically prescribed when traditional PFMR has failed. Anti-incontinence devices, such as bed alarms, catheters, pessaries, penile clamps, and external collection devices, are reserved for special situations depending on patient's symptoms, cognition, mobility status, and overall health status. Supportive interventions such as physical therapy may be beneficial for patients with muscle weakness and slow gait that hinder their ability to reach to the toilet in a timely manner. Last, absorbent products provide greater patient confidence in dealing with unpredictable urine loss.[5]

Surgery is rarely an initial treatment for UI; only considered in patients with significantly bothersome symptoms, and when nonsurgical options are undesired or ineffective. Surgery is not as helpful for bladder underactivity but can be used to manage urethral overactivity due to BPH and bladder outlet obstruction (via endoscopic incision using a cystoscope). It is most effective for SUI by stabilizing the urethra and bladder neck and/or augmenting urethral resistance. Common approaches are injection of periurethral bulking agents and midurethral sling procedure. SUI in men is best treated by implanting an artificial urinary sphincter.[5]

There are three approved procedural treatments in the United States for women with persistent urgency incontinence symptoms or medication intolerance: percutaneous tibial nerve stimulation, sacral neuromodulation, and onabotulinumtoxin A injections into the bladder. Percutaneous tibial nerve stimulation is an office-based percutaneous treatment for UUI or OAB. Therapy consists of weekly 30-minute treatments with a needle placed

Patient Encounter 1, Part 2

PMH: Hypertension for 5 years, hyperlipidemia for 3 years, diabetes mellitus type 2 for 3 years, seasonal allergies for 10 years

SH: Married for 31 years, recently widowed and lives alone. Works as a financial advisor in a big corporate firm. One son (age 30), one daughter (age 28), and five grandkids. Drinks one glass of wine with dinner; drinks one cocktail at bedtime (started when her husband passed away due to stroke last year). Consumes two cups (total 16 oz) of cappuccino coffee in the morning and one cup (8 oz) of regular coffee after lunch. Former smoker, quit for 5 years ago

All: NKDA

Meds: Losartan 50 mg once daily, atorvastatin 10 mg once daily, metformin 500 mg twice daily, fexofenadine 60 mg twice daily

ROS: Alert and pleasant. Denies dysuria, lower abdominal fullness, decreased force of stream, or other urological symptoms besides her chief complaints

PE:

VS: BP 155/87 mm Hg, HR 78 beats/min, RR 18 breaths/min, T 36.8°C (98.3°F), Wt 199 lbs (90 kg), Ht 5′7″ (170 cm)

HEENT: PERRLA; EOMI, TMs WNL

Neck/LN: Supple w/o LAD or masses

Lungs/Thorax: CTA

CV: RRR w/o murmurs, rubs, gallops

Abd: soft, NT/ND w/o masses; normal bowl sounds

GU: WNL; no atrophic vaginitis or uterine prolapse

MS/Ext: WNL, no edema

Neuro: DTRs 2+, CN II–XII intact

Labs: All within normal limits. SCr 1.0 mg/dL (88 μmol/L), fasting glucose 130 mg/dL (7.2 mmol/L), lipid profile and hepatic function tests within normal limits, HbA1c 8.0%

Given this additional information, what is your assessment of the patient's condition?

What are the goals of pharmacotherapy for this patient?

What nonpharmacologic and pharmacologic options are available to the patient?

posterior to the medial malleolus of the ankle over the course of 3 months, followed by monthly maintenance therapy. The efficacy is similar to oral drug therapy with 60% subjective improvement and low rates of transient local adverse events. However, long-term efficacy and safety data are lacking.[5,11]

Surgical treatment for UUI generally consists of implantation of a sacral nerve stimulator (neuromodulation) or endoscopic office-based injection of botulinum toxin A directly into the smooth or striated muscle.[5,11] Sacral neuromodulation is an outpatient procedure in which an implanted electrode is placed along the third sacral nerve root to deliver nerve stimulation. After a successful test, a permanent external stimulator can be implanted (lasts 5 years). It is 60% to 90% effective with a cure rate of 30% to 50%.[5,11] Intrabladder (intravesical) onabotulinumtoxin A (100 U) injections are performed in the office generally with local anesthesia. The duration of effect of the toxin is about 4 to 8 months after which repeated injections are necessary to maintain effect. The drug blocks the presynaptic release of acetylcholine to decrease muscarinic receptor activation involved in detrusor contraction and increase bladder capacity/compliance. The efficacy is similar to or better than that of oral anticholinergics (about 65% at 6 to 12 months).[5,11] It reduced more UI episodes than sacral neuromodulation but with increased rates of UTI and urinary retention (need for catheterization).[15]

Patients with UUI and an elevated PVR volume may require intermittent self-catheterization along with frequent voiding between catheterizations. Surgical placement of a suprapubic catheter may be necessary in cases when intermittent catheterization is not possible. Catheterization can be combined with pharmacologic treatment for symptom relief.[5]

Pharmacologic Treatment

The ideal treatment agent must have clinical efficacy, minimal side effects, minimal drug–drug or drug–disease interactions, convenient administration, and affordability. **KEY CONCEPT** Patient characteristics (e.g., age, comorbidities, concurrent drug therapies, ability to adhere to the prescribed regimen including drug affordability) can influence drug therapy selection.[5]

▶ *Urgency Urinary Incontinence*

Anticholinergic/Antimuscarinic Antimuscarinic agents are the second-line treatment for UUI or OAB after nonpharmacologic interventions (Table 53–3).[6] They are effective in suppressing premature detrusor contractions, enhancing bladder storage, and relieving symptoms. When used with or without bladder training, these agents improved symptoms and quality of life in patients with UUI or OAB. However, they restore continence in less than 15% of patients and reduce UI episodes by only 0.5 to 1 episodes per day.[16] They are considered equally effective based on statistical superiority over placebo or active controls. Their efficacy ranges from 53% to 80% reduction in UI episodes and 12% to 32% reduction in urinary frequency (placebo 30% to 47%, and 8% to 15%, respectively). About 50% of patients experience symptom control with common side effects of dry mouth and constipation. Less than half of individuals continue therapy beyond 6 months and less than 36% beyond 1 year.[11]

All antimuscarinic agents have similar contraindications and precautions, including urinary retention, gastric retention, and uncontrolled narrow-angle glaucoma.[5,11] Older immediate release (IR) agents, such as oxybutynin and tolterodine, have been associated with high rates of dry mouth, constipation, headache, dyspepsia, dry eyes, cognitive impairment, tachycardia, and urinary retention (Table 53–4). Older patients are especially susceptible to these adverse events. Significant dry mouth may cause dental caries, ill-fitting dentures, and swallowing difficulty. Chewing sugarless gum or use of saliva substitutes can help to alleviate dry mouth.

Orthostatic hypotension and sedation can be particularly troublesome to frail patients with cognitive impairment or at risk for falls. Issues with tolerability and multiple daily dose administration associated with IR products may jeopardize medication adherence and can prevent dose titration. Thus, IR products are generally not preferred in patients with functional limitations and/or those who are already taking complicated drug regimens. Nevertheless, adverse events are not universal and the severity varies with individuals. Older agents, when initiated at the lowest possible dose and gradually titrated, are reasonable to consider in cases when long-acting products are undesirable (e.g., need to crush medications due to inability to swallow).

Extended-release (ER) agents (oxybutynin XL, tolterodine LA, trospium ER, darifenacin ER, fesoterodine ER) cause less dry mouth compared with IR products.[5,7] These products cannot be chewed, crushed, or divided, and must be swallowed whole. Oxybutynin transdermal patch and topical gel are alternatives for patients who cannot take or tolerate oral drugs. They cause less dry mouth but more application site reactions. Rotation of application sites may help to minimize local side effects.

Patients receiving any antimuscarinic agent should be informed about sedation as a possible side effect and warned against operating heavy machinery, such as driving, especially during the initial phase of therapy. Patients with existing cognitive dysfunction or difficulty with balance should be monitored closely for mental status change and fall risk. Older individuals are more prone to experience constipation because they may take medications which affect bowel function. Patients should contact their physicians in case of severe abdominal pain or constipation that lasts for 3 or more days. Clinicians should monitor potential drug interactions between antimuscarnic agents and acetylcholinesterase inhibitors for dementia (antagonism), as well as concomitant use with anticholinergic agents (additive side effects).

KEY CONCEPT Antimuscarinic agents should be initiated at the lowest possible dose and gradually dose-titrated based on clinical response; not to exceed the maximum recommended dose. A trial of at least 4 weeks is required to evaluate its efficacy. Consider switching to another agent if the patient reports intolerable side effects or inadequate symptom relief despite optimized dose and therapy duration.

Mirabegron Mirabegron, a β_3-adrenergic agonist, is also considered the second-line therapy for OAB. It reduces

Patient Encounter 1, Part 3

Based on the information presented, create a care plan for this patient. Your plan should include:

(a) A statement of the drug-related needs and/or problems

(b) A patient-specific detailed therapeutic plan, including patient counseling to enhance medication adherence, ensure successful therapy, and minimize adverse effects

(c) A plan for follow-up to evaluate therapeutic outcome and drug tolerability

Table 53–3

Approved Drugs for the Management of UUI in Adults

Parameter	Oxybutynin	Tolterodine	Trospium Chloride	Solifenacin	Darifenacin	Fesoterodine	Mirabegron
Dosage forms	IR tablets, solution SR-ER tablets, SR-TD patch, topical gel	IR tablets SR-LA capsules	IR tablets ER tablets	IR tablets	ER tablets	ER tablets	ER tablets
Dosing	IR: 2.5–5 mg 2–4 times daily (pediatrics 0.3–0.5 mg/kg/day in three doses) SR (oral): 5–30 mg once daily (pediatrics: 0.3–0.5 mg/kg/day) SR (TD): 3.9 mg/day patch applied twice weekly; available over-the-counter SR (gel): 1 sachet (100 mg) applied once daily	IR: 1 or 2 mg twice daily (pediatrics: 1 mg twice daily) ER: 2 or 4 mg once daily (pediatrics: 2 mg once daily)	IR: 20 mg twice daily ER: 60 mg once daily	5–10 mg once daily	7.5–15 mg once daily	4–8 mg once daily	25 mg once daily, then 50 mg once daily after 8 weeks
Kinetics	Active metabolite (*N*-desethyl) Not altered in renal or hepatic disease or advanced age	Active metabolite (5-hydroxymethyl) Polymorphic metabolism (CYP 2D6) Not altered in advanced age. Significantly altered in hepatic disease (decreased CL in cirrhosis) and renal disease (decreased CL)	Food: decreased F by 70%–80% Significantly altered in renal disease (decreased CL) but not in hepatic disease or advanced age	Metabolized via CYP 3A4 but only one active metabolite (4-hydroxy) Significantly altered in severe renal impairment, moderate hepatic impairment (Child-Pugh B), and advanced age (decreased CL in all)	Complex metabolism (polymorphic CYP 2D6, CYP 3A4) Not altered in advanced age, renal impairment, mild hepatic impairment (Child-Pugh A) Significantly altered in moderate hepatic impairment (Child-Pugh B) (decreased CL)	Prodrug (for 5-hydroxmethyl tolterodine) Inactive metabolites Not altered in advanced age Significantly altered in renal disease (decreased CL) and moderate hepatic impairment (Child-Pugh B) (decreased CL)	Terminal elimination half-life 50 hours Moderate inhibitor of CYP 2D6
Contraindications and precautions	Use with caution if CYP 3A4 inhibitors are also being taken (decreased oxybutynin CL)	Reduce dose 50% in those taking CYP 3A4 inhibitor(s) or with hepatic cirrhosis or with CrCl < 30 mL/min (0.50 mL/s) Antacid-SR (oral) prep, interaction (dose-dumping) (not seen with PPIs)	Give on empty stomach Do not use ER when CrCl < 30 mL/min (0.50 mL/s); use IR 20 mg once daily at bedtime	Do not exceed 5 mg/day if CrCl < 30 mL/min (0.50 mL/s), patient has moderate hepatic impairment, or patient is taking CYP 3A4 inhibitor(s) If severe hepatic impairment, do not use	Do not exceed 7.5 mg/day if patient is taking potent CYP 3A4 inhibitor(s) Use caution if patient is taking moderate CYP 3A4 inhibitor(s) or CYP 3A4 or 2D6 substrate(s) Do not chew, divide, or crush the ER tablets	Do not exceed 4 mg/day if CrCl < 30 mL/min (0.50 mL/s) or patient is taking potent CYP 3A4 inhibitor(s) If severe hepatic impairment, do not use	Limit dose to 25 mg once daily if severe renal impairment or moderate hepatic disease Avoid in end-stage renal disease or severe hepatic impairment, or more BP 180/110 mm Hg Monitor for increased BP and urinary retention Do not chew, divide, or crush

BP, blood pressure; CL, total body clearance; CrCl, creatinine clearance; ER, extended release; F, bioavailability; IR, immediate release; LA, long acting; PPIs, proton pump inhibitors; SR, sustained release; TD, transdermal.

Table 53–4

Adverse Event Incidence Rates with Approved Drugs for Bladder Overactivity[a]

Drug	Dry Mouth (%)	Constipation (%)	Dizziness (%)	Vision Disturbance (%)
Oxybutynin IR	71	15	17	10
Oxybutynin XL	61	13	6	14
Oxybutynin TDS	7	3	NR	3
Oxybutynin gel	10	1	3	3
Tolterodine	35	7	5	3
Tolterodine LA	23	6	2	4
Trospium chloride IR	20	10	NR	1
Trospium chloride XR	11	9	NR	2
Solifenacin	20	9	2	5
Darifenacin	24	18	2	2
Fesoterodine	27	5	NR	3
Mirabegron ER	3	3	3	NR

[a] All values constitute mean data, predominantly using product information from the manufacturers.

urinary frequency and UI episodes by less than one per day (see Table 53–3).[6,17] It increases bladder capacity by relaxing the detrusor smooth muscle during the storage phase of the urinary bladder fill-void cycle. It requires 4 to 8 weeks of therapy for optimal efficacy.[17] It is as effective as antimuscarinics (symptom control rates range from 43% to 46% at 1 year of therapy.[11]

Mirabegron is available as ER tablets and should be swallowed whole without chewing, dividing, or crushing. Most commonly reported adverse reactions are hypertension (7%–11%), nasopharyngitis (4%), UTI (3%–6%), and headache (3%–4%). Patient should be monitored for increased blood pressure and urinary retention, particularly in patients with bladder outlet obstruction or those who are taking anticholinergic drugs.[5] Mirabegron and solifenacin combination therapy provided improvement in OAB symptoms over monotherapies with good tolerability in a 1-year study.[18] Other β_3-adrenergic agonists in the drug development pipeline are solabegron, ritobegron, vibegron, and others.[19-21]

Older Agents[5] Tricyclic antidepressants (TCA), such as desipramine, nortriptyline, imipramine, and doxepin, are generally no more effective than oxybutynin IR. They may cause potentially serious adverse effects (e.g., orthostatic hypotension, cardiac conduction abnormalities, dizziness, and confusion). Thus, TCA use is limited to individuals who have one or more indicated comorbidities (e.g., depression or neuropathic pain), MUI (because of their effect of decreasing bladder contractility and increasing outlet resistance), and possibly nocturnal incontinence associated with altered sleep patterns. Other older agents, including propantheline, flavoxate, dicyclomine, and hyoscyamine are not recommended for UI.[5]

▶ *Stress Urinary Incontinence*

The goal of pharmacologic therapy of urethral underactivity is to improve the urethral closure mechanism by:

- Stimulating α-adrenoceptors in the smooth muscle of the proximal urethra and bladder neck
- Enhancing the supportive structures underlying the urethral mucosa
- Enhancing the positive effects of serotonin and norepinephrine in the afferent and efferent pathways of the micturition reflex

In general, systemic pharmacologic therapy is not recommended for SUI.[8,10] PFMT is the first-line therapy in women with SUI.[10] Nevertheless, SUI in women is frequently curable by surgery, thus obviating years of drug therapy that may not provide adequate symptom relief. Surgery (tension-free vaginal tape sling) is a more cost-effective therapy of SUI than duloxetine in women failing PFMR.[22] Automatic pelvic exercise devices, incontinence pessaries, and disposable intravaginal bladder support devices can also be considered for SUI.[10]

Estrogens[5] KEY CONCEPT Local vaginal estrogen preparations can effectively relieve the genitourinary syndrome of menopause, including urinary complaints of frequency, urgency, and SUI.[23] Estrogen products are believed to work by a trophic effect on uroepithelial cells and underlying collagenous subcutaneous tissue, enhancement of local microcirculation by increasing the number of periurethral blood vessels, and enhancement of the number and/or sensitivity of α-adrenoceptors.

Local estrogens (conjugated equine estrogen cream, estradiol rings) have demonstrated subjective improvement in SUI and UI in general.[24] Local products, such as the estrogen ring, may have dual effects: functioning like an incontinence pessary by supporting the bladder neck while simultaneously providing estrogen locally (Table 53–5). In contrast, oral hormone replacement therapy increases the risk of new-onset SUI, UUI, MUI while carrying numerous risks, including mastodynia, uterine bleeding, nausea, thromboembolism, cardiac or cerebrovascular ischemic events, and breast or endometrial cancer.[24]

α-Adrenoceptor Agonists[5] Phenylpropanolamine, ephedrine, and pseudoephedrine have been used alone or with estrogen for mild and moderate SUI. However, recent data showed that they are not better than placebo or PFMR.[23] The major impediment to using α-adrenoceptor agonists is the extensive list of contraindications (see Table 53–5). Side effects of pseudoephedrine, an over-the-counter medication, include hypertension, headache, dry mouth, nausea, insomnia, and restlessness.

Duloxetine This selective serotonin-norepinephrine reuptake inhibitor is approved to treat SUI in Europe but is off-label in the United States. It enhances central serotonergic and adrenergic tone, which is involved in ascending and descending control of urethral smooth muscle and the internal urinary sphincter, and thereby enhances urethral and urinary sphincter smooth muscle

Table 53–5

Drugs Used for SUI[a]

Parameter	Estrogens	Pseudoephedrine	Duloxetine
Dosage forms	Avoid systemic (parenteral, oral, TD); use vaginal: tablet, cream, intravaginal ring	Tablets, solution	DR capsules
Dosing	Estradiol 25-mcg vaginal tablets (insert one PV daily for 14 days, then one PV twice weekly) Estradiol vaginal cream (0.1 mg/g) (2–4 g daily PV for 1–2 weeks; then 1 g PV daily or less frequently) CEE vaginal cream (0.625 mg/g) (0.5–2 g daily PV; consider 3 weeks on, 1 week off; may be able to decrease frequency of use over time) Estradiol 2-, 12.4-, 24.8-mg vaginal rings (1 ring PV every 3 months)	15–60 mg three times daily	40–80 mg/day in one or two doses for 12 weeks (titrate and taper dosage)
Kinetics	Use local route to minimize systemic F and side effects Estradiol less likely to be absorbed; CEE 1 mg or more daily sufficiently absorbed to cause systemic side effects	Less than 1% of dose is metabolized (inactive metabolites) Primarily renal elimination of unchanged drug Would not expect hepatic impairment to have an effect (no data) Expect significant effect if renal impairment and no effect if advanced age (beyond decreased CrCl with age) (no data)	Extensive metabolism via CYP 2D6 and 1A2 (inactive metabolites) Not altered in advanced age, mild-to-moderate renal impairment (CrCl 31–80 mL/min [0.51–1.34 mL/s]), mild hepatic impairment (Child-Pugh A) Significantly altered in severe renal disease (CrCl < 30 mL/min [< 0.50 mL/s]) and moderate hepatic impairment (Child-Pugh B)
Contraindications/ precautions	Known or suspected breast or endometrial cancer Abnormal genitourinary bleeding of unknown etiology Active thromboembolism (or history of TE associated with previous estrogen use)	Hypertension, tachyarrhythmias, coronary artery disease, MI, cor pulmonale, hyperthyroidism, renal failure, narrow-angle glaucoma	Multiple drug–drug interactions possible with CYP 2D6 and 1A2 substrates/inhibitors Avoid if CrCl < 30 mL/min (0.50 mL/s) and in all patients with hepatic disease Can raise BP Do not discontinue abruptly (withdrawal syndrome) Suicide risk even in patients without psychiatric disease Avoid in uncontrolled narrow-angle glaucoma (causes mydriasis) Hepatotoxic; avoid in alcoholics even if signs/symptoms of hepatic disease are absent

[a] None of these agents are FDA approved for treatment of SUI. Duloxetine is approved in Europe only.

BP, blood pressure; CEE, conjugated equine estrogens; CrCl, creatinine clearance; CYP, cytochrome P-450; DR, delayed-release; F, bioavailability; MI, myocardial infarction; PV, per vagina; TD, transdermal; TE, thromboembolism.

tone during the filling phase.[25] It may benefit incontinence and quality of life in men with SUI after radical prostatectomy.[26]

The use of duloxetine in SUI is complicated by intolerability (e.g., high rate of nausea), numerous precautions or contraindications, CYP P450 drug–drug interactions, and the possibility of withdrawal symptoms if abruptly discontinued.[25] It may be considered if there are comorbidities such as depression, anxiety, fibromyalgia, diabetic neuropathy, and chronic musculoskeletal pain. The usual dosage is 40 to 80 mg/day (in one or two doses) for 12 weeks. Gradual dose titration (starting from 20 mg once daily for at least 1 week, then titrate no shorter than weekly interval) may help to reduce the risks of nausea, dizziness, and premature therapy cessation. Similarly, dose reduction of 50% for 2 weeks before discontinuation or slow tapering over 4 to 6 months is reasonable to minimize withdrawal symptoms.

▶ *Overflow Incontinence*[5]

There is no established effective pharmacologic therapy for OUI due to bladder underactivity (atonic bladder). A trial of bethanechol (25–50 mg three or four times daily) may be reasonable if contraindications do not exist. Bethanechol is a cholinomimetic with uncertain efficacy and bothersome and potentially life-threatening side effects (muscle and abdominal cramping, hypersalivation, diarrhea, and bronchospasm), particularly in patient with preexisting conditions. α-Adrenoceptor antagonists, such as silodosin, prazosin, terazosin, doxazosin, tamsulosin, and alfuzosin, may be beneficial for OUI by relaxing the bladder outflow tract and hence reducing outflow resistance. If pharmacologic therapy fails, intermittent urethral catheterization three or four times per day is recommended. Less satisfactory alternatives include indwelling urethral or suprapubic catheters, or urinary diversion. In OUI due to obstruction, such as BPH, the goal of treatment is to relieve the obstruction.

▶ *Mixed Urinary Incontinence*[5]

MUI is usually a combination of UUI plus SUI with one dominant component. It accounts for one-third of UI cases in women. A reasonable management approach is a combination of lifestyle or behavioral modifications and PFMR with pharmacotherapy appropriate to the dominant type of UI. For instance, antimuscarinics can be offered in UUI-predominant cases, whereas duloxetine, local estrogen, and α-adrenoceptor agonists in SUI-predominant cases. In some cases, the less dominant form of UI may respond, but usually not to a degree that is considered adequate by the patient. Most experts feel that SUI-predominant MUI is best treated initially using nonpharmacologic approach plus surgery for SUI. Unfortunately, these patients with MUI are expected to have a lower success rate with surgery compared to those with pure SUI. The urge component may improve, stay the same, or worsen after surgery.

▶ *Nocturia*

Desmopressin Nocturia may be caused by a wide array of factors, such as uncontrolled diabetes mellitus, congestive heart failure, bladder or prostate diseases, and use of medications (e.g., diuretics). Intranasal desmopressin, a synthetic vasopressin analog, was approved in 2017 in the United States for the treatment of nocturia due to nocturnal polyuria in adults who awaken at least 2 times per night to void. Its use is limited due to multiple contraindications. The manufacturer announced the discontinuation of this product in 2019.[27] A sublingual formulation is approved in Canada for nocturia. Desmopressin oral and sublingual formulations are indicated for primary nocturnal enuresis.

OUTCOME EVALUATION

- Monitor the patient for symptom relief. Has the treatment achieved the desired outcomes jointly developed by the healthcare team, patient, and caregiver? If so, to what degree? Inspect the daily diary completed by the patient or caregiver and quantitate the clinical response (e.g., micturitions, UI

Patient Care Process: Urinary Incontinence

Collect Information:

- Identify urinary symptoms and ask the patient how the symptoms affect his or her daily living.
- Identify exacerbating factors and UI complications.
- Review concurrent medical conditions and obtain a thorough medication history, including use of prescription, nonprescription, and complementary/alternative products.
- Identify allergies or serious adverse events related to the use of medications and other substances.
- Ask the patient and caregiver about their goals of therapy and socioeconomic factors that affect medication access and other aspect of care. In cognitively intact elderly patients, focus communications to elicit the preferences of the patient, not those of potential proxies.

Assess the Information:

- Assess the severity of urinary symptoms. Assess changes in quality of life (physical, psychological, social functioning, and well-being).
- Based on reported signs, symptoms, and exacerbating factors, determine whether a referral to specialized professional is required.
- Evaluate whether or not urinary symptoms could be exacerbated by disease states or drugs (see Table 53–1). Determine if any current or previous treatments are/were helpful for UI.

Develop a Care Plan:

- Help the patient and caregiver to set realistic goals of therapy.
- Consider whether lifestyle or behavioral modifications, fluid management, and other nonpharmacologic treatment are feasible or desirable.
- Determine whether pharmacotherapy is indicated or desired by patient. Choose appropriate treatment regimen (drug choice, dosage, administration) for his or her type(s) of UI.
- Evaluate the patient for medication adherence, drug-related adverse events, allergies, and drug interactions with concomitant medications or disease states.

Implement the Care Plan:

- Educate the patient on lifestyle modifications that may improve symptoms: smoking cessation, weight reduction (for those patients with SUI and UUI), constipation prevention in patients at risk, caffeine reduction, and diet or fluid modification. Note the timing and quantity of fluid intake, as well as possibility of avoiding foods or beverages that worsen UI.
- Provide patient education regarding the disease state, lifestyle modifications, and drug therapy (see Tables 53–3 and 53–5).
- Address any patient or caregiver concerns about disease state and its management, including timing of medication intake, potential adverse events, potential drug–drug or drug–disease interactions, and importance of treatment adherence.

Follow-up: Monitor and Evaluate:

- Monitor for patient response in 1 or 2 weeks after therapy initiation.
- Develop a plan to assess efficacy after a minimum of 4 weeks.
- Determine whether the patient is experiencing any adverse effects or drug interactions.

episodes, and pad use) since the last visit. If a diary has not been used, ask the patient how many incontinence pads have been used and how they have been doing in terms of "accidents" since the last visit. If appropriate, administer a short-form instrument to measure the impact of symptoms, including quality of life. Compare the findings with previous results.

- Ask patients about adverse effects of drug therapy using a nonleading approach. Ask the patient or caregiver to judge their severity and what measures, if any, they have used to alleviate. Assess medication adherence (ask patient or caregiver about missed doses or do a pill count if the prescription containers are available at the visit).
- Clinical response and tolerability should guide the dose titration or tapering of drug therapy. Consider stopping/tapering off the regimen and initiate another drug option if bothersome adverse effects compromise patient safety and/or medication adherence.

PEDIATRIC ENURESIS

INTRODUCTION

UI, or pediatric enuresis, is a common problem. In children less than 5 years old, treatment is unnecessary because spontaneous cure is likely. After 5 years of age, a child with intermittent or continued incontinence is considered to have pediatric enuresis. Pediatric enuresis is subdivided into categories to clarify expectations of the condition and response to therapy:[28,29]

- Monosymptomatic enuresis: Enuresis in children without other lower urinary tract symptoms or bladder dysfunction
- Primary enuresis: Enuresis in children who have never been consistently dry throughout the night
- Secondary enuresis: Enuresis in patients who have resumed wetting after a period of dryness of at least 6 months in duration
- Nonmonosymptomatic enuresis: Enuresis in children with other lower urinary tract symptoms (e.g., urgency, frequency, daytime incontinence, genital or lower urinary tract pain)

Emotional and developmental impacts from enuresis are significant and include social stigma and low self-esteem. Missing camp getaways and sleepovers can have a negative effect on peer relationships.[30]

EPIDEMIOLOGY AND ETIOLOGY

A total of 5 to 7 million children and adolescents in the United States suffer from nocturnal enuresis; however, with each year of maturity, the percentage of bed-wetters may decline by 15% without treatment.[29,31,32] In the enuretic population, 75% are monosymptomatic, 5% to 10% are nonmonosymptomatic, and less than 5% have an organic cause.[32] Primary enuresis is twice as common as secondary enuresis.[33] The prevalence of enuresis is as follows:

- 5 years of age: 15% to 25%
- 7 years of age: 5% to 10%
- 12 years of age: 8% (boys) and 4% (girls)
- During adolescence: 1% to 3%

The etiology of enuresis is poorly understood. A genetic link has been identified but with a discordance between enuretic genotype and phenotype.[29] Loci for enuresis are located on chromosomes 5, 12, 13, and 22. Risk factors may be familial; when both parents have a history of enuresis as children, the child's incidence is 77% as compared to 44% with one parental history.[30,33] Sleep apnea, attention deficit disorder, autism, and obesity are also associated with pediatric enuresis.[30,31] Drug-induced causes of pediatric enuresis include lithium, clozapine, risperidone, valproic acid, selective serotonin reuptake inhibitors, and theophylline. In a minority of cases, psychological factors (e.g., divorce of parents, school trauma, sexual abuse, or hospitalization) may contribute to secondary enuresis. Potentially treatable organic causes of enuresis are listed in Table 53–6.

Table 53–6

Major Potentially Treatable Organic Causes of Enuresis

Potentially Treatable by Surgery
- Ectopic ureter
- Lower UTI congenital anomalies
- Neurogenic bladder
- Bladder calculus (stone) or foreign body
- Obstructive sleep apnea

Potentially Treatable by Medications
- UTI
- Diabetes mellitus
- Diabetes insipidus
- Fecal impaction
- Constipation

UTI, urinary tract infection.

PATHOPHYSIOLOGY

Microstructural abnormalities and maturational delays of neuronal circuits have been identified in the frontal cortex of children with enuresis.[30] Physiological factors associated with pediatric enuresis include reduced bladder function and/or capacity, altered arousal to a full bladder, detrusor overactivity at night, and/or nocturnal polyuria from lack of circadian rhythm of nocturnal ADH secretion.[30]

Patient Encounter 2, Part 1

An 8-year-old girl is brought into your clinic. Her father seeks advice regarding his child's inability to stay dry for more than a few nights in a row. In the last 2 weeks, the child has also been having hard stools on defecation. Her father had a history of bedwetting as a child until 11 years of age, when it resolved. He is asking for an over-the-counter medication to help his child. The child is frustrated because she wants to have a sleepover and concerned about bedwetting. She is having a hard time keeping her grades up this year. Parents have tried giving the child more fluids at night and waking the child every hour to go to the bathroom to get her acclimated to waking up for a full bladder, which is not working. They are very eager to help their daughter.

What additional information do you need to know before creating a treatment plan for this child?

What risk factors does the child have for pediatric enuresis?

Definitions applicable to pediatric patients are helpful in discerning the etiology:[29]

- Bladder capacity: (30 mL + [30 × age in years]). Adult values of 400 mL/day may be reached in adolescence.
- Normal functional bladder capacity: Maximum voided volume greater than 70% of expected bladder capacity for age
- Nocturnal polyuria: Urine production greater than 130% of expected bladder capacity for age

TREATMENT

Desired Outcomes

- Reduction in the number of enuresis episodes and restoration of continence[28]
- Partial response: 50% to 89% reduction
- Response: 90% or more reduction
- Full response: 100% reduction or less than one symptom occurrence monthly
- Prevention of relapse (less than one symptom recurrence monthly) and maintenance of treatment success
- Continued success: No relapse in 6 months after the cessation of treatment
- Complete success: No relapse in 2 years after the cessation of treatment
- Prevention or minimization of disease complications (delay in childhood developmental milestones, adverse psychological effects on the child/caregivers)
- Minimization of adverse effects and treatment costs
- Improved quality of life of the child and caregivers

Clinical Presentation and Diagnosis: Pediatric Enuresis

General

Proper assessment of the child or adolescent with enuresis should be thorough, including the genitourinary and nervous systems. The minimum assessment should also include:[24,29,30]

- Interview of the child and parent(s), being sensitive to the emotional consequences of the enuresis.
- Direct physical examination, looking for enlarged adenoids/tonsils, bladder distention, fecal impaction, abnormal genitalia, spinal cord anomalies, and abnormal neurologic signs (look for an organic cause amenable to surgery or medications; see Table 53–6).
- Obtain urinalysis for glucose, protein, WBC, or leukocyte esterase; obtain urinalysis and urine culture if symptoms of UTI are present.
- A 7- or more day diary of wet and dry nights prior to intervention helps in monitoring the response to treatment.
- Nonmonosymptomatic enuresis may require a more extensive workup, including voiding cystourethrogram, renal and/or bladder ultrasound, urodynamics, and sleep studies.

General Approach to Treatment

Treatment is guided by patient assessment. Referral to a urologist is needed in cases of daytime wetting, abnormal voiding (e.g., unusual posturing, discomfort, straining, poor stream), history of recurrent UTIs, or abnormalities of the genitalia. Psychotherapy is recommended in cases with a psychological cause. Guidelines have been developed for the evaluation and management of nocturnal enuresis.[29,34,35] Management of primary monosymptomatic nocturnal enuresis in children may involve one or a combination of interventions. The management of secondary nocturnal enuresis focuses on addressing the underlying contributing factor. However, most children with secondary enuresis are treated in the same manner as those with primary enuresis. The National Institute for Health Care and Excellence algorithm (Figure 53–1) outlines treatment approaches based on the child's age, maturity, and abilities, and the frequency of enuresis.[35]

Initial management with education and motivational or behavioral therapy, called urotherapy (Table 53–7), is effective in 15% to 20% of patients and should be tried for 3 to 6 months.[32,36] If this fails, an enuresis alarm or pharmacologic treatment may be chosen. **KEY CONCEPT** Enuresis alarms are the most effective and lasting first-line therapy. For a faster response or in unmotivated families, desmopressin is an effective agent for the short-term control of pediatric enuresis, especially for sleepovers or camp attendance. **KEY CONCEPT** Pharmacotherapy is indicated in patients who have difficulty adhering to nonpharmacologic therapy or

ROS: (+) Nocturnal incontinence five to six nights per week; no daytime incontinence; no UTIs, urgency, frequency, dysuria, or other lower urinary track symptoms; abdomen feels full, with possible fecal impaction

PE:

VS: BP 110/70 mm Hg, P 72 beats/min, RR 16 breaths/min, T 37.0°C (98.6°F), Weight 25 kg

Resp: Clear breath sounds bilaterally

CV: Clear to auscultation, no murmurs

Abd: Slightly firm, nontender, nondistended; (+) bowel sounds; bladder not palpable

Neuro: WNL (gross sensory, motor, reflexes)

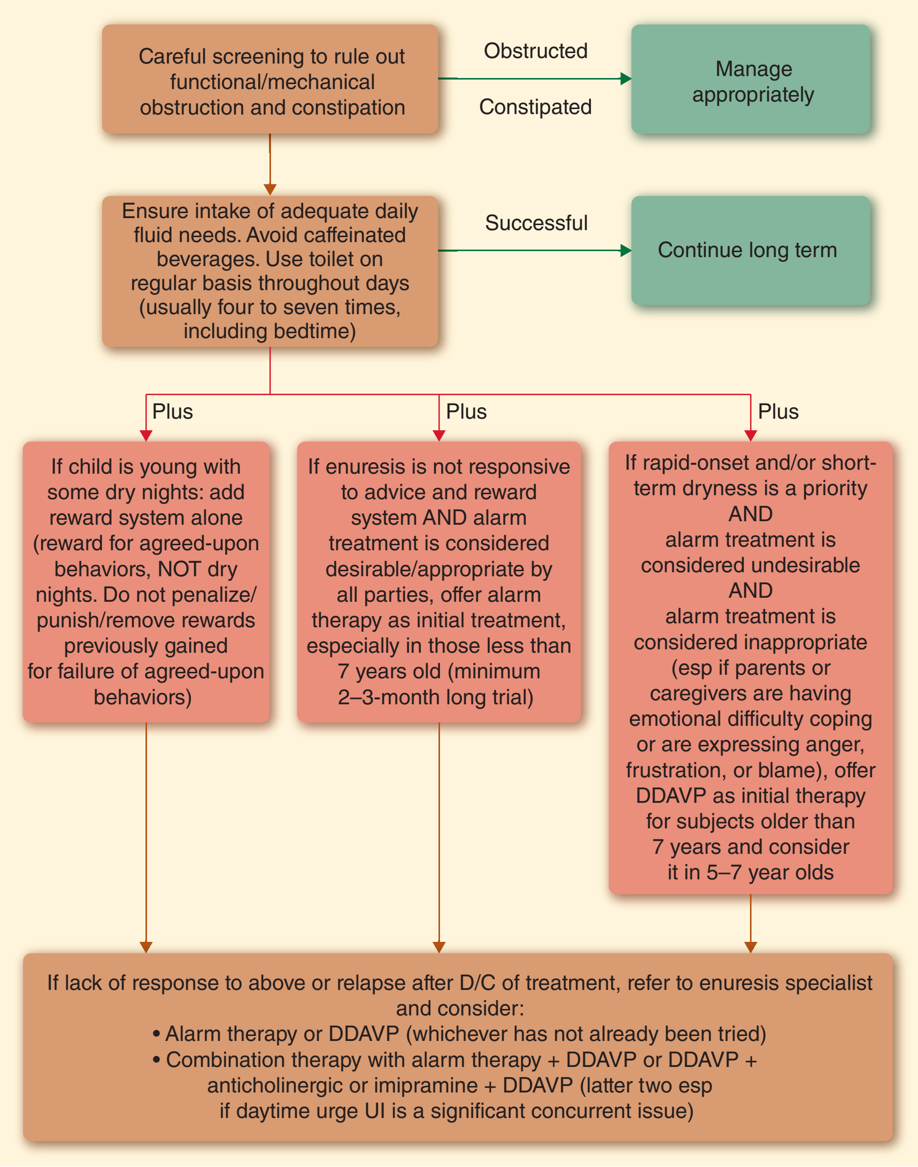
GU, Rectal: Deferred

Labs: Urinalysis WNL. Urine production: 200 mL/day while awake

Given this additional information, what is your assessment of this child's enuresis?

Identify your treatment goals for this patient.

What nonpharmacologic and pharmacologic interventions are appropriate for this child?



Careful screening to rule out functional/mechanical obstruction and constipation
Obstructed
Constipated
Manage appropriately
Ensure intake of adequate daily fluid needs. Avoid caffeinated beverages. Use toilet on regular basis throughout days (usually four to seven times, including bedtime)
Successful
Continue long term
Plus
Plus
Plus
If child is young with some dry nights: add reward system alone (reward for agreed-upon behaviors, NOT dry nights. Do not penalize/punish/remove rewards previously gained for failure of agreed-upon behaviors)
If enuresis is not responsive to advice and reward system AND alarm treatment is considered desirable/appropriate by all parties, offer alarm therapy as initial treatment, especially in those less than 7 years old (minimum 2–3-month long trial)
If rapid-onset and/or short-term dryness is a priority AND alarm treatment is considered undesirable AND alarm treatment is considered inappropriate (esp if parents or caregivers are having emotional difficulty coping or are expressing anger, frustration, or blame), offer DDAVP as initial therapy for subjects older than 7 years and consider it in 5–7 year olds
If lack of response to above or relapse after D/C of treatment, refer to enuresis specialist and consider:
• Alarm therapy or DDAVP (whichever has not already been tried)
• Combination therapy with alarm therapy + DDAVP or DDAVP + anticholinergic or imipramine + DDAVP (latter two esp if daytime urge UI is a significant concurrent issue)

FIGURE 53–1. Enuresis treatment protocol. (D/C, discontinuation; DDAVP, desmopressin; UI, urinary incontinence.) (Modified from Nunes VD, O'Flynn N, Evans J, Sawyer L; Guideline Development Group. Management of bedwetting in children and young people: summary of NICE guidance. BMJ. 2010;341:c5399.)

Table 53–7

Initial Management of Pediatric Enuresis

Education and Advice to Children and Caregivers

- Enuresis is common; it occurs at least once per week in up to 25% of 5-year-old children; enuresis resolves on its own in the majority of children.
- Enuresis is the fault of neither the child nor the caregivers; children should not be punished for bedwetting.
- Reduce the impact of bedwetting by using bed protection and washable/disposable products.
- Keep a calendar of wet and dry nights to determine the effect of interventions.
- Encourage daily fluid intake in the morning and early afternoon. Restriction of fluids in the early evening can be attempted and continued if successful.
- The child should attempt to void every 2–3 hours during the day and just before going to bed.
- Teach the child to delay urination in the daytime to increase bladder capacity.
- Avoid high-sugar and caffeine-based drinks, particularly in the evening hours.
- Encourage the child to decide whether they wish to use diapers and pull-ups.

Motivational Therapy

- Motivational therapy is a good first-line therapy for nocturnal enuresis in younger children between the ages of 5 and 7 years who do not wet the bed every night.
- Motivate the child by keeping a record of progress and giving rewards for accomplished agreed-upon behavior, such as going to the toilet before bedtime. For example, a sticker on a calendar for each night using toilet at bedtime, a book for seven consecutive, etc. Do not use penalties (ie, removal of previously gained rewards).

if desired outcomes are not achieved with nonpharmacologic therapy. A general approach to therapy selection is:[34,37,38]

1. Child with nighttime normal urine output, normal bladder capacity: either alarm or desmopressin therapy
2. Child with reduced bladder capacity or nocturnal detrusor overactivity: alarm therapy
3. Child with nocturnal polyuria, normal functional bladder capacity: desmopressin
4. Child with excessive urine output and reduced nocturnal bladder capacity: combination of alarm and desmopressin therapy or anticholinergic agents

▶ *Nonpharmacologic Treatment*

Urotherapy The goal of urotherapy is to regulate bladder emptying and storage. Education about the condition, fluid/diet modification, management of constipation, journaling, and behavioral or motivational therapy are the first steps in managing pediatric enuresis (Table 53–7).[30,33,34] Motivational therapy allows about 25% of children to achieve 14 consecutive dry nights and 70% of them achieve at least a partial response. About 5% of children experience more than two wet nights in 2 weeks. If motivational therapy fails to lead to improvement after 3 to 6 months, active interventions, such as enuresis alarms (Table 53–8) or desmopressin, may be added.[39,40]

Alarm Therapy Enuresis alarms are an established first-line therapy and indicated for motivated families and children.[29] They are the most effective way of controlling nocturnal enuresis and preventing relapses and may be used in children younger than 7 years.[41] They condition the child or caregiver to wake to the alarm sound or vibration and stop urinating until they go to the toilet. There are two kinds of alarm, one that is attached to the child and another that is placed by the bedside. Both are equally effective.[34,36] The alarm signals the child to wake enough to inhibit bladder contraction in response to the physiologic conditions present before wetting the bed completely. Enuresis alarms are curative in 60% to 80% of patients, with long-lasting effects in 55% of children.[30,31] Alarm therapy is as effective as desmopressin and more effective than TCAs and anticholinergic agents.[33,34,38,42] Enuresis alarms can be combined with pharmacotherapy in patients who are partial- or nonresponders to drug therapy alone.[42]

The advantage of this therapy is providing a real cure without adverse effects. Because alarms modify conditioning, they are slow in onset and require patience and motivation. Other disadvantages include alarm failure, inability to wake the child, disruption of caregivers and family members, and cost, since most are not covered by insurance.[34] Follow-up should be assessed 1 to 2 weeks after initiating alarm therapy to ensure caregiver understanding of the alarm. A full response, classified as a minimum of 14 consecutive dry nights, is not expected until 3 to 6 months of use.[32,38] Relapse may occur in up to one-third of cases, in which case the alarm can be reinitiated.[32,34,38] If there is no improvement with alarm therapy, alternative interventions should be considered. If enuresis persists after other interventions, alarm therapy may be tried again every 2 years regardless of initial response.[29]

Measures that have limited effectiveness include:[30,43]

- Bladder stretching exercises
- Hypnotherapy
- Dietary changes
- Allergen desensitization
- Acupuncture
- Chiropractic

▶ *Pharmacologic Therapy*

Desmopressin (DDAVP)[37,44] A synthetic analogue of arginine vasopressin, desmopressin decreases urine production by enhancing water reabsorption in the collecting tubules. It is indicated for nocturnal enuresis in children 6 years or older who do not respond to initial management (Figure 53–1), or when a fast response is needed. Desmopressin is most effective in a child with nocturnal polyuria and normal functional bladder capacity. It decreases the number of wet nights per week by about one night. About 30% of children become full responders and another 30% of children are partial responders.[29] However, 62% to 82% of them experience relapses.[30,38] Therapies for pediatric enuresis are listed in Table 53–9.

KEY CONCEPT Desmopressin is a pharmacologic first-line therapy in the management of pediatric enuresis.[29] Desmopressin is an alternative therapy to enuresis alarms. It works faster, which allows the child to attend camp or sleepovers on short notice. Oral tablets may be started at 0.2 mg (one tablet) 1 hour before

Table 53–8

Behavioral Treatments for Enuresis

Lifting	Procedure wherein the caregiver takes the child to the toilet at regular intervals during the night to urinate without fully awakening him or her may work as a short-term measure
Night awakening	Procedure wherein the caregiver fully awakens the child to void at regular intervals or randomly, used on a short-term basis
Alarm	An alarm device and a moisture-sensitive sensor are used in combination, with the sensor being placed under the sheets, or more commonly, attached to the child's pajamas or underwear near the urethra. The arousal device is usually an auditory alarm and/or a vibrating belt or pager
Overlearning	This is started at a minimum of 2 weeks after the alarm has rendered the child dry; the child drinks 500 mL (about 16 oz) during the hour before going to bed; alarm use is continued until he or she is dry for 14 consecutive nights with the extra fluid intake; is used to reduce relapse rates seen with alarm use alone
Dry-bed training	This begins with an intensive first night of training that involves increased fluid consumption, hourly awakenings, praise when the bed is dry at hourly awakenings, and, when the alarm goes off, cleanliness training (child changes wet clothes and bed linens, remakes the bed, resets the alarm); before going to bed and after each wetting, the child engages in 20 practice trials of appropriate toileting (ie, positive practice): for each practice trial, the child lies in bed, counts to 50, arises and attempts to urinate in the toilet, then returns to bed; on subsequent nights, child is woken only once, usually about 3 hours after the child has gone to bed; after a dry night, the night awakening moves up 30 minutes earlier; it is discontinued when it is scheduled to occur 1 hour after bedtime; after 7 consecutive dry nights, the alarm is discontinued, but is reinstated if two episodes of wetting occur in a 1-week period

Table 53–9

Therapies for Pediatric Enuresis

Therapy (FDA approval)	Dosage form	Dose (generic)	Advantages	Disadvantages	Adverse effects
Enuresis alarms	Sound and/or vibration		• Best response • Low relapse rates	• Requires motivation • Slow-acting	• Sleep disruption
Desmopressin (≥ 6 years of age)	Oral, tablet 0.1 mg, 0.2 mg (generic)	0.2 mg, increased to 0.4 mg (maximum 0.6 mg)	• Reduces urine volume at night • Faster acting than enuresis alarms	• Low response rate • High rate of relapse	• Water intoxication, hyponatremia, seizures
Imipramine (≥ 6 years of age)	Oral, tablet 10 mg, 25 mg, 50 mg (generic)	10 to 25 mg (maximum: 50 mg if < 12 years of age; 75 mg if > 12 years of age)	• Reduces bladder contractions • Equally effective to desmopressin	• High rate of relapse	• Cardiac conduction disturbances; myocardial depression
Anticholinergics: oxybutynin (≥ 5 years of age)	Oral, tablet 5 mg; Syrup 5 mg/mL (generic)	2.5 to 5 mg once or twice a day	• Reduces bladder contractions • Effective in patients with low functional bladder capacity	Ineffective as monotherapy, use in combination therapy	• Constipation, dry mouth
Anticholinergics: solifenacin (≥2 years of age)	Oral, suspension 5 mg/5mL (expected availability 2020)	5–10 mg once a day	• Reduces bladder contractions • Effective in patients with low functional bladder capacity	Ineffective as monotherapy, use in combination therapy, limited data in children	• Constipation, dry mouth

bedtime to reach peak effects. Effects persist for 8 to 10 hours after administration.[33] If response is not achieved in 10 to 14 days, the oral dose may be increased by 0.2 mg to a maximum dose of 0.6 mg.[34,36] If the child cannot swallow the tablet, it may be crushed and consumed with soft foods. Sublingual tablets are not approved by the FDA in pediatric patients. The intranasal formulation is no longer FDA-approved for the management of primary nocturnal enuresis due to postmarketing reports of seizures caused by hyponatremia. Desmopressin lyophilizate oral quick-melting tablets are not FDA approved but are available outside the United States. The starting lyophilizate dose is 120 to 240 mcg at night. Potential advantages of this formulation are improved bioavailability and antidiuretic effect.

Treatment response should be assessed within 1 to 2 weeks after dosage adjustments. If ineffective, desmopressin should be discontinued.[29] If effective, it can be continued for 3 to 6 months, administered nightly or as needed. When it is administered daily, desmopressin should be withheld for 1 week every 3 months to determine whether continued use is necessary.[29,37] Lack of response to desmopressin may be due to reduced nocturnal bladder capacity, daytime wetting, or suboptimal dosing. To minimize relapses, daily desmopressin should be tapered over a 2- or 4-week period, by reducing the daily dose by one-half or giving the dose every other day.[29,45]

The most serious complication of desmopressin therapy is water intoxication from dilutional hyponatremia, and seizures. This occurs most frequently with the nasal formulation. Electrolyte monitoring in patients taking the oral formulation is recommended if comorbidities may exacerbate renal or electrolyte complications. To reduce risk of hyponatremia, children should drink no more than 8 oz (240 mL) of fluid from 1 hour before to 8 hours after administration of desmopressin. During episodes of fluid and/or electrolyte imbalance (e.g., diarrhea, vomiting, vigorous exercise, fever, or dehydration), more water intake may be allowed or treatment can be interrupted.[29,31]

Diuretics play a minor role in the treatment of enuresis and are not recommended. However, in cases of poor response to desmopressin or symptom deterioration after established positive response, oral furosemide 0.5 mg/kg in the early morning may be helpful. Furosemide works by reversing the abnormal circadian rhythm of renal tubular sodium handling, which is common in individuals with enuresis.[46]

Anticholinergics Anticholinergic agents increase bladder capacity during sleep and reduce detrusor muscle overactivity. They are the primary therapy for a child with low bladder functional capacity and a second-line option in the treatment of pediatric enuresis.[29] Monotherapy is typically ineffective in monosymptomatic enuresis, so it is common to use them in combination with other therapies. Residual urine and constipation should be successfully treated before starting therapy and if enuresis resurges after an initial successful response. Several anticholinergic agents have been used for the treatment of nocturnal enuresis, including oxybutynin, solifenacin, tolterodine, and fesoterodine. Tolterodine and fesoterodine are not approved by the FDA in children.

Oxybutynin is approved in children 5 years of age and older and available in tablets and syrup (5 mg/5 mL). Initial doses of IR oxybutynin are 2.5 to 5 mg orally.[29] Doses are administered 1 hour before bedtime. In a child who has concomitant daytime incontinence, oxybutynin may be administered two or three times a day. Maximal therapeutic effects occur within 2 months. If the response is not optimal and the patient is not experiencing adverse effects, either oxybutynin dose may be increased or desmopressin may be added.[29,34,36] If response is achieved, medications are discontinued gradually every 3 months.[29] Children should be monitored for potential adverse events, such as urinary retention (may lead to UTIs), constipation (worsens urinary tract dysfunction), tachycardia, blurred vision, behavioral changes, and dry mouth (can lead to dental caries).

Solifenacin was recently approved by the FDA in children aged 2 years and older for neurogenic detrusor overactivity. It is available as an oral suspension administered once daily. Doses range from 2.5 to 10 mg orally 1 hour before bedtime. Adverse effects are similar to those reported with oxybutynin. In addition, QT prolongations and anaphylaxis have been reported with solifenacin.

Tricyclic Antidepressants Imipramine was first used to treat enuresis in the 1960s. It is FDA-approved for pediatric enuresis for children aged 6 years and older but is considered a third-line pharmacotherapy option for monosymptomatic enuresis.[29] TCAs are as effective as desmopressin but are associated with more adverse reactions.[34,38] Their place in therapy is in a child who has failed an alarm, desmopressin, and anticholinergic therapies. Mechanisms of action include anticholinergic and antispasmodic effects, relaxing detrusor muscle, elevating plasma ADH concentrations, and lowering arousal threshold.[31,33] Although trials involving other TCAs have been performed, there is insufficient evidence to assess their efficacy compared with imipramine.

Response to imipramine, defined as one less wet night per week, is expected in 50% of children.[29] However, relapse rates are up to 67%.[30] The usual initial dose is 10 to 25 mg at bedtime which may be increased if there is no response after 1 week. The usual dose is 25 to 50 mg orally once daily, 1 hour before bedtime.[29,34] The dose should not exceed 50 mg in children 6 to 12 years old and 75 mg in children 12 or older. After 1 month of successful response, the dose should be reduced to the lowest effective amount. As the patient continues the therapy, the medication may be discontinued for 2 weeks every 3 months to reduce drug tolerance and reevaluate necessity of drug therapy.[34] When discontinuing imipramine, the dose should be reduced gradually by 50% over 1 to 2 weeks.[29]

About 25% of children treated with TCAs experience gastrointestinal symptoms. Neurologic adverse effects including nervousness, personality change, or sleep disturbances occur in approximately 5% of patients. Clinicians should monitor for increased suicidality, particularly in children and young adults with preexisting depressive symptoms.[31]

Other serious adverse effects of TCAs include cardiac conduction disturbances, QT prolongation, and myocardial depression, particularly in cases of overdose. A history of syncope or palpitations in the child or family history of sudden cardiac death may preclude the use of TCAs unless cleared by a pediatric cardiologist. Safer options should be considered before starting any TCA for pediatric enuresis.

Combination Therapies In children who fail to respond to one therapy or who have frequent relapses, combinations of urotherapy, imipramine, oxybutynin, desmopressin, and/or alarm therapy can improve response.[30,31] In a child with small bladder volume and refractory enuresis, combination therapy with desmopressin and anticholinergic agents is more effective than desmopressin alone. The combination of alarm and desmopressin is not useful in the long-term.[34,44] Imipramine in combination with oxybutynin was shown to be more effective than imipramine monotherapy.[47] Imipramine and desmopressin therapy was as effective as imipramine alone but more effective than desmopressin alone.[47,48]

Other Drugs Other medications, including indomethacin, phenmetrazine, sertraline, amphetamine sulfate, ephedrine, atropine, furosemide, diclofenac, aripirazole, clonidine, and chlorprothixene, have been used. Data suggest that indomethacin, diclofenac, and diazepam are superior to placebo, but not better than desmopressin.[49] Current guidelines do not recommend any of these agents for pediatric enuresis.

▶ *Comparison of Therapies*

Multiple meta-analyses have compared treatments for enuresis, although most trials enrolled a small number of subjects and were of poor methodological quality.[47,49] Overall, enuresis alarms are the most effective treatment method from the standpoint of effectiveness and reduced relapse rate. The initial rate for success (less than one wet night per month) is 66%, with 55% long-term success rate after discontinuation. Alarm therapy is as effective as desmopressin but has significantly lower relapse rates (46% vs 60%–70% for desmopressin).[33,34,38] Combining enuresis alarms and other complex behavioral therapy further reduces relapse rates. However, the data are inadequate to compare various commercial brands of alarms available.

▶ *Treatment of Relapse*

A relapse is defined as more than one wet night per month after a period of dryness.[33] When it occurs, clinicians should consider reinitiation of the intervention which was previously effective (Figure 53–1). For children with multiple recurrences after discontinuation of desmopressin, gradual dose tapering of desmopressin may be helpful. For relapse following successful treatment with alarm therapy, adding desmopressin may be effective.[35] Management of therapy-resistant monosymptomatic nocturnal enuresis may include periodic new trials of the enuresis alarm with or without desmopressin, desmopressin alone, or a trial of imipramine, or a combination therapy that includes oxybutynin.[30]

Nonresponders experience less than 50% improvement in symptoms despite active interventions.[28] When motivated children and families do not respond to at least a 3-month trial of enuresis alarm and/or desmopressin, referral to a specialist (e.g., developmental-behavioral pediatrician, pediatric urologist) may be warranted.[30]

OUTCOME EVALUATION

- Monitor the patient for symptom relief in 2 weeks, 1 month, and every 3 months until symptom resolution. Has the treatment plan achieved the desired outcomes developed by the healthcare team, the patient, and parents/guardians? If so, to what degree?
- Evaluate the diary completed by the patient or parents/guardians since the last clinic visit and quantify the clinical response (number of dry nights per week, number of nights with two or more enuresis episodes, etc). If a diary has not been kept, elicit from the patient and caregiver the clinical response since last visit. Consider dosage modification or alternative therapy depending on patient response and adverse effects of therapy.
- Elicit adverse events of therapy, including severity, using a nonleading manner. Ask the patient or parents/guardians

Patient Encounter 2, Part 3

Based on the information available, develop a care plan for this patient's enuresis. Your plan should include:

(a) A statement about the drug-related needs and/or problems

(b) A patient-specific detailed therapeutic plan

(c) Monitoring parameters to assess efficacy and safety

Patient Care Process: Pediatric Enuresis

Collect Information:

- Identify urinary symptoms, exacerbating factors, and family issues.
- Review medical history.
- Obtain a thorough medication history, including use of prescription, nonprescription, and complementary/alternative drug products.

Assess the Information:

- Determine whether the enuresis is due to secondary causes. Assess whether there are any exacerbating factors or enuresis-related complications.
- Are there any potentially treatable organic or drug-induced causes of enuresis (Table 53–6)? Assess parental motivation when attempting nonpharmacologic approaches.
- Could patient's medical/medication history contribute to enuresis (Table 53–6)? Determine which, if any, treatments in the past have helped.

Develop a Care Plan:

- Establish realistic treatment goals with the involvement of the child and caregiver.
- If patient is already receiving nonpharmacological interventions and/or drug therapy, assess treatment choice, drug dosing, efficacy, adverse effects, adherence, etc.
- Have the child and caregiver given the current treatment plan an adequate duration of trial? How is the child responding to the current treatment plan?
- Patient-specific detailed therapeutic plan for therapies for pediatric enuresis (Table 53–9).

Implement the Care Plan:

- Educate the patient and/or caregiver on pediatric enuresis, urotherapy, and motivational therapy (Table 53–7). The patient and/or caregiver should be offered behavioral therapy and/or enuresis alarm with proper education using the "teach back" method (Table 53–8).
- Provide the patient and/or caregiver with education regarding drug therapy (timing of drug administration, adverse effects, potential drug–drug interactions, etc).

Follow-up: Monitor and Evaluate:

- Evaluate the patient for adverse events, allergies, and interactions (drug–drug and drug–disease) and adherence.
- Evaluate treatment response in 1 to 2 weeks after therapy initiation. Adjust medication dosing if needed.
- Allow at least 3 months to assess efficacy of treatment.
- Identify expected adverse effects and educate regarding avoidance and management of these adverse effects.

what measures, if any, were used to alleviate adverse effects. Assess therapy adherence.

- The balance of clinical response, tolerability, and burden on the caregiver will determine the management approach. As most nonpharmacologic approaches are "all or none" and drug titration is limited by the maximum recommended dose, clinicians may consider changing therapy if clinical results are inadequate.
- Refer patients with refractory enuresis to a healthcare professional who specializes in the management of bedwetting.

Abbreviations Introduced in This Chapter

ADH	Antidiuretic hormone
BPH	Benign prostatic hyperplasia
CYP	Cytochrome P450
DDAVP	Desmopressin
ER	Extended release
IR	Immediate release
MUI	Mixed urinary incontinence
OAB	Overactive bladder
OUI	Overflow urinary incontinence
PFMR	Pelvic floor muscle rehabilitation
PVR	Postvoid residual
SUI	Stress urinary incontinence
TCA	Tricyclic antidepressant
UI	Urinary incontinence
UTI	Urinary tract infection
UUI	Urge urinary incontinence

Drug Hypersensitivity Reactions

J. Russell May, Dixie D. Griffin, and Kathleen May

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the potential incidence of immunoglobulin-E (IgE)- and non-IgE-mediated (immune and nonimmune) drug hypersensitivity reactions and why it is difficult to obtain accurate estimates.
2. Understand the Gell and Coombs categories of immunologic reactions and more recently described immunologic mechanisms.
3. Identify the classes of drugs most commonly associated with IgE- and non–IgE-mediated drug hypersensitivity reactions.
4. Recommend specific treatment for anaphylaxis.
5. Recommend an approach to drug selection in patients with multiple drug sensitivities.
6. Understand the utility of drug challenge and desensitization procedures.

INTRODUCTION

Drug hypersensitivity reactions collectively encompass immunoglobulin E (IgE)- and non–IgE-mediated (immune and nonimmune, previously "pseudoallergic") drug hypersensitivity reactions. These reactions are rarely confirmed by testing and are subject to both overreporting and underreporting, making statistical analysis imprecise. KEY CONCEPT Approximately 5% to 10% of adverse drug reactions occur on an allergic or immunologic basis. However, these represent a disproportionate 24% of reported adverse drug reactions in hospitalized patients and are costly, with accompanying morbidity and mortality.[1,2] Between 10% and 20% of hospital inpatients experience drug adverse events versus 7% in the general population, with about one-third possibly due to hypersensitivity; however, many such reactions may not be reported, especially in pediatrics.[1,3,4] Costs of inpatient drug hypersensitivity reactions (in US dollars) are estimated at up to $600 million annually in 2002, which equates to at least $850 million in 2020.[5] Financial burden calculations include indirect costs: time and lost labor, use of more expensive alternative medications, and treatment failures, in addition to direct reaction treatment costs. Accurate data regarding outpatient reaction rates are even more elusive. The term "drug allergy" in a patient record/electronic medical record (EMR) often conveys little medical meaning, as such information is self-reported, and may not delineate symptoms or incorporate provider assessment of probable causality (eg, adverse effect vs IgE-mediated). Potential clinical outcomes might therefore range from inappropriately excessive treatment to lack of recognition of anaphylaxis risk. Clearly, an understanding of mechanisms of drug hypersensitivity reactions and how these might be accurately identified, documented, managed, and ideally prevented is of vital importance.

PATHOPHYSIOLOGY

Drug hypersensitivity reactions are a result of diverse mechanisms of immune recognition and activation, resulting in a broad array of clinical findings. The fundamental Gell and Coombs classification, used for decades, remains a framework for considering mechanisms of immunologic drug reactions (Table 54–1).[6,7]

With advances in immunologic understanding, the underlying mechanisms for many drug hypersensitivity reactions have been found to be more complex and interrelated than suggested by the Gell and Coombs classification.[8] Yet, this classification remains the most commonly used initial method to describe drug hypersensitivity reactions. KEY CONCEPT Immediate or type I reactions describe classic allergic reactions mediated by drug-specific IgE antibodies; type II reactions are cytotoxic reactions mediated by drug-specific IgG or IgM antibodies; type III reactions result from deposition of immune complexes circulating in the serum; and type IV reactions are mediated by diverse cellular mechanisms and may be further subcharacterized by specific effector cell.[9]

Immune Mechanisms

The cellular immune mechanisms involved in drug hypersensitivity are notably complex.[10] The immune system must first recognize nonself material (antigens). This recognition is predominantly controlled by T lymphocytes. Two distinct signals are typically required for T-cell activation, namely, the presentation of a foreign substance by an antigen presenting cell (APC) to the T-cell with a concomitant second activation signal. If the second signal is not provided, the T-cell becomes nonresponsive or anergic. Thus, the second signal controls whether a T-cell immune response will occur.

Dependent on antigen exposures and the specific cytokines (immune chemical messengers) involved in activation, naïve

Table 54–1

Reaction Classification, Clinical Symptoms, and Potential Causative Drugs[6,7]

Gell and Coombs Classification	Immune Response	Clinical Symptoms	Potential Causative Drugs[a]
Type I	IgE	Anaphylaxis, urticaria	β-Lactam antibiotics: penicillins (primarily), cephalosporins, carbapenems Non–β-lactam antibiotics: sulfonamides, vancomycin Others: insulins, heparin
Type II	IgG	Hemolytic anemia, thrombocytopenia	Quinidine, methyldopa, penicillins, heparin
Type III	IgG, IgM	Vasculitis, serum sickness, lupus	Penicillins, sulfonamides, radiocontrast agents, phenytoin, minocycline
Type IV			β-Lactam antibiotics, sulfonamides, phenytoin
Iva	Th1 cytokines	Tuberculin reaction eczema	See text for examples
IVb[b]	Th2 cytokines	Maculopapular and bullous exanthema	
IVc[b]	Cytotoxic T cells (CD4 and CD8)	Same as IVb, also eczema, pustular exanthema	
IVd	T-cells (IL-8)	Pustular exanthema	

[a] These drugs represent a list of causative agents. Many drugs can cause these reactions.

[b] IVb and IVc reactions may combine to produce erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis.

Ig, immunoglobulin; IL, interleukin; Th, T-helper cell.

T-helper cells (CD4+ T-cells) can differentiate into disparate specialized effector T-helper cell groups. Each of these groups possesses a unique regulatory element, pattern of cytokine production, and function. Type 1 effector T-helper cells (Th1) are associated with T-cell recruitment of phagocytic cells, via cytokines such as interferon-gamma (IFNγ), and activation of B-cells to produce IgG antibody. Th1 responses can cause delayed hypersensitivity reactions (type IV Gell-Coombs); notably, this is the same mechanism for a positive purified protein derivative (PPD) test indicating tuberculosis. Th2-immune responses induce IgE production from B-cells yielding an immediate allergic reaction (type I Gell-Coombs) or can increase tissue eosinophils, causing a type of delayed hypersensitivity. In type I reactions, specific IgE antibody is produced in response to an antigen (in allergic reactions, "allergen") causing membrane-binding of that IgE to mast cells. Upon antigen (allergen) reexposure, crosslinking of IgE occurs on mast cells resulting in rapid and massive release of preformed mediators including histamine (H). More recently described T-helper-effector cell subtypes including Th22 may be responsible for certain inflammatory patterns seen in drug hypersensitivity.[11]

Drugs as Antigens

Many drugs are small molecules not normally recognized as antigens. As a result, there are several models explaining how drugs might elicit an immune response.[10] The first one widely accepted was the hapten mechanism, in which the drug becomes covalently bound to a normal "self" protein. This drug–protein conjugate becomes large enough to be recognized as foreign, yielding an immune response in susceptible people.[10] The related pro-hapten mechanism involves a nonreactive drug becoming chemically reactive during metabolism and then covalently binding to self-proteins. An example of this is sulfamethoxazole metabolism to sulfamethoxazole-nitroso, the latter being highly reactive. Thirdly, a drug (or metabolite) can directly bind to the T-cell receptor, initiating a pharmacologic interaction immune response, or *p-i* mechanism. In this case, T-cells are activated directly without an APC, bypassing usual signaling requirements.

The location of drug metabolism often plays a critical role in the reaction seen in an organ or organ system. The fact that many drugs are primarily hepatically metabolized helps explain why the liver is frequently involved in drug hypersensitivity reactions. Skin, via keratinocytes, is increasingly recognized as a site of drug metabolism. This may also help explain the skin involvement common to many forms of reactions elicited by different drugs.[12] Some of the most common life-threatening drug reactions are predominantly cutaneous, including Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), and drug reaction with eosinophilia and systemic symptoms (DRESS) or drug-induced hypersensitivity syndrome (DIHS).[13]

Nonimmune (Non-IgE) Drug Reactions

KEY CONCEPT Reactions occur that clinically resemble IgE-mediated or immune drug reactions but lack an immune basis, previously called "pseudoallergic" "anaphylactoid." These reactions include the entire spectrum of clinical severity, but occur via other, less well understood mechanisms.

Nonimmune drug hypersensitivity reactions are important in counseling and management considerations. They represent common nonspecific occurrences such as direct histamine release by vancomycin or opiates, whereas immunologic (or IgE-mediated) reactions are based on drug structure and the immune system. Even a history of mild IgE-triggered symptoms to a drug may portend risk of anaphylaxis on readministration. In contrast, nonimmune drug reactions tend to remain constant, whether mild or severe, and are dose-related. Ionic radiocontrast media administration, as a classic example, can consistently cause urticaria in some and life-threatening hypotension in others.

Nonimmune drug hypersensitivity reactions, then, are reactions where the components of the immune system react similarly, but without the "learning" response by T-cells and generally without the much greater danger that true immunologic sensitization implies. Indicators of immune activation are not observed with such reactions but direct release of preformed mediators from mast cells occurs, via a recently identified G coupled protein regulator.[14] A prototypical example is seen with vancomycin infusion. Pruritus and an erythematous rash involving the face, neck, and upper torso (referred to as vancomycin flushing) are commonly associated with vancomycin infusions administered over less than 1 hour, previously known as a "red man" reaction.[15]

Clinical Presentation and Diagnosis of IgE-mediated and Other Immune Drug Reactions

Reaction	Mediators Involved	Signs and Symptoms
Anaphylaxis	IgE-driven reaction resulting in mast cell degranulation and histamine release.	Skin (eg, pruritus, urticaria), respiratory tract (eg, dyspnea, wheezing), gastrointestinal tract (eg, nausea, cramping), and cardiovascular system (eg, hypotension, tachycardia)
Note: Onset is usually within 30 minutes, but can be 2 hours or more. Treatment must begin immediately. Anaphylaxis may recur 6 to 8 hours after initial exposure, warranting observation for up to 12 hours.		
Cytotoxic Reactions	Drug-specific IgG or IgM antibodies	Hemolytic anemia, thrombocytopenia, granulocytopenia, or agranulocytosis
Immune Complex Reactions	IgG, IgM deposition	Serum sickness-like syndrome (eg, arthralgias, fever, malaise, and urticaria) that typically develops 7 to 14 days after exposure to the causative antigen
Dermatologic Reactions	IgE or cellular mechanisms (see Table 54–1)	See below for dermatologic reaction types

- *Urticaria*: These are itchy, raised, swollen areas on the skin; also known as hives.
- *Maculopapular rash*: A rash that contains both macules and papules. A macule is a flat, discolored area of the skin, and a papule is a small raised bump. A maculopapular rash is usually a large area that is red and has small bumps.
- *Erythema multiforme*: A rash characterized by papular (small raised bump) or vesicular (blister) lesions and reddening or discoloration of the skin, often in concentric zones about the lesion.
- *Stevens-Johnson syndrome*: A severe expression of erythema multiforme (known as erythema multiforme major). It typically involves the skin and mucous membranes, with the potential for severe morbidity and even death.
- *Toxic epidermal necrolysis*: A life-threatening skin disorder characterized by blistering and peeling of the top layer of skin.

PROBLEMATIC DRUG CLASSES AND TREATMENT OPTIONS

The first priority is to avoid doing serious harm by administering a drug the patient cannot tolerate. One can frequently establish the likelihood of a relationship between the suspected drug and observed reaction, and also whether it is likely to be an immune or idiopathic event, by objectively reviewing the time course and specific signs and symptoms. Associated physical findings and available laboratory values in the context of preexisting diseases may further clarify the need to change treatments and treat the reaction.

Table 54–2

Problematic Drug Classes

β-Lactam antibiotics
Sulfonamide antibiotics
Aspirin and nonsteroidal anti-inflammatory drugs
Radiocontrast media
Opiates
Cancer chemotherapy
Anticonvulsants

Reviewing the original indications for the treatment that caused the reaction is important. If definitive indications for treatment are established, options must be evaluated including adjusting the dose or administration rate, finding an effective and unrelated alternative, or desensitizing the patient to the original drug.

When adverse drug reactions occur, all aspects of the reaction and the potential for it to recur should be carefully evaluated. The term "drug allergy" is often associated with anaphylaxis, potentially increasing patient anxiety. Thus, a label of drug allergy may hamper future medical care, with treatment refusals, nonadherence to therapy, or resultant use of more toxic or less effective alternative treatments. When the original reaction is clearly documented, healthcare providers can appropriately counsel patients about risk.

Anaphylaxis is a true medical emergency and must be treated immediately. Otherwise, managing drug reactions begins with holding the offending agent and considering alternative options. Understanding risk of an allergic reaction and potential for cross-allergenicity between similar drugs is critical to decision making. Desensitization (discussed later in the chapter) is a management option for certain IgE-mediated drug reactions if there is a definitive indication and alternative therapies are not available. Although any agent may cause an allergic (IgE-mediated), immune or nonimmune (pseudoallergic) reaction, several drugs and drug classes are strongly associated with such reactions (Table 54–2). These classes will be discussed individually.

β-Lactam Antibiotics

Hypersensitivity reactions with β-lactam antibiotics, especially penicillin, may encompass any of the types I through IV Gell-Coombs classifications. The most common reactions are maculopapular and urticarial eruptions.[16] Although rare (< 0.05%), anaphylactic reactions to penicillins cause the greatest concern, because they are responsible for the majority of all drug-induced anaphylaxis deaths in patients, accounting for 75% of all anaphylaxis cases in the United States.[6,17] The treatment of anaphylaxis is given in Table 54–3.[18,19]

The healthcare professional is faced with a difficult task when approaching a patient who notes a history of penicillin allergy. Although as many as 12% of hospitalized patients report an allergy to penicillin, about 90% will have negative penicillin skin tests.[20] Penicillin skin testing has been successful as an antimicrobial stewardship initiative resulting in a reduction of carbapenems, aztreonam, vancomycin, and other broad spectrum agents used.[21]

KEY CONCEPT Penicillins and cephalosporins both have a β-lactam ring joined to an S-containing ring structure (penicillins: a thiazolidine ring; cephalosporins: a dihydrothiazine ring). The extent

Table 54–3

Pharmacologic Management of Anaphylactic Reactions[18,19]

Immediate Intervention

Epinephrine 1:1000 (1 mg/mL)
- Adults: 0.3–0.5 mg IM, repeat every 5 to 15 minutes as needed
- Pediatrics: 0.01 mg/kg (maximum 0.3 mg) IM, repeat every 5–15 minutes as needed

Subsequent Interventions

Normal saline infusion
- Adults: 1–2 L at a rate of 5–10 mL/kg in the first 5 minutes, followed by slow infusion
- Pediatrics: up to 30 mL/kg in the first hour

Epinephrine infusion

If patient is NOT responding to epinephrine injections and volume resuscitation:
- Adults: epinephrine infusion (1 mg in 250 mL D_5W): 1–4 mcg/min, titrating based on clinical response or side effects
- Pediatrics: epinephrine infusion (0.6 × body weight [in kg] = number of mg diluted to a total of 100 mL normal saline: 1 mL/hour delivers 0.1 mcg/kg/min)

Other Considerations after Epinephrine and Fluids

Diphenhydramine
- Adults: 25–50 mg IV or IM
- Pediatrics: 1–1.25 mg/kg (maximum of 300 mg/24 hours)

Famotidine
- Adults: 20 mg IV over 2 minutes
- Pediatrics: 0.25 mg/kg, (maximum 20 mg/dose) IV over 2 minutes

Inhaled β-agonist (bronchospasm resistant to epinephrine)
- 2.5–5 mg in 3 mL of normal saline, nebulized, repeat as needed

Dopamine (hypotension refractory to fluids and epinephrine)
- 2–20 mcg/kg/min titrated to maintain systolic blood pressure > 90 mm Hg

Hydrocortisone (severe or prolonged anaphylaxis)
- Adults: 250 mg IV (prednisone 20 mg can be given orally in mild cases)
- Pediatrics: 2.5–10 mg/kg/24 hours

D_5W, dextrose 5% in water; IM, intramuscularly; IV, intravenous.

Adapted from Lieberman P, Nicklas RA, Oppenheimer J, et al. The diagnosis and management of anaphylaxis practice parameter: 2010 update. J Allergy Clin Immunol. 2010;126:477–480 and LoVerde D, Iweala O, Enginli A, et al. Anaphylaxis. Chest. 2018;153:528–543.

Patient Encounter 1

A 65-year-old man is admitted to the hospital with a skin infection. When asking about allergies, the patient states he believes he is allergic to penicillin. When questioned further, the patient cannot remember the type of reaction but was told by his mother 50 years ago that he was allergic to penicillin. Because of this history, the physician wants to use meropenem to treat the infection instead of nafcillin. The staphylococcus causing the infection is susceptible to both. The patient doesn't remember if he has received penicillin since his youth.

How might this patient be managed at present?

Once steps have been taken to confirm the allergy status, what should be noted in the patient's medication reaction history?

of cross-allergenicity appears to be relatively low, with an estimate of approximately 2%.[22] Cross-allergenicity is less likely with newer generation cephalosporins compared with the first-generation agents. Anaphylactic reactions to cephalosporins are rare, with a predicted range of 0.0001% to 0.1%. Minor skin reactions including urticaria, exanthems, and pruritus are the most common allergic reactions with cephalosporins, showing severe reactions less often than with penicillins.[23]

For other β-lactam agents, the recommendations are fairly straightforward. Carbapenems should be considered potentially cross-reactive with penicillins and used with caution.[24] Monobactams (eg, aztreonam) do not cross-react with any β-lactam drugs except ceftazidime because they share an identical R-group side chain. Other cephalosporins sharing identical R-group specific side chains share cross-reactivity as well.

Sulfonamide Antibiotics

Sulfonamides are compounds that contain a sulfonamide moiety (ie, SO_2NH_2). This group includes sulfonamide antibiotics (sulfonylarylamines), and nonarylamine sulfonamides such as furosemide, thiazide diuretics, sulfonylureas, and celecoxib. The sulfonamide antibiotics contain an aromatic amine at the N4 position and a substituted ring at the N1 position. Newer evidence suggests that most patients allergic to antimicrobial sulfonamides will tolerate nonarylamine sulfonamides.[25] Predisposition to allergic reactions is a more likely reason for dual sensitivity than cross-reactivity between these differing molecules.[26] The term "sulfa allergy" should not be used as it can be confusing to patients and healthcare providers. The sulfonamide antibiotics are significant because they account for the largest percentage of antibiotic-induced TEN and SJS cases.[27]

KEY CONCEPT Reactions to sulfonamide antibiotics, ranging from mild (most common) to life-threatening (rare), occur in 2% to 4% of healthy patients, with rates as high as 65% in patients with acquired immunodeficiency syndrome (AIDS).[28] Anaphylaxis or nonimmune anaphylactoid reactions almost always occur within 30 minutes but may happen up to 90 minutes after exposure, most commonly after parenteral administration. Isolated angioedema or urticaria can occur within minutes to days. Serum sickness occurs within 1 to 2 weeks. Fixed drug eruptions (lesions) occur within 30 minutes to 8 hours. These lesions resolve within 2 to 3 weeks after drug removal. The more severe conditions of SJS and TEN tend to occur 1 to 2 weeks after initiation of therapy. Because trimethoprim-sulfamethoxazole is the drug of choice for patients with *Pneumocystis jiroveci* pneumonia, desensitization may be necessary. A history of SJS or TEN is an absolute contraindication for the desensitization procedure.

Patients With Multiple Antibiotic Allergies

Addressing a history of multiple antibiotic reactions can be challenging. Combining knowledge of cross-allergenicity with a careful assessment of specific history may be helpful in designing an antimicrobial regimen. Table 54–4 outlines a series of questions that can be useful in treatment planning.[29] If available and indicated, drug challenge (discussed later in the chapter) or allergy skin testing may help complete the puzzle and often may allow use of an antibiotic of choice when the patient's initial history might have precluded it. Based on data gathered, the patient's record should reflect antibiotics safe to use, those to be avoided, and antibiotics requiring desensitization. Although Table 54–4 was designed with antibiotics in mind, it can be modified for other multiple drug allergy situations.

Table 54–4

Multiple Antibiotic Allergies: Obtaining Background Information[29]

For **each** antibiotic to which the patient claims to be allergic, gather the following information:

- What type of infection was being treated?
- Have you ever received the drug without experiencing a reaction?
- How many times have you received the drug and experienced a reaction?
- What was the drug dose and route of administration with the last reaction?
- How many doses did you take before the onset of the last reaction?
- How many doses did you take after the last reaction?
- Can you describe the adverse reaction?
- What was the duration of the reaction?
- What treatment was given for the reaction?
- Was there any permanent damage?

For **each** antibiotic the patient has received and does not claim allergy, gather the following information:

- What was the last type of infection being treated?
- What was the drug dose and route of administration?
- Have you received this drug more than once without reactions?

Other information to be gathered:

- Have you had adverse reactions to any other drugs? If so, give dates and describe the reaction.
- Document any risk factors for allergic reactions such as chronic urticaria, liver or kidney disease, HIV (human immunodeficiency virus), or any other immune deficiencies.

Adapted from Macy E. Multiple antibiotic allergy syndrome. Immunol Allergy Clin North Am. 2004;24:533–543.

Aspirin and Nonsteroidal Anti-Inflammatory Drugs

Aspirin and the nonsteroidal anti-inflammatory drugs (NSAIDs) can induce allergic and nonallergic reactions. Because these drugs are so widely used and over-the-counter, the healthcare professional must have a basic understanding of the types of reactions that can occur and how to prevent them. Three general types of reactions occur: bronchospasm with rhinoconjunctivitis, urticaria/angioedema, and anaphylaxis. Those with gastric discomfort or bruising from these agents may also inappropriately describe themselves as being "allergic."

Two specific nonallergic/non-IgE–mediated conditions—aspirin-exacerbated respiratory disease (AERD) and chronic idiopathic urticaria (CIU)—are important because they are commonly seen. AERD may include asthma, rhinitis with nasal polyps, and aspirin sensitivity.[30] Upon exposure to aspirin or NSAID, patients with AERD experience rhinorrhea, nasal congestion, conjunctivitis, laryngospasm, and bronchospasm/asthma. CIU exacerbations with aspirin/cyclooxygenase (COX)-1 inhibiting NSAID are characterized by worsening urticaria or angioedema following administration.[31] Cross-reactivity between aspirin and older COX-1 inhibiting NSAIDs exists in those with either AERD or CIU. Despite COX-2 inhibitor NSAID product warnings contraindicating use in these conditions, there are no reports of cross-reactivity in AERD and only rare reports in CIU.[32]

KEY CONCEPT IgE-mediated urticarial/angioedema reactions and anaphylaxis are associated with aspirin and NSAIDs. Urticaria is the most common form of an IgE-mediated reaction. However, most reactions are the result of metabolic idiosyncrasies, such as AERD, which may produce severe and even fatal bronchospasm. This class is second only to β-lactams in causing anaphylaxis. Most reactions in this class are nonallergic/non-IgE–mediated and instead are due to a complex metabolic pattern, which causes increasingly recurrent and severe nasal polyps and often refractory asthma. The metabolic problem is constant once it emerges, accounting for the persistence and difficulty of these clinical problems. The same metabolic process is also capable of causing severe, sometimes fatal, acute reactions to aspirin, and many, if not all, other NSAIDs. Rare reports of non–cross-reactive severe reactions suggest possible specific IgE-mediated reactions to individual NSAIDs, and there are some occurrences of urticaria related to specific NSAIDs as well. Because aspirin therapy is highly beneficial in coronary artery disease (CAD), aspirin desensitization should be considered in select patients. Aspirin single dose or graded drug challenges can be considered for patients with vague histories or those with adverse effects mischaracterized as drug allergy. Desensitization is contraindicated in patients who have experienced aspirin-induced (nonallergic) anaphylaxis, hypotension, tachypnea, or altered consciousness. Alternate agents must be used. A comprehensive approach to aspirin-sensitive patients with CAD has been described.[33]

Radiocontrast Media

KEY CONCEPT Radiocontrast media may cause serious, immediate nonimmune hypersensitivity reactions, such as urticaria/angioedema, bronchospasm, shock, and death. These reactions have been reduced with the introduction of nonionic, lower osmolality products. Because a small percentage of patients who have reacted previously to radiocontrast media will react if reexposed, several preventive steps (listed below) should be taken. These steps should also be followed in those with known risk factors: asthma, β-blocker use, and cardiovascular disease.[5] The steps are as follows:

- Determine whether the study is essential.
- Be sure the patient understands the risks.
- Ensure adequate hydration.
- Use nonionic, lower osmolar agents.
- Typical protocols include pretreatment with prednisone 50 mg orally 13, 7, and 1 hour(s) before the procedure and diphenhydramine 50 mg orally 1 hour before the procedure.

Reactions with nonionic radiocontrast media occur in 0.7% to 3% of patients.[34] Although reactions are occasionally severe, most are mild and manifest as maculopapular rashes, fixed eruptions, erythema multiforme, and urticarial eruptions.

Patient Encounter 2

A 17-year-old male is hospitalized for cellulitis that failed outpatient treatment with clindamycin. He is started on vancomycin. Five minutes into the infusion he complains of itching. When evaluated by his nurse, he has significant flushing in his face and torso without additional symptoms.

What kind of reaction did the patient experience with vancomycin?

Could vancomycin be used for treatment of this current infection? Discuss rationale.

Opiates

KEY CONCEPT Opiates (morphine, meperidine, codeine, hydrocodone, and others) stimulate mast cell mediator release directly, resulting in pruritus and urticaria with occasional mild wheezing. Though these reactions are not IgE-mediated, many patients state they are "allergic" to one or more of the opiates. Pretreatment with an antihistamine may reduce these reactions which are rarely, if ever, life-threatening.[6] Avoiding other mast cell degranulating medications while patients require opiates also reduces the chances of frightening and uncomfortable reactions. Patients may also commonly state they are "allergic" if they have experienced gastrointestinal upset or constipation with opiates. Obtaining a thorough history from the patient will prove useful. If a more serious reaction has occurred, a nonnarcotic analgesic should be selected.

Cancer Chemotherapy

Hypersensitivity reactions have occurred with all chemotherapy agents. Reactions are most common with the taxanes, platinum compounds, asparaginases, and epipodophyllotoxins.[16] Reactions range from mild (flushing and rashes) to severe (dyspnea, bronchospasm, urticaria, and hypotension). IgE-mediated type I reactions are the most common. To reduce the risk, patients are routinely premedicated with corticosteroids and H_1- and H_2-receptor antagonists. The platinum compounds have produced anemia, probably via a cytotoxic immunologic mechanism.

Anticonvulsants

A wide range of hypersensitivity reactions, ranging from mild maculopapular skin eruptions to severe life-threatening reactions, can occur with anticonvulsants.[35] Aromatic anticonvulsants, primarily phenytoin, carbamazepine, phenobarbital, and primidone as well as some of the newer agents (lamotrigine, oxcarbazepine, felbamate, and zonisamide) can cause a life-threatening syndrome with symptoms including fever, a maculopapular rash, and evidence of systemic organ involvement. The rash may be mild at first but can progress to exfoliative dermatitis, erythema multiforme, SJS, or TEN. This syndrome is known as anticonvulsant hypersensitivity syndrome (AHS), or DRESS. The causative agent should be withdrawn immediately. Cross-sensitivity among aromatic anticonvulsant drugs ranges between 40% and 80%.[36] If a patient is hypersensitive to an aromatic anticonvulsant, a nonaromatic agent (ethosuximide, gabapentin, levetiracetam, topiramate, lacosamide, valproic acid) or the benzodiazepines may be useful.[36]

Biologic Therapies and Immune Checkpoint Inhibitors

Biologically derived antibodies and cytokines used as therapeutic agents have the potential to cause nonimmune cytokine release and infusion-related adverse drug reactions. Rarely, an IgE-mediated anaphylaxis can occur to these products. Desensitization is possible for both allergic and nonallergic reactions to these agents.[37] Immune checkpoint inhibitors promote or inhibit T-cell activation, and have a range of associated adverse effects including autoimmunity.[38]

Drug Desensitization

Drug desensitization, also referred to as temporary induction of drug tolerance, may be undertaken for some drugs in the absence of useful alternative medications. The risk of severe systemic reactions and anaphylaxis associated with desensitization must be compared with the risk of not treating the patient with a drug of concern. A thorough evaluation should establish that the drug probably caused the reaction. Because of the dangers involved with drug desensitization, an expert review of the patient's indication for the drug should be conducted. Consider an alternative therapeutic choice or the possibility that the patient does not really need the drug.

KEY CONCEPT Desensitization is a potentially life-threatening procedure and requires continuous monitoring in a hospital setting, with suitable access to emergency treatment and intubation if required. It should only be undertaken under the direction of healthcare providers with suitable training and experience. In such hands, desensitization may present less risk than treatment failure with a less effective alternative medication.

The possibility of readministering a suspected drug may be safely tested by gradual dose escalation in some cases, and there are certainly many more patients who are harmed by inappropriately withholding medications than there are those who suffer significant harm from testing and desensitization.[39]

Induction of drug tolerance is not limited to IgE-mediated mechanisms but can be utilized for non-IgE–immune mechanisms, pharmacologic and unknown mechanisms. Desensitization may occur within hours to several weeks, unlike specific immunotherapy injections for inhalant allergy (ie, "allergy shots," which have effects over months to years). Like immunotherapy injections, temporary drug tolerance is accomplished by administration of incremental drug doses. The mechanism of drug desensitization is poorly understood but produces temporary drug-specific tolerance of the offending drug. Any interruption of therapy of 24 hours or more requires full repeat desensitization, and abrupt significant increases of dosage have been reported to break through the tolerance with some drugs.

The desensitization process probably involves either: (a) cross-linking small subthreshold numbers of bound IgE molecules gradually depleting mast cells of their mediators, or (b) binding of the IgE by monomers or hapten-protein entities that cannot cross-link the antibody. The low doses used at the beginning of all protocols would provide small amounts of antigen, favoring these mechanisms. Both drug-specific IgE and IgG serum concentrations increase after successful desensitization, but skin test positivity generally decreases.[40]

Oral and intravenous (IV) protocols are available for most drugs in this category, with the oral route producing somewhat milder reactions, but the IV route providing more precision in dosing. IV administration can also be used in unresponsive patients for whom the oral route is not feasible. Protocols generally begin at about 1% of the therapeutic dose and increase in intervals defined by the patient's reaction and the distribution and metabolism of the drug itself. Half-$\log_{10}$ dose increases (about threefold) are often tolerated.

Penicillin desensitization is the most common drug desensitization protocol. It is required for penicillin-allergic patients when penicillin is clearly the only treatment option. Protocols have been adopted for most antibiotics. Specific procedures for oral and IV penicillin desensitization have been developed.[41]

Aspirin desensitization is useful in diseases for which low-level antiplatelet action is needed and in the care of patients with aspirin sensitivity and intractable nasal polyps.[42, 43] As with all desensitizations, constant daily administration is required once the desired dose is reached.

All desensitization procedures are expected to produce mild symptoms in the patient at some point, and the patient must be made to understand this before doses are started. Mild sensitivity

Patient Encounter 3

A 26-year-old woman develops fever on day 14 of sulfasalazine. She is managed by her rheumatologist for autoimmune dysfunction. She later develops full body rash and itching. She presents to the emergency department for evaluation. Her complete blood count (CBC) demonstrates elevated absolute eosinophil count and liver function enzymes.

What type of reaction to the sulfa drug does this patient have?

What would be the management of this drug hypersensitivity in the future?

Would she be a candidate for drug desensitization?

to the drug still remains, and large dose increases as well as missing doses should be avoided. Late complications, such as urticaria, may occur with type I desensitization, and serum sickness or hemolytic anemia may also occur with high-dose therapy in allergic, desensitized patients.

Some regimens are designed for outpatient administration over much longer time periods and have been used with allopurinol dermal reactions. Such late-onset morbilliform reactions, sometimes overlapping with erythema multiforme minor, are difficult to evaluate because it is often unclear to what extent the patients were at risk for a recurrent reaction.

Severe life-threatening reactions not mediated by IgE, such as SJS and TEN, are absolute contraindications to testing, desensitization attempts, and readministration.

Drug challenge, where the suspected drug is administered as described below, should be considered for patients in whom likelihood of drug allergy is negligible. It is not used to determine if allergy is present to a drug but rather to confirm that drug allergy does not exist. Again, meticulous history regarding the reaction and temporal relationship with the drug must be ascertained. In certain instances, as with penicillin, skin testing for detection of IgE specificity can be performed prior to graded drug challenge, decreasing the risk for reaction.

To perform a drug challenge, usually two doses of the drug are given, although up to five steps have been described. A graded drug challenge does not affect the drug-immune response. Care must be taken to avoid temporary induction of drug tolerance which can occur when small incremental doses are given. Traditionally, the two-step drug challenge begins with 1/10 of the full drug dose followed by the full dose 1 hour later. The type of reaction determines the interval time between steps. Graded drug challenges are contraindicated in non-IgE–mediated severe life-threatening reactions like SJS, TEN, and DRESS. However, exceptions are made if benefits of the drug outweigh the risk, such as when the treatment could be life-saving without safer alternative therapies.[6]

KEY CONCEPT Drug challenge is performed to rule out drug allergy. It should be performed by an experienced physician familiar with risks and treatment of immediate and delayed drug reactions. It is not intended to change an individual's immune response to a drug or to induce drug tolerance.

OUTCOME EVALUATION

To successfully treat a patient with IgE-mediated or non-IgE (immune or nonimmune) drug hypersensitivity, several goals must be accomplished:

- If a reaction occurs, it must be identified and managed quickly.
- The patient should be educated about the reaction.

Patient Care Process

Collect Information:

- Perform a medication history for use of prescription and nonprescription medications and dietary supplements.
- Review the medical history and physical assessment findings.
- Speak with patient or caregiver to gain their perspective on the reaction.

Assess the Information:

- Based on the medication history, physical examination, and review of systems, determine the likelihood of the reaction being a drug-related problem. See Clinical Presentation and Diagnosis of IgE-mediated and Other Immune Drug Reactions. Tables 54–1 and 54–2 may also be helpful.
- Use questions given in Table 54–4 to establish the nature of the reaction and the likelihood it was caused by the suspected drug. For nonantibiotics, the first question regarding infection type is not needed.

Develop a Care Plan:

- Document the reaction, in detail, in the patient's medical record.
- Recommend an alternative choice if the prescribed drug is contraindicated, and develop a plan to assess safety and effectiveness.
- Consult with healthcare professionals trained in desensitization if the patient has a true allergy and no acceptable alternative medication is available.

Implement the Care Plan:

- If reaction is anaphylactic in nature, see Table 54–3.
- The offending drug should be discontinued.
- The treatment goal is relief of symptoms. For mild symptoms such as rash or itching, an antihistamine such as diphenhydramine may be used. For wheezing, bronchodilators such as albuterol may be helpful.
- Recommend an alternative option for the contraindicated drug, or if no alternative is available, consult with appropriate healthcare professional regarding desensitization.
- Educate patients about drug hypersensitivities so they are able to work with healthcare providers to avoid these reactions in the future.

Follow-up: Monitor and Evaluate:

- Follow up daily or more often, if necessary, to ensure resolution of the reaction and optimal response to alternate therapy.

- True drug contraindications should be avoided if possible.
- Patients should receive the medications they need or a suitable alternative. If this is not possible due to an IgE-mediated mechanism, desensitization should be considered.
- Patients should always be monitored for adverse drug reactions.

Abbreviations Introduced in This Chapter

AERD	Aspirin-exacerbated respiratory disease
AHS	Anticonvulsant hypersensitivity syndrome
AIDS	Acquired immunodeficiency syndrome
APC	Antigen presenting cell
CAD	Coronary artery disease
CIU	Chronic idiopathic urticaria
CBC	Complete blood count
COX	Cyclooxygenase
D_5W	Dextrose 5% in water
DIHS	Drug-induced hypersensitivity syndrome
DRESS	Drug reaction with eosinophilia and systemic symptoms
EMR	Electronic medical record
H (H_1, H_2)	Histamine
HIV	Human immunodeficiency virus
IFNγ	Interferon-gamma
Ig	Immunoglobulin (followed by the specific type of immunoglobulin: E, G, or M)
IL	Interleukin
IM	Intramuscular
IV	Intravenous
NSAIDs	Nonsteroidal anti-inflammatory drugs
p-i	Pharmacologic interaction
PPD	Purified protein derivative
SJS	Stevens-Johnson syndrome
TEN	Toxic epidermal necrolysis
Th	T-helper cell

55 Solid Organ Transplantation

Steven Gabardi, Miae Kim, and Ali J. Olyaei

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the reasons for solid organ transplantation.
2. Differentiate between the functions of cell-mediated and humoral immunity and how they relate to organ transplant.
3. Describe the roles of antigen-presenting cells (APCs) in initiating the immune response.
4. Compare and contrast the types of rejection including hyperacute, acute, chronic, and antibody-mediated rejection.
5. Define the terms "host–graft adaptation" and "tolerance," paying close attention to their differences.
6. Discuss the desired therapeutic outcomes and appropriate pharmacotherapy utilized to avoid allograft rejection.
7. Compare and contrast currently available immunosuppressive agents in terms of mechanisms of action, adverse events, and drug–drug interactions (DDI).
8. Develop a therapeutic drug-monitoring plan to assess the efficacy and safety of immunosuppressive drugs.
9. Design an appropriate therapeutic regimen for the management of immunosuppressive drug complications based on patient-specific information.
10. Write appropriate patient education instructions and identify methods to improve medication adherence following transplantation.

INTRODUCTION

In the early 1900s, French surgeon Alexis Carrel pioneered the art of surgical techniques for transplantation.[1] Together with Charles Guthrie, Carrel experimented in artery and vein transplantation. Using revolutionary methods in **anastomosis** operations and suturing techniques, Carrel laid the groundwork for modern transplant surgery. He was one of the first to identify the dilemma of rejection, an issue that remained insurmountable for nearly 50 years.[1]

Prior to the work of Carrel, malnourishment was the prevailing theory regarding the mechanism of **allograft** rejection.[1] However, in 1910, Carrel noted tissue damage in the transplanted organ was likely caused by multiple, circulating biological factors. It was not until the late 1940s, with the work of Peter Medawar, that transplant immunology became better understood. Medawar defined the immunologic nature of rejection using skin allografts. In addition, George Snell observed that grafts shared between inbred animals were accepted but were rejected when transplanted between animals of different strains.[1]

The seminal work by early transplant researchers eventually led to the concept of histocompatibility.[1] Histocompatibility describes the process by which polymorphic genes encode cell membrane antigens that serve as targets for immune response, even within a species. Further research in transplant immunobiology led to more accurate understanding of the alloimmune response.[1]

Joseph Murray performed the first successful organ transplant in 1954, a kidney transplant between identical twins.[1] This was a success largely because no immunosuppression was necessary as donor and recipient were genetically identical. Murray's achievement laid the groundwork for modern-day transplantation. Organ transplants performed in the United States reached a record high of 39,036 in 2020, an almost 15% increase from 2017.[2]

EPIDEMIOLOGY AND ETIOLOGY

Heart

More than 6 million Americans are afflicted with heart failure. Cardiac transplantation is the treatment of choice for patients with severe end-stage heart failure. Candidates for cardiac transplantation generally present with New York Heart Association (NYHA) class III or IV symptoms and have an ejection fraction of less than 20% (0.20). General indications for cardiac transplantation include rapidly declining cardiac function, requirement of intravenous (IV) inotropes, and a projected 1-year mortality rate of greater than 75%. Mechanical support with an implantable left ventricular assist device may be appropriate bridge-therapy while patients await a viable organ.[1] Most heart transplants are **orthotopic**; however, in certain situations, **heterotopic** transplants have been performed. There were 3658 heart transplant procedures in the United States in 2020.[2] Indications for heart transplant include:

- Cardiomyopathy (ie, dilated myopathy, hypertrophic cardiomyopathy, restrictive myopathy)
- Congenital heart disease
- Coronary artery disease
- Valvular heart disease

Intestine

Intestinal transplant may involve the use of an entire small bowel or shortened segment. Most intestine transplants completed in the United States involve the transplant of the full small intestines and are often performed in conjunction with liver transplantation. Although most intestine transplants involve organs harvested from a deceased donor, recent advances have made it possible for living donor intestinal segment transplants. There were only 91 intestine transplants in the United States in 2020.[2] Indications for intestine transplant include:

- Functional bowel problems (ie, Hirschsprung disease, neuronal intestinal dysplasia, pseudoobstruction, protein-losing enteropathy, microvillous inclusion disease)
- Short gut syndrome (ie, intestinal atresia, necrotizing enterocolitis, intestinal volvulus, massive resection secondary to inflammatory bowel disease, tumors, mesenteric thrombosis)

Kidneys

Nearly 37 million Americans have chronic kidney disease (CKD), with an additional 20 million at increased risk for kidney disease. End-stage renal disease (ESRD) constitutes a small portion of CKD patients, with more than 700,000 patients living with ESRD in the United States today. All patients with ESRD should be considered for renal transplantation if they are healthy enough to undergo surgery.

Most kidney transplants are heterotopic, where the kidney is implanted above the pelvic bone and attached to the patient's iliac artery and vein. The ureter of the transplant kidney is attached directly to the recipient's bladder or native ureter. The native kidneys are usually not removed, and data have shown that removal of the native kidneys does not influence patient survival (ie, survival of the transplant patient, without regard to function or survival of the allograft) and allograft survival.[1] There were 22,817 (17,583 deceased donor and 5234 living donor) kidney transplants performed in the United States in 2020.[2] Indications for kidney transplant include:

- Congenital, familial, and metabolic disorders (ie, congenital obstructive uropathy, Fabry disease, medullary cystic disease, nephrolithiasis)
- Diabetes mellitus (DM)
- Glomerular diseases (ie, antiglomerular basement membrane disease, focal segmental glomerular sclerosis, Immunoglobulin [Ig] A nephropathy, hemolytic uremic syndrome, systemic lupus erythematosus, Alport syndrome, amyloidosis, membranous nephropathy, Goodpasture syndrome)
- Hypertension
- Neoplasm (ie, renal cell carcinoma, Wilms tumor)
- Polycystic kidney disease
- Renovascular disease
- Tubular and interstitial diseases (ie, analgesic nephropathy, drug-induced nephritis, oxalate nephropathy, radiation nephritis, acute tubular necrosis, sarcoidosis)

Liver

Liver transplantation may involve the use of the entire organ or a segment. The majority of cases involve utilizing the full organ. In recent years, segmental transplants have been conducted using living donors. This procedure requires donation of the left hepatic lobe, which accounts for nearly 60% of the overall liver mass. This is possible because the liver can regenerate; therefore, both donor and recipient, in theory, will have normal liver function shortly after the transplant procedure. There were 8906 (8415 deceased donor and 491 partial lobe-living donor) liver transplants done in the United States in 2020.[2] Indications for liver transplant include:

- Acute hepatic necrosis (ie, chronic or acute hepatitis B or C)
- Biliary atresia
- Cholestatic liver disease/cirrhosis (ie, primary biliary cirrhosis)
- Metabolic disease (ie, Wilson disease, primary oxalosis)
- Neoplasms (ie, hepatoma, cholangiocarcinoma, hepatoblastoma, bile duct cancer)
- Nonalcoholic fatty liver disease (ie, nonalcoholic steatohepatitis, isolated steatosis)
- Noncholestatic cirrhosis (ie, alcoholic cirrhosis, postnecrotic cirrhosis, drug-induced cirrhosis)

Lungs

Lung transplants may involve deceased donation of two lungs or a single lung. More recently, lobar transplants from blood group-compatible living donors have been performed for a small segment of the population. Most have been performed on cystic fibrosis patients. On rare occasions, a simultaneous heart-lung transplant occurs, but is reserved for patients with severe pulmonary and cardiac disease. There were 2539 (all deceased donor) lung transplants and 58 simultaneous heart–lung transplants in the United States in 2020.[2] Indications for lung transplant include:

- α-1-Antitrypsin deficiency
- Congenital disease (ie, Eisenmenger syndrome)
- Cystic fibrosis
- Emphysema/chronic obstructive pulmonary disease
- Idiopathic pulmonary fibrosis
- Primary pulmonary hypertension

Pancreas

Exact nationwide prevalence of all diseases of the pancreas has not been fully quantified; however, DM, both types 1 and 2, affects nearly 34 million people in the United States. Some people suffering from DM may also be afflicted with ESRD. A small percentage of these patients undergo a simultaneous pancreas-kidney (SPK) transplant. Transplant of a pancreas may involve either the entire organ or a pancreas segment. Currently, whole-organ transplant is the most common procedure, with a portion of the duodenum often transplanted along with the pancreas. Living donors are often the source of segmental transplants. In recent years, isolation and transplantation of β-islet cells alone have been completed. Islet transplantation is intended to treat organ dysfunction by replacing nonfunctioning islet cells. Islet transplants are still experimental, and long-term benefit and/or risk of this procedure needs to be studied extensively. Future success of islet cell transplantation is dependent on identifying a nontoxic immunosuppressive combination. There were 135 pancreas transplants and 827 SPK procedures in the United States in 2020.[2] Indications for pancreas transplant include:

- DM (ie, type 1 and 2, DM secondary to chronic pancreatitis or cystic fibrosis)
- Pancreatic cancer

PATHOPHYSIOLOGY

Major Histocompatibility Complex

The primary target of the immune response posttransplant is the major histocompatibility complex (MHC).[1,3] The MHC is a region of highly polymorphic genes located on the short arm of chromosome 6. The human MHC is known as human leukocyte antigen (HLA). HLA is a set of glycoproteins expressed on the surface of most cells. These proteins are involved in immune recognition, which is the discrimination of self from nonself, but are also the principal antigenic determinants of allograft rejection.[1,3]

HLA have been classified into two major groups, class I and II:

- Class I: expressed on surfaces of all nucleated cells and recognized by CD8$^+$ cells (ie, cytotoxic T-cells); subclasses are HLA-A, HLA-B, and HLA-C.
- Class II: expressed solely on antigen-presenting cells (APCs). The APCs serve to stimulate CD4$^+$ cells (ie, helper T-cells); subclasses are HLA-DP, HLA-DQ, and HLA-DR.

T and B Lymphocytes

Lymphocytes are one of five types of white blood cells. Mature lymphocytes are astonishingly diverse in their functions. The most abundant are T lymphocytes (ie, T-cells) and B lymphocytes (ie, B-cells).

▶ *T Lymphocytes*

KEY CONCEPT T-cells play a major role in the cell-mediated immune response. These cells are produced in the bone marrow, but mature in the thymus, hence the abbreviation "T." There are three recognized subclasses of T-cells:

- Cytotoxic T-cells (CD8$^+$) promote target cell destruction by activating cellular apoptosis or killing via the release of cytotoxic proteins.
- Helper T-cells (CD4$^+$), once activated, proliferate and secrete cytokines that regulate the function of effector cells. Some helper T-cells secrete cytokines that recruit cytotoxic T-cells, B-cells, or APCs, whereas others secrete cytokines that turn off the immune response.
- Regulatory T-cells, or suppressor T-cells, suppress activation of immune responses.

▶ *B Lymphocytes*

B-cells play a key role in the humoral immune response. In humans, B-cells are produced and mature in the bone marrow. The human body produces several types of B-cells. Each is unique, with a distinctive cell surface receptor protein that binds to only one particular antigen. Once B-cells encounter their antigen and receive a cytokine signal from helper T-cells, they can further differentiate into plasma or memory B-cells. Plasma cells secrete antibodies that destroy target antigens through complement recruitment and/or opsonization. Memory B-cells play a role in long-term immunity, as they are capable of rapidly responding to subsequent exposures to their target antigen.

Antigen-Presenting Cells

KEY CONCEPT An APC is a cell that displays a foreign antigen complexed with MHC on its cell surface. Its major responsibility is to present foreign antigens to T-cells, which identify this complex using their T-cell receptors (TCRs). There are three main types of APCs: dendritic cells (DCs), macrophages, and activated B-cells. DCs are present in tissues in contact with the environment, such as skin and the lining of the nose, lungs, stomach, and intestines. They are responsible for phagocytosis, after which they express the foreign antigen on their cell surface and then migrate to lymphoid tissues to interact with T- and B-cells to initiate the immune response. Macrophages' main role is removal of pathogens and necrotic debris. However, like DCs, macrophages also phagocytize antigens. The first time an antigen is encountered, the DCs and macrophages act as the primary APCs. However, if the same antigen is encountered again, memory B-cells become the most important APC because they initiate the immune response quickly after antigen presentation. It appears that both DCs and macrophages have the most activity in terms of allorecognition.

Allorecognition

KEY CONCEPT Recognition of the antigens of the transplanted organ (alloantigens) is the main event that initiates the antiallograft immune response. There are currently two accepted pathways for allorecognition:

- Direct pathway: Donor APCs migrate from the allograft into the recipient's lymph nodes and present donor MHC molecules to the recipient's T-cells.
- Indirect pathway: Recipient APCs migrate into the graft and phagocytize alloantigens. The recipient's APCs present donor MHC molecules to the recipient T-cells in lymph nodes.

T-Cell Activation

Whether it is by direct or indirect pathways, T-cells become activated against the allograft via two interactions or signals that take place between the APCs and recipient's T-cells[1,3]:

- Signal 1 is the interaction of the TCR with foreign antigens presented by APCs.
- Signal 2 is an interaction between one of several costimulatory receptors and paired ligands on the cell surfaces of APCs and T-cells, respectively. Both interactions must occur simultaneously as Signal 1, in the absence of Signal 2, induces T-cell anergy.
- Signal 3 follows T-cell activation and is the process by which T-cells undergo clonal expansion under the influence of cytokines, specifically interleukin-2 (IL-2). These steps elicit an antidonor T-cell response resulting in graft damage.

Mechanisms of Acute Rejection

After activation, cytotoxic T-cells infiltrate the graft and trigger the immune response. These cells induce graft destruction via two mechanisms: (a) secretion of cytotoxic proteins (ie, perforin, granzyme) and (b) induction of cellular apoptosis through interaction. Besides the cytotoxic T-cells, several other cell lines may play a role in allograft destruction, including B-cells, granulocytes, and natural killer (NK) cells.

Types of Rejection

▶ *Hyperacute Rejection*

Hyperacute rejection is an immediate recipient immune response against the allograft due to the presence of preformed recipient antibodies directed against the donor's HLA. This type of reaction generally occurs within minutes of transplantation. The organ must be removed immediately to prevent severe systemic responses. In the case of cardiac or lung transplantation, in which the organ cannot be promptly removed, short-term mechanical circulatory support is required until an alternative organ becomes available. Those at the highest risk for hyperacute rejection include any patients who have preformed HLA or ABO blood group antibodies, including those with a history of organ transplant or multiple blood transfusions, as well as women who have had children. Hyperacute rejection has been largely eliminated due to routine pretransplant surveillance testing.

▶ *Acute Rejection*

Acute rejection is a cell-mediated process that generally occurs early posttransplant; however, it can occur at any time after transplant. This reaction is mediated through alloreactive T-cells. Table 55–1 presents organ-specific signs and symptoms of acute rejection.[1]

▶ *Antibody-Mediated Rejection*

Antibody-mediated rejection (AMR) is the process of creating graft-specific antibodies.[4] This occurs less frequently than cell-mediated acute rejection. Histologic findings are similar to those of hyperacute rejection, but the severity of rejection is usually less with AMR. AMR is generally characterized by deposition of immunoglobulins and complement in allograft tissues. However, AMR may be diagnosed without the presence of complement. Although rare, donor-specific antibodies (DSA) may be present or develop later following transplant. Presence of DSA is a strong predictor of AMR which might lead to allograft injury and failure posttransplantation. Treatment for this type of rejection is not well defined; however, several reports have shown that plasmapheresis, immunoglobulin therapy, or bortezomib may be effective.[4]

▶ *Chronic Rejection*

Chronic rejection has traditionally been thought of as a slow, insidious form of acute rejection, resulting in worsening organ function over time. Exact immunologic processes of chronic rejection are poorly understood; however, many believe both the cell-mediated and humoral immune systems, along with drug-induced toxicities, play a vital role in its development. Currently, retransplantation is the only effective treatment option.[1,3]

Host–Graft Adaptation

"Host–graft adaptation" describes the decreased immune response against the allograft over time.[1,3] This phenomenon is evident by the reduced incidence of acute rejection seen months after transplantation. In theory, host–graft adaptation is thought to be secondary to a weakened T-cell response to donor antigens while patients receive maintenance immunosuppression.[1,3]

Tolerance

Tolerance is the process that allows organ-specific antigens to be accepted as self.[1] This means the immune system would cease to respond to the allograft, and immunosuppressive medications would not be required. Immune tolerance has been achieved in the lab, but rarely in humans.[1]

Immunologic Barriers to Transplantation

One of the more common barriers to transplantation is the presence of preformed HLA antibodies or ABO blood group incompatibility.[4] In cases in which these antibodies exist, if they are not adequately removed prior to transplant, they are likely to result in AMR and poor graft survival. To improve outcomes, assessment of pretransplant immune risk factors plays an important role in prevention of immune-mediated allograft injuries. The introduction of pretransplant cross-matching and the use of ABO-compatible donors has largely eliminated hyperacute rejection. However, these immunologic barriers are present in several potential recipients with willing organ donors, and patients are left to wait for a deceased donor, undergo pretransplant

Table 55–1

Organ-Specific Signs and Symptoms of an Acute Rejection Episode[1]

Organ	Clinical Symptoms	Laboratory Signs
Heart	Lethargy, weakness, SOB, DOE, hypotension, tachycardia, atrial flutter, ventricular arrhythmias	Leukocytosis, biopsy positive for mononuclear infiltrates
Kidney	Weight gain, decreased urine output, malaise, hypertension, edema	Increased SCr, donor-derived cell-free DNA, BUN, leukocytosis, biopsy positive for lymphocytic infiltration
Intestine	GI symptoms (ie, bloating, cramping, diarrhea, increased stomal output)	There are no reliable biochemical markers for intestine transplant rejection, but biopsies may be helpful
Liver	Graft tenderness and swelling, back pain, anorexia, ileus, tachycardia, jaundice, ascites, encephalopathy	Abnormal LFTs, increased bilirubin, alkaline phosphate, transaminases, biopsy positive for mononuclear cell infiltrate with evidence of tissue damage
Lung	Fever, impaired gas exchange, SOB, malaise, anxiety	Decreased FEV, infiltrate on CXR, biopsy positive for lymphocytic infiltration
Pancreas	Graft tenderness and swelling, polyuria, abdominal pain	Increased FBS, leukocytosis, decreased C-peptide and urinary amylase levels

BUN, blood urea nitrogen; CXR, chest x-ray; DOE, dyspnea on exertion; FBS, fasting blood sugar; FEV, forced expiratory volume; GI, gastrointestinal; LFTs, liver function tests; SCr, serum creatinine; SOB, shortness of breath.

immunomodulation in an attempt to prevent these antibodies from affecting the allograft, or enter a donor exchange program.[4]

▶ *ABO Incompatibility*

The expanding deceased donor waiting list encouraged some centers to evaluate the use of ABO desensitization protocols in transplant patients who had willing, but ABO-incompatible, donors.[4] The desensitization protocol most commonly used involves reducing ABO antibody titers through plasmapheresis with IV immunoglobulin (IVIG). Use of plasma exchange to achieve an ABO antibody titer of less than 1:8 to 1:32 resulted in long-term renal transplant results that are comparable to those of ABO-compatible transplants, despite an incidence of acute AMR that approaches 10% to 30%.[4] High rates of AMR in this population have resulted in most ABO incompatible donors-recipient pairs being entered into kidney exchange programs.

TREATMENT

Desired Outcomes

KEY CONCEPT The major focus of pharmacotherapy in transplantation is to achieve long-term patient and allograft survival while avoiding major adverse events.[1,3,5,6] Short-term outcomes (eg, acute rejection rates, 1-year graft survival) have improved significantly since the first successful transplant due to an improved understanding of the immune system, enhancements in surgical techniques and organ procurement, immunosuppression, and posttransplant care. However, the frequency of graft loss remains higher than desired.[1,3,5,6]

It is imperative that transplant practitioners be aware of specific advantages and disadvantages of available immunosuppressants, as well as adverse reactions and drug–drug interaction (DDI) profiles. There are generally three stages of medical immunosuppression: (a) induction therapy, (b) maintenance therapy, and (c) treatment of rejection. KEY CONCEPT Immunosuppressive regimens utilize multiple medications working on different targets. Refer to Table 55–2 for a list of all available immunosuppressive agents.[1,5,6]

Induction Therapy

KEY CONCEPT The goal of induction therapy is to provide a high level of immunosuppression in the early posttransplant period, when the risk of acute rejection is highest.[5] This stage of immunosuppression is initiated intraoperatively and concluded within the first 1 to 10 days after transplantation. Antibody induction

Table 55–2

Currently Available Immunosuppressive Agents[1,5,6]

Generic Name (Brand Name)	Common Dosage	Common Adverse Effects
Induction Therapy Agents		
Alemtuzumab (Campath)	30 mg × single dose	Flu-like symptoms, chills, rigors, fever, rash, myelosuppression
Antithymocyte globulin equine (ATGAM)	15 mg/kg IV × 5–14 days	Flu-like symptoms, chills, rigors, fever, rash, myelosuppression
Antithymocyte globulin rabbit (Thymoglobulin)	0.75–1.5 mg/kg IV × 3–7 days	Flu-like symptoms, chills, rigors, fever, rash, myelosuppression
Basiliximab (Simulect)	20 mg IV × 2 doses	None reported compared to placebo
Maintenance Immunosuppressants		
Cyclosporine (Sandimmune, Neoral, Gengraf)	1–4 mg/kg/day by mouth twice a day	Neurotoxicity, gingival hyperplasia, hirsutism, hypertension, hyperlipidemia, glucose intolerance, nephrotoxicity, electrolyte abnormalities
Tacrolimus (Prograf, Astagraf XL, Envarsus XR)	0.05–0.1 mg/kg by mouth twice a day or once daily if using Astagraf XL; 0.14 mg/kg once daily if using Envarsus XR	Neurotoxicity, alopecia, hypertension, hyperlipidemia, glucose intolerance, nephrotoxicity, electrolyte abnormalities
Azathioprine (Imuran)	1–3 mg/kg by mouth once a day	Myelosuppression, GI disturbances, pancreatitis
Mycophenolate mofetil (CellCept)	0.5–1.5 g by mouth twice a day	Myelosuppression, GI disturbances
Enteric-coated MPA (Myfortic)	720 mg by mouth twice a day	Myelosuppression, GI disturbances
Sirolimus (Rapamune)	1–10 mg by mouth once a day	Hypertriglyceridemia, myelosuppression, mouth sores, hypercholesterolemia, GI disturbances, impaired wound healing, proteinuria, lymphocele, pneumonitis
Everolimus (Zortress)	0.75-1 mg by mouth twice daily	Hypertriglyceridemia, myelosuppression, mouth sores, hypercholesterolemia, GI disturbances, impaired wound healing, proteinuria, lymphocele, pneumonitis
Prednisone (Deltasone)	Maintenance: 2.5–20 mg by mouth once a day	Mood disturbances, psychosis, cataracts, hypertension, fluid retention, peptic ulcers, osteoporosis, muscle weakness, impaired wound healing, glucose intolerance, weight gain, hyperlipidemia
Belatacept (Nulojix)	De Novo therapy: 10 mg/kg on postop days 1 and 4; 10 mg/kg at the end of postop weeks 2, 4, 8, and 12; 5 mg/kg at the end of postop week 16 and every 4 weeks thereafter Conversion therapy: 5 mg/kg every 2 weeks × 5 doses; followed by 5 mg/kg every 4 weeks thereafter	GI disturbances, electrolyte abnormalities, headache

GI, gastrointestinal; IV, intravenous; MPA, mycophenolic acid.

therapy is not a mandatory stage of recipient immunosuppression and is typically predicated on immunologic risk. However, since acute rejection is a major concern in solid organ transplant (SOT) recipients and its impact on chronic rejection is undeniable, induction therapy is considered essential in some organs, such as kidney, pancreas, and intestine transplantation.[5] The use of induction therapy among heart and lung transplant recipients is also becoming more common.

▶ *Goals of Induction Therapy*

KEY CONCEPT Induction agents are highly immunosuppressive, allowing for significant reductions in acute rejection and improved 1-year graft survival.[5] Due to their unique pharmacologic effect, these agents are often considered essential in patients at high risk for poor short-term outcomes, such as patients with preformed antibodies, history of previous transplants, multiple HLA mismatches, or transplantation of organs with prolonged cold ischemic time or from expanded-criteria donors. Induction therapy plays an important role in preventing early-onset calcineurin inhibitor (CNI)–induced nephrotoxicity. With induction therapy, CNI initiation can be delayed until the graft regains some degree of function. Induction therapy is imperative when employing corticosteroid sparing or avoidance protocols.[5]

The improved short-term outcomes gained from induction therapy come with a degree of risk.[5] By using highly immunosuppressive agents, particularly the antilymphocyte antibodies (ALA; the antithymocyte antibodies and alemtuzumab), risk of opportunistic infections and malignancy is increased. Cytokine release syndrome is a common complication of T-cell depleting agents and may require use of diphenhydramine and acetaminophen before infusions.[5]

▶ *Currently Available Induction Therapies*

Induction agents are categorized as depleting and nondepleting. Depleting agents exert their pharmacological effects through depletion of T and B lymphocytes (antithymocyte globulin rabbit [r-ATG], antithymocyte globulin equine [e-ATG], alemtuzumab), while nondepleting agents exert their pharmacological effects through inhibition of T-cell activation (basiliximab).

Basiliximab Basiliximab, a chimeric monoclonal antibody, acts as an IL-2 receptor antagonist and inhibits IL-2–mediated activation of lymphocytes, which is an important step in T-cell clonal expansion.[5,7] Basiliximab is not a T-cell depleting agent and can be given with or without premedications.

The basiliximab dose is 20 mg IV given 2 hours prior to transplant, followed by a second 20 mg dose on postoperative days 2 to 4.[5,7] This dosing schedule can be used for children greater than or equal to 35 kg (77 lb) and adults. Two 10 mg doses with the same schedule should be used for children less than 35 kg (77 lb). There are no dosage adjustments needed in renal or hepatic impairment.[5,7] Incidence of adverse reactions with basiliximab was similar to placebo in trials, and there are no reported DDIs with basiliximab.[5,7]

Antithymocyte Globulin Rabbit r-ATG is a polyclonal antibody that induces T-cell clearance, but more importantly, alters T-cell activation, homing, and cytotoxic activities.[7] It is also believed r-ATG plays a role in inducing T-cell apoptosis. This agent is typically dosed at 0.75-1.5 mg/kg/day and is usually administered for 3 to 7 days after transplantation.[5] Many renal transplant centers aim to initiate the first dose intraoperatively to reduce organ reperfusion injury.[8]

Adverse reactions are common and may include fever (63.4%), chills (57.3%), headache (40.2%), nausea (36.6%), diarrhea (36.6%), malaise (13.4%), dizziness (8.5%), leukopenia (57.3%), thrombocytopenia (36.6%), and generalized pain (46.3%).[9-11] Incidence of infection is 36.6%, with cytomegalovirus (CMV) disease occurring in 13.4% of patients. There are no reported DDIs with the use of r-ATG.[5,7]

Antithymocyte Globulin Equine e-ATG is a polyclonal antibody that contains antibodies against several T-cell surface markers, similar to r-ATG. However, e-ATG is rarely used in transplantation due to poor outcomes in comparison to r-ATG.

Alemtuzumab Alemtuzumab is a monoclonal antibody that binds to CD52, which is present on most B and T lymphocytes, macrophages and NK cells, and a subpopulation of granulocytes.[5,7] After complexing with CD52, alemtuzumab induces antibody-dependent cell lysis. This agent produces a rapid and extensive lymphocyte depletion that takes several months to years to return to pretransplant levels. Although not Food and Drug Administration (FDA) approved for use in organ transplantation, studies have demonstrated that a single dose of 30 mg IV at the time of transplant is effective in preventing acute rejection.[5]

Alemtuzumab is associated with serious adverse reactions including anemia (47%), neutropenia (70%), thrombocytopenia (52%), headache (24%), dysesthesias (15%), dizziness (12%), nausea (54%), vomiting (41%), diarrhea (22%), infusion-related reactions (15%–89%), and infection (37%; CMV viremia occurred in 15% of patients).[7] Premedication with acetaminophen and diphenhydramine 30 minutes before infusion will reduce the incidence of infusion-related reactions, but subcutaneous administration will also prevent these reactions.[5]

Comparative Efficacy There are a few studies that help to delineate the ideal induction therapy agent in renal transplant. Studies comparing r-ATG and e-ATG show that r-ATG is more effective in lowering acute rejection rates and improving 1-, 5-, and 10-year allograft outcomes.[9,10,12] Conversely, a study evaluating the use of basiliximab versus r-ATG demonstrated similar short-term efficacy between both groups.[13] However, other analyses of these two agents demonstrated similar results for allograft and patient survival, but a benefit for r-ATG in lowering incidence of acute allograft rejection.[11,14] An analysis showed that alemtuzumab improved transplant outcomes when compared with basiliximab in patients with a low immunologic risk, and similar outcomes compared to r-ATG in patients with high immunologic risk.[15] Alemtuzumab is associated with significantly higher rates of DSA formation when compared to basiliximab and r-ATG, but the impact on long-term allograft function has not been evaluated.[16] When choosing an agent for induction therapy, one must weigh the risks versus benefits. Overall, the ALAs are considered to be most effective, but are associated with higher incidence of infectious disease and malignancy.[5]

Maintenance Immunosuppressive Therapy

Goals of maintenance immunosuppression are to prevent rejection and optimize patient and graft survival.[6] Antirejection medications require careful selection and dose titration to balance the risks of rejection with toxicities.

KEY CONCEPT Maintenance immunosuppressive agents include:

- Calcineurin inhibitors (CNI; cyclosporine and tacrolimus)
- Antiproliferatives (azathioprine and mycophenolic acid [MPA] derivatives)

Patient Encounter Part 1

A 64-year-old man presents to your transplant center to undergo cardiac transplant after a suitable organ was identified for him.

PMH:

- Ischemic cardiomyopathy—myocardial infarction 10 years ago, status post drug-eluting stent.
- Heart failure (NYHA III)
- Hypothyroidism
- Paroxysmal atrial fibrillation
- Depression
- Gout
- Insulin-dependent DM type 2

FH: Father is alive and living with a history of cardiovascular disease and mother is alive and living with a history of basal cell carcinoma.

SH: Patient is a retired school teacher. He used to drink alcohol socially (three or four drinks per week) but stopped after worsening heart failure and denies any tobacco or IV drug use.

Admission Meds:

- Aspirin 81 mg by mouth once daily
- Sacubitril/valsartan 49 mg/51 mg by mouth twice daily
- Metoprolol succinate 40 mg by mouth once daily
- Spironolactone 25 mg by mouth once daily
- Rosuvastatin 40 mg by mouth once daily
- Torsemide 20 mg by mouth twice daily
- Levothyroxine 50 mcg by mouth once daily
- Sertraline 50 mg by mouth once daily
- Allopurinol 100 mg by mouth once daily
- Insulin glargine inject subcutaneously 13 units every night
- Insulin aspart 6 units inject subcutaneously three times daily with meals

Allergies/intolerance:

- Sulfa drugs—hives
- Prednisone—Labile glucose

Misc:

- CMV Serostatus: Donor is CMV IgG-positive.
- CMV Serostatus: Recipient is CMV IgG-negative.
- Epstein Barr Virus (EBV) Serostatus: Donor is EBV IgG-positive.
- EBV Serostatus: Recipient is EBV IgG-negative.

Identify your treatment goals for this patient.

Create a plan for induction therapy (ie, would you recommend induction therapy, and if so, which agent?).

- Target of rapamycin (ToR) inhibitors (sirolimus and everolimus)
- Corticosteroids
- Costimulatory blockade (belatacept)

Maintenance immunosuppression is generally achieved by combining two or more medications from the different classes, specifically targeting unique components of the immune response.[6] Refer to Figure 55–1 for a schematic representation of different drug mechanisms and Figure 55–2 for an example protocol for administration of immunosuppressive medications posttransplant. This method of medication selection also minimizes toxicities by choosing agents with different adverse event profiles. Immunosuppressive regimens vary between organ types and transplant centers, but most often include a CNI with an adjuvant agent, plus corticosteroids. Selection of an immunosuppressive regimen should be patient-specific, and one must take into account the patient's comorbidities, medication regimens, and preferences.[6]

▶ *Calcineurin Inhibitors*

KEY CONCEPT Cyclosporine and tacrolimus are the cornerstone of modern immunosuppressive protocols. The CNIs work by complexing with cytoplasmic proteins (cyclosporine with cyclophilin and tacrolimus with FK binding protein-12).[6,7] These complexes inhibit calcineurin phosphatase, which results in reduced IL-2 gene transcription and a reduction in IL-2 synthesis. This diminishes T-cell activation.[6,7]

Cyclosporine Cyclosporine USP was first approved in 1983, but was associated with a variable oral absorption. The development of a newer formulation, cyclosporine microemulsion USP (ie, modified), introduced in 1994, allowed for more consistent drug exposure due to a more reliable pharmacokinetic profile.[1] Cyclosporine modified is the formulation of choice for most transplant centers utilizing cyclosporine. The two formulations are not interchangeable.[6]

The usual oral adult dose of cyclosporine ranges from 2 to 8 mg/kg/day in two divided doses.[7] Appropriate selection of the starting dose depends on the organ type, the patient's comorbidities, and other concomitant immunosuppressive agents utilized. Cyclosporine modified is available as 25 mg and 100 mg capsules and an oral solution. An IV formulation of conventional cyclosporine is also available. When converting a patient from oral to IV, the dosage should be reduced to approximately one-third of the total daily oral dose.[7]

Cyclosporine whole-blood trough concentrations (C_0) have traditionally been obtained to help monitor for efficacy and safety. Therapeutic C_0 may range from 50 to 400 ng/mL (mcg/L; 42–333 nmol/L). Target levels should be individualized for each patient, usually depending on the organ transplanted, patient's condition, method of assay (liquid chromatography coupled to tandem mass spectrometry [LC-MS/MS], or various immunoassay techniques), and time since transplantation.[6]

Tacrolimus Tacrolimus was approved in 1997. Oral starting doses range from 0.1 to 0.2 mg/kg/day in two divided doses. Tacrolimus is available in 0.5 mg, 1 mg, and 5 mg capsules and as an injectable.[7] Two once-daily tacrolimus formulations are also available. LCP-Tacrolimus once daily is associated with lower incidence of neurotoxicity and is theorized to be a better option for patients considered to be rapid metabolizers. Due to improved bioavailability, the recommended LCP-Tacrolimus starting dose is 0.14 mg/kg/day, given as a single dose. Tacrolimus C_0 should be monitored and maintained between 4 and 15 ng/mL (mcg/L;

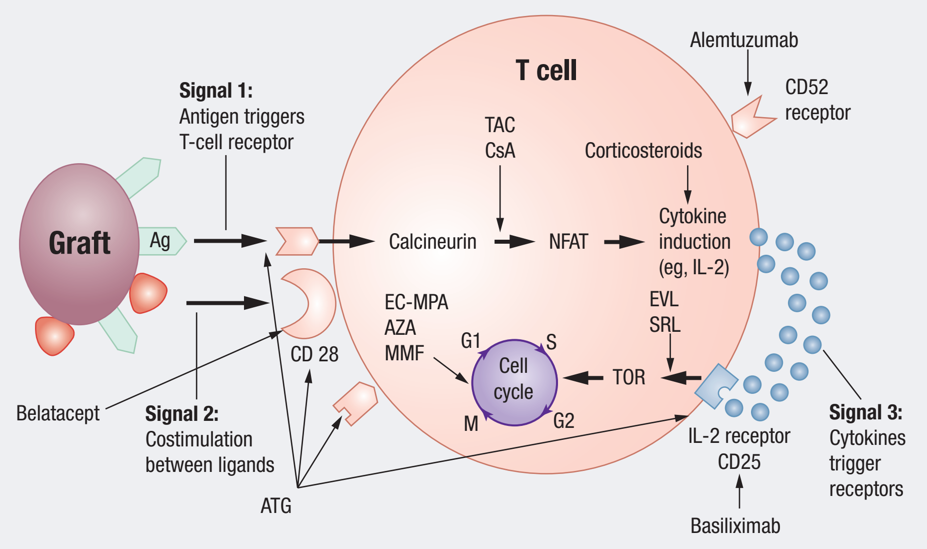

FIGURE 55–1. Identification of the sites of action of the various immunosuppressive medications. Allograft recognition through Signal 1 occurs when the antigen-major histocompatibility complex (MHC) molecule is recognized by the T-cell receptor (TCR). A costimulatory signal, Signal 2, initiates signal transduction with activation of second messengers, one of which is calcineurin. Together, Signal 1 and Signal 2 activate calcineurin phosphatase, which removes phosphates from the nuclear factors, allowing them to enter the nucleus with a subsequent increase in interleukin-2 (IL-2) gene transcription. Signal 3 occurs with the interaction of IL-2, with the IL-2 receptor on the cell membrane surface. This culminates in a signal that passes through the mammalian target of rapamycin (ToR) and induces cell proliferation and production of cytokines specific to the T-cell. (ATG, antithymocyte globulin; AZA, azathioprine; CsA, cyclosporine; EC-MPA, enteric-coated mycophenolic acid; EVL, everolimus; MMF, mycophenolate mofetil; NFAT, nuclear factors; SRL, sirolimus; TAC, tacrolimus.)

5 and 19 nmol/L), again depending on the transplanted organ, patient's condition, and time since transplant.[6]

One of the major issues with tacrolimus-based therapy is there is significant intrapatient variability seen with this medication. High tacrolimus intrapatient variability has been evaluated as an independent risk factor for shortened graft survival.[17] Nonadherence is often considered to be the dominant factor in high tacrolimus intrapatient variability.

The tacrolimus IV formulation is usually avoided due to the risk of anaphylaxis, because of its castor oil component, and nephrotoxicity.[6] Doses for IV administration are recommended to start at 0.01 mg/kg/day. In an effort to avoid IV tacrolimus, many transplant centers utilize sublingual (SL) tacrolimus in their patients unable to receive the medication by mouth.[6]

Adverse Drug Reactions KEY CONCEPT One of the major disadvantages of the CNIs is their ability to cause nephrotoxicity. Acute nephrotoxicity has been correlated with high doses and is usually reversible.[7] Chronic CNI toxicity, however, is typically irreversible and linked to chronic drug exposure. Table 55–3 expands on the more common CNI–associated adverse events.[1,6]

Comparative Efficacy Even though cyclosporine and tacrolimus are both CNIs, there are several differences between the two. A meta-analysis comparing cyclosporine to tacrolimus in kidney transplantation showed tacrolimus was associated with significantly lower risk of allograft loss at 6 months and lower rates of acute rejection at 1 year.[18] Tacrolimus is the primary CNI in most transplant centers for all organs.[6]

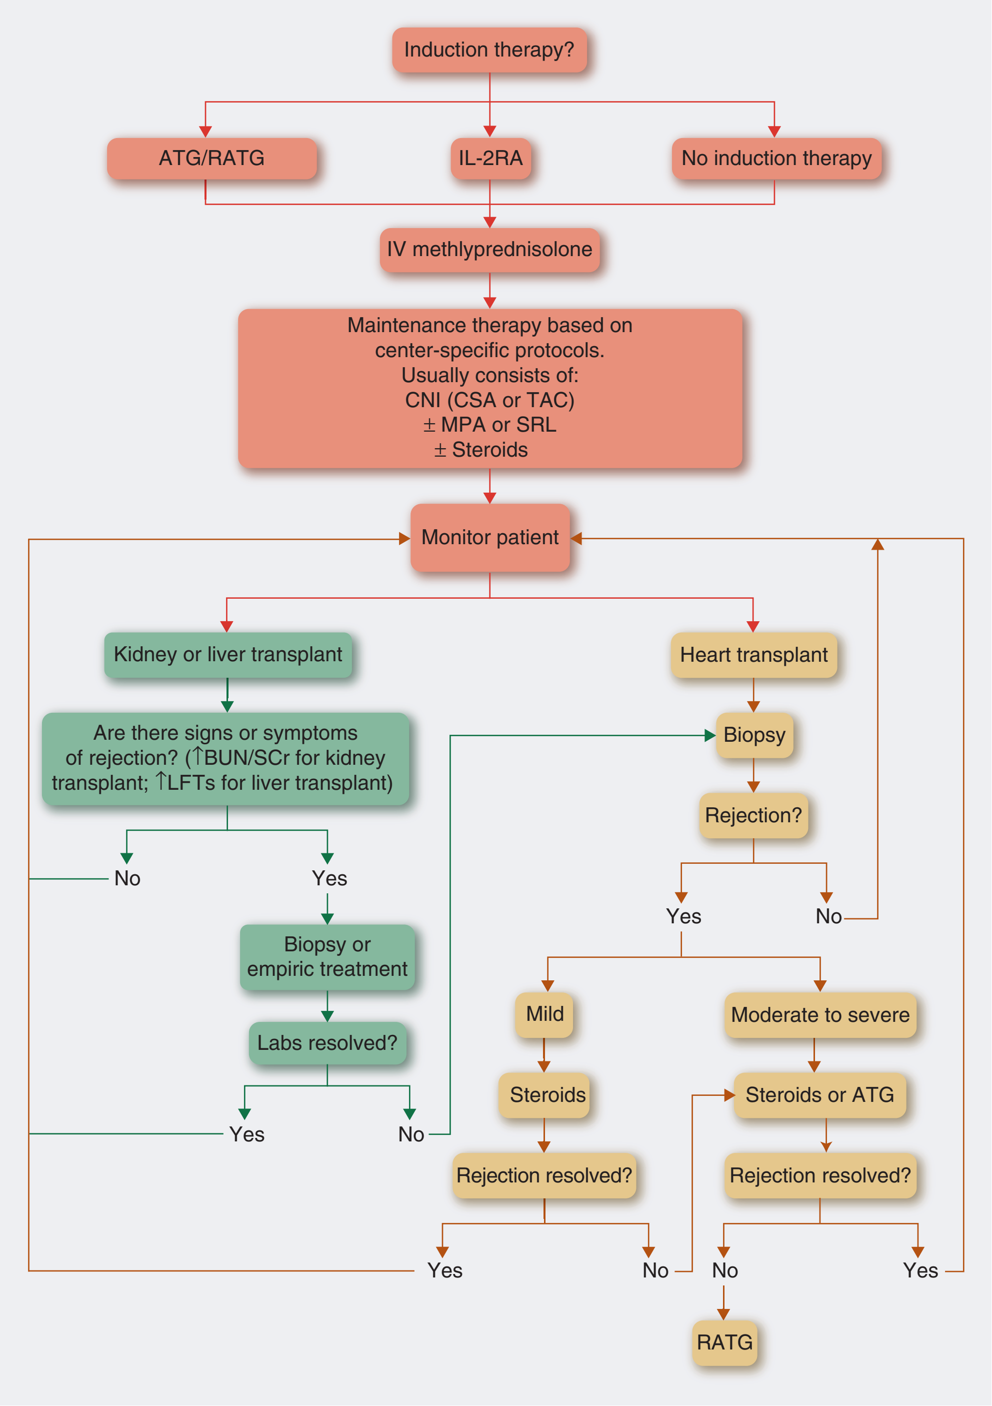
▶ *Antiproliferatives*

These agents are considered to be adjuvant to CNIs.[6]

Azathioprine Azathioprine was approved in 1968. Prior to the advent of cyclosporine, the combination of azathioprine and corticosteroids was the mainstay of immunosuppressive therapy. Use of azathioprine has declined markedly due to superiority of the MPA derivatives. KEY CONCEPT Azathioprine is a prodrug for 6-mercaptopurine (6-MP), a purine analog. 6-MP acts as an antimetabolite and inhibits DNA replication with a resultant reduction in T-cell proliferation.[6] It is available in oral and IV dosage forms.[7] The typical oral dose of azathioprine for organ transplantation is 1 to 3 mg/kg once a day.[7] Thiopurine methyltransferase (TPMT) is the main enzyme for inactivation of azathioprine. Approximately 10% of transplant recipients have reduced TPMT activity and are at risk for drug toxicity. Dose reductions due to drug accumulation are needed to avoid toxicities. In addition, the dose should be adjusted for renal function since 6-MP and its metabolites are renally eliminated.[7] Trough concentrations of 6-MP are not monitored; however, most clinicians often monitor for signs of myelosuppression. KEY CONCEPT Myelosuppression (mainly leukopenia and thrombocytopenia) is a frequent, dose-dependent and dose-limiting complication (greater than 50% of patients) that often prompts dose reductions.[7] Other common adverse events include hepatotoxicity (2% to 10%) and adverse gastrointestinal (GI) events (10% to 15%; mostly nausea and vomiting). Importantly, pancreatitis and venoocclusive disease of the liver occur in less than 1% of patients following chronic azathioprine therapy.[7]

Mycophenolic Acid Derivatives Mycophenolate mofetil was approved in 1995 and enteric-coated MPA in 2004. Both agents are considered adjunctive immunosuppressants.[6] KEY CONCEPT Both mycophenolate mofetil and enteric-coated MPA are prodrugs for MPA. MPA acts by inhibiting inosine monophosphate dehydrogenase, a vital enzyme in the de novo pathway of purine synthesis. Inhibition of this enzyme prevents the proliferation of most cells that are dependent on the de novo pathway for purine synthesis, including T- and B-cells.[6]

Mycophenolate mofetil is available in 250 mg and 500 mg capsules, an oral suspension (100 mg/mL; in cherry syrup),



Induction therapy?
ATG/RATG
IL-2RA
No induction therapy
IV methlyprednisolone
Maintenance therapy based on center-specific protocols. Usually consists of: CNI (CSA or TAC) ± MPA or SRL ± Steroids
Monitor patient
Kidney or liver transplant
Heart transplant

FIGURE 55–2. Example protocol of immunosuppressive medication use in organ transplantation. Center-specific protocols may use rabbit antithymocyte immunoglobulin (RATG), an interleukin-2 receptor antagonist (IL-2RA), or no induction therapy. In any situation, patients receive intravenous (IV) methylprednisone prior to, during, or immediately following the transplant operation. The patient then will begin the maintenance immunosuppressive regimen. The center-specific protocol will specify which calcineurin inhibitor (cyclosporine or tacrolimus) is used in combination with mycophenolate mofetil or sirolimus, with or without steroids. Patients are then monitored for signs and symptoms of rejection. If rejection is suspected, a biopsy can be done for definitive diagnosis, or the patient may be treated empirically for rejection. Empirical treatment generally involves administration of corticosteroids. If signs and symptoms of rejection are resolved with empirical therapy, the patient will continue to be monitored according to the center-specific protocol. If rejection is confirmed by biopsy, treatment may be based on the severity of rejection. High-dose corticosteroids are used most frequently for mild to moderate rejection. RATG can be used for moderate to severe rejections or steroid-resistant rejections. Protocols and algorithms may differ across transplant centers. (ATG, antithymocyte globulin; BUN, blood urea nitrogen; CNI, calcineurin inhibitor; CSA, cyclosporine; LFT, liver function test; MPA, mycophenolic acid; SCr, serum creatinine; SRL, sirolimus; TAC, tacrolimus.) (Adapted from Jennings DL, Johnson HJ. Solid organ transplantation. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach. 11th ed. New York: McGraw-Hill; 2020.)

Table 55–3

Management of Common Adverse Effects of Calcineurin Inhibitors (CNIs)[1,6]

Adverse Event	Most Likely Offending CNI	Monitoring Parameters	Therapeutic Management Options
Nephrotoxicity	Either	• SCr • BUN • Urine output • Biopsy-proven CNI-induced nephrotoxicity	• Reduce CNI dose (if possible) • Use of CCB for hypertension control • Modify regimen (change to non-CNI containing regimen [ToR inhibitor or belatacept])[a]
Hypertension[b]	Cyclosporine	• Blood pressure • Heart rate	• Initiate patient-specific antihypertensive therapy • Reduce cyclosporine dose (if possible) • Modify regimen (change to tacrolimus or non-CNI containing regimen)[a]
Hyperlipidemia[b]	Cyclosporine	• Fasting lipid panel	• Initiate patient-specific cholesterol-lowering therapy • Reduce cyclosporine dose (if possible) • Modify regimen (change to tacrolimus or non-CNI containing regimen)[a]
Hyperglycemia[c]	Tacrolimus	• Blood glucose (fasting and nonfasting) • Hemoglobin A_{1c}	• Lifestyle modifications • Reduce tacrolimus dose (if possible) • Reduce steroids (if patient is taking them and if possible) • Initiate patient-specific glucose-lowering therapy (insulin or oral therapy) • Modify regimen (change to cyclosporine or non-CNI containing regimen)[a]
Neurotoxicities[c]	Tacrolimus	• Fine hand tremor • Headache • Mental status changes	• Reduce tacrolimus dose (if possible) • Modify regimen (change from tacrolimus to cyclosporine or non-CNI containing regimen)[a]
Hirsutism	Cyclosporine	• Patient complains of excessive hair growth or male-pattern hair growth	• Reduce cyclosporine dose (if possible) • Cosmetic hair removal • Modify regimen (change to tacrolimus or non-CNI containing regimen)[a]
Alopecia	Tacrolimus	• Patient complains of excessive hair loss	• Reduce tacrolimus dose (if possible) • Hair growth treatments (ie, minoxidil, finasteride in males only) • Consider use of multivitamin with thiamine and folic acid, and/or biotin 5000 mcg daily • Modify regimen (change to cyclosporine or non-CNI containing regimen)[a]
Gingival Hyperplasia	Cyclosporine	• Patient complains of excessive gum growth • Discuss options for therapy with patient's dentist	• Reduce cyclosporine dose (if possible) • Oral surgery (gum resection) • Modify regimen (change to tacrolimus or non-CNI containing regimen)[a]

[a] Modifying the immunosuppressive regimen increases risk for rejection, even in stable patients. This option should be chosen cautiously and implemented with proper monitoring and follow-up.

[b] Tacrolimus is also associated with hypertension and hyperlipidemia, but to a much lower extent compared to cyclosporine.

[c] Cyclosporine is also associated with hyperglycemia and neurotoxicities, but to a much lower extent compared to tacrolimus.

BUN, blood urea nitrogen; CCB, calcium channel blocker; SCr, serum creatinine; ToR, target of rapamycin.

and as an injectable.[7] The recommended starting dose of mycophenolate mofetil is 1000 to 1500 mg given twice daily. The conversion between oral and IV mycophenolate mofetil is 1:1. Enteric-coated MPA is available in 180 mg and 360 mg tablets. The appropriate equimolar conversion between mycophenolate mofetil and enteric-coated MPA is 1000 mg of mycophenolate mofetil to 720 mg of enteric-coated MPA.[6] Recommended starting dose of enteric-coated MPA is 720 mg given twice daily. Conversion of mycophenolate mofetil to enteric-coated MPA has been proven safe. MPA C_0 can be monitored; however, it is not routinely recommended.[6]

KEY CONCEPT The most common adverse events associated with these agents are GI (18%–54%; diarrhea, nausea, vomiting, and gastritis) and myelosuppression (20%–40%).[7] Despite its enteric coating, enteric-coated MPA has the same degree of GI adverse events as mycophenolate mofetil.[6,19] However, data suggest that there is a benefit in converting patients with documented mycophenolate-induced GI disease from mycophenolate mofetil to enteric-coated MPA or to azathioprine.[20] Both MPA products are governed under a FDA-mandated Risk Evaluation and Mitigation Strategy program due to their teratogenic potential.

Comparative Efficacy The MPA derivatives have replaced azathioprine as the primary antiproliferative agent and are generally considered to provide a more specific immunosuppressive effect compared with azathioprine.[6] Mycophenolate mofetil and enteric-coated MPA have similar safety and efficacy data in transplant recipients.[19] The decision to choose one agent over another is a purely practitioner-dependent preference.

▶ *Target of Rapamycin Inhibitors*

Sirolimus KEY CONCEPT Sirolimus and everolimus inhibit T-cell activation and proliferation by inhibiting activation of the mammalian ToR, which suppresses cellular response to IL-2 and other cytokines (ie, IL-4, IL-15).[6,7,21] Studies have shown that ToR inhibitors may be used safely and effectively concomitantly with either cyclosporine or tacrolimus instead of an antiproliferative.[22] Sirolimus can also be used as an alternative agent for patients who do not tolerate CNIs due to nephrotoxicity or other adverse events.[6]

Sirolimus is available in 0.5 mg, 1 mg, and 2 mg tablets and a 1 mg/mL oral solution. Although some may elect not to do a loading dose, the package insert indicates that the current approved dosing regimen for sirolimus is a 6 mg loading dose followed by a 2 mg/day maintenance dose.[7] Use of a sirolimus loading dose of 5 to 15 mg/day for 1 to 3 days will allow for a more rapid achievement of adequate immunosuppression.[7] Maintenance doses of sirolimus usually range from 1 to 10 mg/day given once daily. Sirolimus blood C_0 should be maintained between 3 and 10 ng/mL (mcg/L; 3 and 11 nmol/L), depending on the institution-specific protocols.[6] Of note, sirolimus has a half-life of approximately 62 hours, meaning it will not reach steady state after dosage changes for several days.[7]

KEY CONCEPT The most common adverse events reported with sirolimus are leukopenia (20%), thrombocytopenia (13% to 30%), and hyperlipidemia (38% to 57%).[7] Other adverse effects include delayed wound healing, anemia, diarrhea, arthralgias, rash, proteinuria, pneumonitis, and mouth ulcers. Sirolimus has a black-box warning in newly transplanted liver and lung recipients due to severe and potentially life-threatening adverse events.[7] The long-term use of sirolimus in these populations may be appropriate, but not in the initial posttransplant period (ie, 3 to 6 months posttransplant).

Everolimus Everolimus is a derivative of sirolimus and has the same mechanism of action.[7,23] Everolimus is only indicated for prevention of rejection in low- to moderate-risk renal and liver transplant recipients. This agent is available in 0.25 mg, 0.5 mg, 0.75 mg, and 1 mg tablets. Recommended starting dose is 0.75 to 1 mg twice daily without the need for a loading dose. Maintenance everolimus doses should be maximized to achieve a C_0 goal of 3 to 8 ng/mL (mcg/L; 3–8 nmol/L).[7,23] With a significantly shorter half-life, everolimus steady state can be reached within 4 to 6 days. The adverse event profile of everolimus is similar to that of sirolimus.[7,23]

For both ToR inhibitors, their primary roles have evolved for use only in patients who have a history of or de novo squamous or basal cell carcinoma, due to antiproliferative activity. However, some centers will continue to utilize these agents in patients intolerant of other oral immunosuppressants.[23]

▶ *Corticosteroids*

Traditional triple-therapy immunosuppressive regimens have consisted of a primary agent (ie, CNI, ToR inhibitor, belatacept), an antiproliferative, and corticosteroids.[6] In recent years, many renal and liver transplant protocols have focused on corticosteroid sparing or avoidance. Corticosteroid withdrawal may be possible in other organs, but is generally reserved for patients intolerant of steroid-induced adverse events. Avoidance or sparing of corticosteroids has been supported in the literature, although more studies are needed to help better characterize which patients should follow these protocols.[6,24] A typical taper includes a bolus of IV methylprednisolone 100 to 1000 mg at the time of transplant, then tapered over days to months, depending on the type of organ, to a maintenance dose of prednisone 5 to 10 mg/day. Although most centers still use low-dose steroids for immunologically high-risk patients, a number of renal and liver transplant programs have developed an immunosuppression protocol that completely withdraws corticosteroids at some point posttransplantation.[6] Therapeutic drug monitoring of corticosteroids is not employed. Corticosteroids are associated with a variety of metabolic toxicities. The most common adverse events are summarized in Table 55–4.[1,6]

KEY CONCEPT Corticosteroids have various effects on immune and inflammatory responses, although their exact mechanism of immunosuppression is not fully understood. It is believed that high doses are directly lymphotoxic, and lower doses inhibit the production of various cytokines.[6,7]

The most commonly used corticosteroids are methylprednisolone (IV and oral) and prednisone (oral), although prednisolone and dexamethasone are also effective for organ transplantation. Corticosteroid doses vary by center-specific protocols, organ type, and patient characteristics.

▶ *Costimulatory Pathway Blocker*

Belatacept KEY CONCEPT Belatacept was approved in 2011 as the first IV biologic maintenance immunosuppressive agent in transplant.[25] Belatacept blocks CD80 and CD86 ligands, found on APCs.[7] The CD80 and CD86 proteins are responsible for stimulating CD28 on inactive T-cells, an essential costimulatory interaction (Signal 2). Signal 1 without a complementary Signal 2 induces T-cell anergy.[25] Studies have shown that in combination with mycophenolate and corticosteroids, belatacept may be used

Table 55–4

Common Adverse Events Associated with Corticosteroids[1,6]

Body System	Adverse Event
Cardiovascular	Hyperlipidemia
	Hypertension
Central nervous system	Anxiety
	Insomnia
	Mood changes
	Psychosis
Dermatologic	Acne
	Diaphoresis
	Ecchymosis

	Impaired growth
	Osteoporosis
	Skeletal muscle weakness
Ocular	Cataracts
	Glaucoma
Respiratory	Epistaxis

in place of CNIs, demonstrating similar patient and allograft survival compared to a cyclosporine-based regimen.[26,27] Belatacept improved renal function; however, the incidence and intensity of acute rejection was significantly higher. Belatacept was also associated with improvements in blood pressure and lipid levels.[25]

Belatacept is available in a 250 mg vial that requires reconstitution prior to administration.[7] The recommended dosing regimen is 10 mg/kg on the day of transplantation, followed by an additional dose 4 days later, and again at the end of weeks 2, 4, 8, and 12 posttransplant. Beginning at the end of week 16 posttransplant, belatacept is dosed at 5 mg/kg every 4 weeks thereafter.[7,25] Belatacept requires access to an infusion center/suite, or a home infusion service to ensure appropriate administration. The monthly administration of belatacept could potentially improve adherence compared to daily oral CNIs. Additionally, the lack of significant drug–drug interactions has the potential to simplify pharmaceutical care in transplant recipients.

In the United States, belatacept is used most commonly months to years after transplant in patients intolerant of tacrolimus.[26] This is called conversion therapy. In patients who are being converted to belatacept from tacrolimus, the most common dosing schedule is 5 mg/kg every 2 weeks for five doses, then the dosing interval is changed to every 4 weeks. Tacrolimus may be discontinued in as little as 3 to 4 weeks, but in some situations may be tapered off over 6 to 12 months following conversion or used (low-dose) in combination with belatacept.[28]

The most common adverse effects associated with belatacept are infectious (urinary tract infection, 37%; upper respiratory infection, 15%), GI (diarrhea, 39%; constipation, 33%; nausea, 24%; vomiting, 22%), metabolic (hyperkalemia, 20%; hypokalemia 21%), and central nervous system (CNS; headache, 21%) complications.[7] Other adverse effects include peripheral edema, anemia, leukopenia, hypotension, arthralgia, and insomnia.[25] **KEY CONCEPT** Belatacept has a black-box warning for increased risk of posttransplant lymphoproliferative disorders (PTLD). Due to this risk, it is recommended that belatacept only be used in patients with a proven preexisting immunity to Epstein-Barr virus (EBV). An additional black-box warning advises against use of belatacept in liver transplant patients due to an increased risk of allograft loss and patient death.[7,25]

Treatment of Acute Rejection Episodes

Acute rejection is generally treated with a course of high-dose methylprednisolone (250–1000 mg/day IV for 3 days), which is usually sufficient to ameliorate the episode. If the acute rejection episode is resistant to the initial course of steroids, a second course may be administered or the patient may begin therapy with r-ATG (1.5 mg/kg/day for 4 to 14 days) or alemtuzumab (30 mg × 1 dose).[1] Cellular rejection refractory to these treatments is rare and likely due to underlying causes such as an antibody-mediated component or other diagnosis. Treatments of refractory acute rejection may include alemtuzumab, high-dose tacrolimus, IVIG, or organ irradiation.

Managing Highly Sensitized Patients and Antibody-Mediated Rejection

The presence of preformed antibodies, high panel-reactive antibodies (PRA), and DSA are major barriers to successful transplantation.[4] This is true because traditional immunosuppressants do not significantly affect the humoral response and are ineffective at management of AMR, which is a leading cause of allograft loss in kidney and heart transplant recipients. Without some form of intervention, antibody formation and rejection can significantly impact morbidity and mortality. Two major strategies are used for reduction of DSA pretransplant: (a) high-dose IVIG and (b) plasmapheresis plus low-dose IVIG. Each approach has advantages and disadvantages.[4]

In plasmapheresis or plasma exchange, patients' plasma is removed and replaced with albumin or fresh-frozen plasma.[4] Plasmapheresis reduces preformed antibodies and allows transplantation to occur. IVIG administration decreases anti-HLA alloantibody synthesis. The other mechanisms of IVIG are inhibition of complement-mediated injury, reduced B-cell proliferation and NK cells, and a decrease in phagocytosis. Most patients require four to five plasmapheresis sessions with IVIG to remove DSA. In patients at risk for bleeding, the use of albumin should be limited, and fresh-frozen plasma or a combination of both agents should be considered.[4]

In patients who develop AMR posttransplant, there are limited therapeutic options, none of which are FDA-approved. Potential options include plasmapheresis and IVIG, rituximab, proteasome inhibition, tocilizumab and/or complement inhibition.[4] All of these agents have an effect on humoral immunity, which may benefit patients with AMR. The mechanisms of plasmapheresis and IVIG were discussed earlier.[4]

Rituximab is a chimeric monoclonal anti-CD20 antibody targeting B-cells.[4,7] This agent directly inhibits B-cell proliferation and induces cellular apoptosis through complement-mediated antibody-dependent-cellular cytotoxicity. In an analysis of AMR treatment, the use of rituximab in conjunction with plasmapheresis/IVIG improved 3-year graft survival (92% versus 50%) and significantly reduced DSA at 3 months compared with high-dose IVIG alone.[29] Unfortunately, plasma cells lack CD20 and are unaffected by rituximab. However, rituximab may play an important role in reducing memory B-cell response. Overall, it appears that rituximab may provide beneficial effects in managing AMR and patients highly sensitized before transplant when used in combination with other therapies.[4]

Bortezomib and carfilzomib are proteasome inhibitors indicated for treatment of multiple myeloma.[4,7] They work by inducing cell-cycle arrest and apoptosis of plasma cells. Desensitization and treatment protocols using bortezomib have utilized doses of 1.3 mg/m^2 from one to four cycles. Acute hepatic dysfunction has rarely been reported; thus, bortezomib should be used cautiously in patients with moderate-to-severe hepatic impairment. Bortezomib has also been associated with significant myelosuppression and peripheral neuropathy. Bortezomib has been used in combination with plasmapheresis and IVIG or rituximab. The reported outcomes of these cases demonstrate graft survival rates of 85% to 100%. Anti-HLA antibodies are decreased by 50% within 2 weeks of therapy and remain suppressed for up to 5 months.[30,31] Bortezomib also seems effective in AMR refractory to plasmapheresis and IVIG.[4]

Tocilizumab is an interleukin-6 receptor antagonist that has been recently used for management of both acute and chronic AMR.[7,32] In a single-center, observational analysis of seven patients, tocilizumab (8 mg/kg/month) resulted in 50% or greater reduction in DSA in four of six treated patients. In all patients, renal function improved or stabilized following treatment with tocilizumab.[32] Further study is warranted to evaluate the efficacy of tocilizumab in the management of AMR.

Eculizumab is a humanized monoclonal antibody directed against complement protein C5.[7] It inhibits the cleavage to C5a and C5b, thus preventing the generation of the membrane attack complex (MAC) and reducing antibody-dependent-cell lysis. C1 esterase inhibitors also inhibit the complement cascade and may provide some benefit in managing AMR. Eculizumab carries an

FDA-boxed warning of meningococcal infection. Meningococcal vaccination is recommended 14 days prior to eculizumab, but infections have been reported even in vaccinated patients. It is highly recommended to continue penicillin or alternative lifetime therapy in these patients. There are only a few case reports demonstrating efficacy of eculizumab or the C1 esterase inhibitors for treating AMR.[4] Eculizumab is an important agent for the prevention and treatment of atypical hemolytic uremic syndrome (aHUS) posttransplant.

Maintenance Immunosuppressive Therapies—Common Drug–Drug Interactions

KEY CONCEPT As the number of medications a patient takes increases, so does the potential for DDIs. Disease severity, patient age, and organ dysfunction are all risk factors for DDIs. In general, DDIs are either pharmacokinetic or pharmacodynamic interactions:

- Pharmacokinetic interactions result when one drug alters the absorption, distribution, metabolism, or elimination of another drug.
- Pharmacodynamic interactions include additive, synergistic, or antagonistic interactions that can affect efficacy or toxicity.

▶ *Pharmacokinetic Interactions*

Pharmacokinetic DDIs pose a major dilemma with the maintenance immunosuppressants. Pharmacokinetic interactions can either result in: (1) increased concentrations of one or more agents, with an increased risk for drug-induced toxicities, or (2) lowered (ie, subtherapeutic) drug concentrations, possibly leading to allograft rejection. These interactions can be seen during drug absorption, distribution, metabolism, and elimination.

Interactions of Absorption Gut metabolism, modifications in active transport, changes in intestinal motility, and chelation interactions alter immunosuppressant absorption. Active transporters (ie, P-glycoprotein [P-gp]) are present in the gut, brain, liver, and kidneys and play an important role in DDIs. P-gp provides a biological barrier, eliminating xenobiotics that accumulate in organ systems, thereby having a significant impact on absorption and distribution of many medications. P-gp affects the absorption of the CNIs and ToR inhibitors. Medications that inhibit or induce the activity of P-gp have a significant impact on bioavailability of some immunosuppressive agents. For example, P-gp inhibitors, such as verapamil or quinidine, increase concentrations of cyclosporine, tacrolimus, sirolimus, and everolimus due to reduced P-gp-dependent drug elimination from systemic circulation.[7]

There is a prominent interaction between the prokinetic agents and the CNIs seen through changes in intestinal motility. Metoclopramide increases the absorption of cyclosporine and tacrolimus by enhancing gastric motility and emptying, resulting in increased CNI concentrations.[7]

Most of the interactions with MPA derivatives result in reductions in intestinal absorption. Proton pump inhibitors decrease the oral absorption of mycophenolate mofetil, but not enteric-coated MPA.[7] Divalent and trivalent cations (ie, aluminum, magnesium, calcium) decrease MPA absorption through chelation. These agents should be administered at least 1 hour before or 2 hours after MPA. Of note, iron does not appear to interact with the MPA preparations. The clinical implications of these DDIs are unknown, but reductions in MPA exposure can theoretically enhance rejection risk.

Interactions of Distribution Interactions of distribution occur most often with highly protein-bound drugs.[7] MPA is the only highly protein-bound (97%) maintenance immunosuppressant with an interaction of distribution. Concomitant administration of MPA with salicylates increases MPA-free concentrations. The adverse sequelae of this interaction are unknown. Drug interaction studies have not been conducted with MPA derivatives and other highly protein-bound drugs.

Interactions of Metabolism Oxidative metabolism by cytochrome P-450 (CYP) isozymes is the primary method of xenobiotic metabolism. The CNIs and ToR inhibitors are substrates of the CYP3A isozyme system. Most CYP-mediated metabolism takes place in the liver; however, CYP is also expressed in the intestine, lungs, kidneys, and brain. As CYP3A substrates, it is anticipated that cyclosporine, tacrolimus, sirolimus, and everolimus would experience similar DDIs with known substrates, inhibitors, and inducers of the CYP3A isozyme system.[6] Table 55–5 details clinically relevant DDIs that occur with the calcineurin and ToR inhibitors due to inhibition or induction of the CYP isozyme system.[7]

Given how extensive some immunosuppressant DDIs are, empiric dose changes are necessitated in some cases when coadministration with an interacting medication cannot be avoided. For example, it is recommended to reduce tacrolimus doses by one-third in patients initiating voriconazole. Some clinicians utilize interactions of metabolism to reduce the dose of an immunosuppressant, such as using diltiazem to treat hypertension, which also helps reduce tacrolimus doses and decrease pill burden.

Not all metabolic DDIs occur through the CYP system. Azathioprine interacts with allopurinol and febuxostat through the inhibition of xanthine oxidase, which is the enzyme responsible for metabolizing 6-MP to 6-thiouricate.[7] Combining these agents can result in 6-MP accumulation and severe myelosuppression. It is recommended that concomitant therapy with azathioprine and allopurinol or febuxostat be avoided, but if necessary, azathioprine doses must be empirically reduced by 75%.[7]

Interactions of Elimination Mycophenolate is metabolized to MPA-glucuronide (MPAG) via hepatic glucuronosyltransferase, then excreted in bile for gut elimination.[7] Deconjugation of MPAG to MPA by intestinal flora results in continued MPA absorption several hours after its administration. Some medications (ie, cyclosporine, bile-acid sequestrants) interfere with the biliary excretion of MPAG, thereby eliminating MPA reabsorption in the intestines and lowering the MPA area under the curve (AUC).[7] In this type of interaction, separation of doses is ineffective; therefore, proper patient monitoring is warranted.

▶ *Pharmacodynamic Interactions*

Pharmacodynamic interactions are the backbone of modern immunosuppressive therapies that employ multiple medications

Patient Encounter Part 2

Identify your treatment goals for the patient in terms of maintenance immunosuppressants.

Create a plan for maintenance therapy for the patient, making sure to compare and contrast the pros and cons of the different maintenance immunosuppressants.

Identify the need to continue the patient's pretransplant medications, and identify any potential DDIs that may exist with the addition of the maintenance immunosuppressants and the medications he is currently taking.

Table 55–5

Potential Drug–Drug Interactions with the Calcineurin Inhibitors and Target of Rapamycin Inhibitors Mediated through the Cytochrome P-450 (CYP) System 3A Isozyme[7]

Substrates[a]	Inducers[b]	Inhibitors[c]
Alfentanil	Apalutamide	Amiodarone
Alprazolam	Bexarotene	Aprepitant
Amiodarone	Bosentan	Atazanavir
Amlodipine	Carbamazepine	Boceprevir
Atorvastatin	Cenobamate	Ceritinib
Boceprevir	Dabrafenib	Cimetidine
Cilostazol	Dexamethasone	Clarithromycin
Cisapride	Efavirenz	Clotrimazole
Chlorpromazine	Enzalutamide	Cobicistat and cobicistat-containing coformulations
Clonazepam	Eslicarbazepine	Conivaptan
Cocaine	Ethosuximide	Crizotinib
Cortisol	Etravirine	Cyclosporine
Cyclophosphamide	Fosphenytoin	Darunavir
Dantrolene	Lorlatinib	Delavirdine
Dapsone	Lumacaftor	Diltiazem
Diazepam	Lumacaftor-ivacaftor	Dronedarone
Disopyramide	Mitotane	Duvelisib
Enalapril	Modafinil	Erythromycin
Estradiol	Nafcillin	Fedratinib
Estrogen	Nevirapine	Fluconazole
Etoposide	Pexidartinib	Fluoxetine
Everolimus	Phenobarbital	Fosamprenavir
Felodipine	Phenytoin	Fosaprepitant
Flutamide	Primidone	Grapefruit juice
Lidocaine	Rifabutin	Idelalisib
Loratadine	Rifampin (rifampicin)	Imatinib
Lovastatin	Rifapentine	Indinavir
Nevirapine	Rilpivirine	Isavuconazole (isavuconazonium sulfate)
Nicardipine	St. John's wort	Isoniazid
Nifedipine		Itraconazole
Omeprazole		Ketoconazole
Paclitaxel		Lefamulin
Propafenone		Letermovir
Progesterone		Lopinavir
Quetiapine		Miconazole
Quinidine		Mifepristone
Rilpivirine		Nefazodone
Rivaroxaban		Nelfinavir
Sertraline		Netupitant
Simvastatin		Nilotinib
Tamoxifen		Ombitasvir-paritaprevir-ritonavir
Testosterone		Ombitasvir-paritaprevir-ritonavir plus dasabuvir
Tolvaptan		Posaconazole
Triazolam		Ribociclib
Vandetanib		Rilpivirine
Venlafaxine		Ritonavir
Vinblastine		Ritonavir and ritonavir-containing coformulations
Warfarin		Saquinavir
Zolpidem		Telapravir
		Tucatinib
		Verapamil
		Voriconazole
		Zafirlukast

[a] Substrates of the CYP3A4 isozyme will compete with cyclosporine, tacrolimus, and sirolimus for metabolism; therefore, concentrations of these medications will be increased (usually by ≤ 20%).

[b] Inducers of the CYP3A4 isozyme will enhance the metabolism of cyclosporine, tacrolimus, and sirolimus; therefore, concentrations of these medications will be decreased.

[c] Inhibitors of the CYP3A4 isozyme will decrease the metabolism of cyclosporine, tacrolimus, and sirolimus; therefore, concentrations of these medications will be increased.

with different mechanisms of action resulting in additive immunosuppression. Unfortunately, pharmacodynamic interactions can also be problematic, such as when medications with similar adverse events are used concomitantly. For example, nephrotoxic agents, such as amphotericin B, and nonsteroidal anti-inflammatory drugs may potentiate the nephrotoxic effects of the CNIs.[7] The use of myelosuppressive agents, such as sulfamethoxazole-trimethoprim (SMZ-TMP) and valganciclovir, could enhance the myelosuppressive effects of induction therapy and maintenance immunosuppression.[7] In addition to reviewing prescription medications, it is essential to question patients about the use of nonprescription agents and dietary supplements, as these products also have the potential for significant interactions through methods discussed previously. For example, St. John's wort induces CNI and ToR inhibitor metabolism, while willow bark can worsen CNI-induced nephrotoxicity.

Management of Immunosuppressive Drug Complications

▶ *Opportunistic Infections*

KEY CONCEPT Organ transplant recipients are at increased risk of infectious diseases, which are a principal cause of early morbidity and mortality.[33] Prevalence of posttransplant infection depends on many factors, including clinical risk factors, environmental exposures, and the degree of immunosuppression. Anti-infectives are universally prescribed in this population, and their use can be split into three different categories:

- Prophylaxis: antimicrobials given to prevent infection
- Empiric: preemptive therapy given based on clinical suspicion of an infection
- Treatment: antimicrobials given to manage a documented infection

Posttransplant infections generally occur in a standard pattern; therefore, prevention is a key management strategy.[33] Information in this section is designed to highlight prophylaxis options routinely used in organ transplant recipients. Refer to Table 55–6 for a list of agents used for the prevention of *Pneumocystis jirovecii* pneumonia and CMV disease.[34,35]

***Pneumocystis jirovecii* Pneumonia** KEY CONCEPT Without prophylaxis, *P. jirovecii* pneumonia occurs in 5% to 15% of transplant recipients.[34] Antipneumocystis prophylaxis is used in all transplant recipients. Duration of prophylaxis is usually 6 to 12 months after transplant, but may be prolonged in highly immunosuppressed patients (ie, active CMV disease, treatment for rejection) or liver or lung recipients. SMZ-TMP is the preferred agent for prophylaxis. One of its major advantages is its broad spectrum of activity. Not only is it effective against *Pneumocystis*, but it

Table 55–6

Prophylactic Options for *Pneumocystis jirovecii* Pneumonia and CMV[34,35]

Medication	Dosing	Common Adverse Events
Antipneumocystis Prophylaxis		
Sulfamethoxazole-trimethoprim (Bactrim, Septra, SMZ-TMP, cotrimoxazole)	One SS tablet by mouth once a day[a] One DS tablet by mouth once a day[a] One DS tablet by mouth every M/W/F[a]	Hyperkalemia Myelosuppression Nephrotoxicity Neutropenia Photosensitivity Rash
Pentamidine (NebuPent)	300 mg inhaled every 4 weeks	Bronchospasm Cough Hypoglycemia or hyperglycemia
Dapsone (Avlosulfon)	100 mg tablet by mouth once a day 50 mg tablet by mouth once a day if combined with pyrimethamine/leucovorin	Hepatotoxicity Myelosuppression Nephritis
Atovaquone (Mepron)	1500 mg suspension by mouth once a day	Elevated liver transaminases Nausea Rash
Antivirals		
Valganciclovir (Valcyte)	450–900 mg by mouth once a day[a]	Stomach upset Myelosuppression Headache
Ganciclovir (Cytovene)	5 mg/kg IV every day[a]	Stomach upset Myelosuppression Rash
Valacyclovir (Valtrex)	1-2 g by mouth four times a day[a]	Stomach upset Myelosuppression Headache
Letermovir (Prevymis)	480 mg once daily	Stomach upset Headache
CMV hyperimmune globulin (CytoGam) and polyvalent IVIG	The maximum recommended total dosage per infusion is 150 mg/kg beginning within 72 hours of transplantation Follow-up doses and time intervals depend on the type of organ transplanted	Stomach upset Fevers and chills Flushing

[a]Dose adjustment required in renal insufficiency.

CMV, cytomegalovirus; DS, double-strength (800 mg SMZ, 160 mg TMP); IVIG, intravenous immunoglobulin; IV, intravenous; M/W/F, Monday, Wednesday, and Friday; SMZ, sulfamethoxazole; SS, single-strength (400 mg SMZ, 80 mg TMP); TMP, trimethoprim.

also has activity against *Toxoplasma* and other common bacterial infections. Patients who have sulfa allergies, glucose-6 phosphate dehydrogenase (G6PD) deficiency, or are intolerant of SMZ-TMP should be given one of the second-line treatments. Unfortunately, the second-line agents are antiparasitics and have no meaningful activity against common bacteria. These agents include dapsone, atovaquone, and pentamidine.[34]

Cytomegalovirus CMV is a concerning opportunistic pathogen in transplantation due to its association with poor outcomes.[35] CMV infection is present in 30% to 97% of the general population, but CMV disease is typically restricted to immunocompromised hosts. Risk of CMV disease is highest among CMV-naive recipients who receive a CMV-positive organ (donor+/recipient–). Other factors augmenting the risk of CMV disease include organ type (lung and pancreas recipients are highest risk) and immunosuppressive agents (ALA use increases risk). CMV disease characteristically occurs within the first 3 to 6 months posttransplantation, but delayed onset disease has been seen in patients receiving antiviral prophylaxis. Patients with CMV disease may present with flu-like symptoms, including fever, chills, aches, malaise, and fatigue. CMV disease may result in more profound symptoms in the immunosuppressed patient, including leukopenia, thrombocytopenia, and organ dysfunction.[35]

KEY CONCEPT Several antivirals have proven effective in preventing and treating CMV.[35] Valacyclovir and valganciclovir, prodrugs of acyclovir and ganciclovir, respectively, have improved bioavailability compared with their parent compounds and offer the advantage of less frequent dosing. Letermovir is a new antiviral agent that is effective against CMV, but is not yet FDA-approved for use in organ transplant recipients. Its use is limited to those intolerant to valganciclovir or with resistant CMV disease. CMV prophylaxis is typically continued for the first 200 days or longer after transplantation. Although valganciclovir and IV ganciclovir are considered the prophylaxis agents of choice in most organ transplant recipients, national guidelines allow for consideration of prophylaxis with CMV hyperimmune globulin in heart and lung transplant populations. Both IV ganciclovir and oral valganciclovir may be used for preemptive therapy or for treatment of established CMV disease. Alternative agents may be used in the event of ganciclovir-resistant CMV disease, such as foscarnet, cidofovir, IVIG, letermovir or even conversion from a CNI to mToR inhibitor-based immunosuppression.[35] Adverse events are similar among these agents and include myelosuppression and GI effects.[7]

Fungal Infections Fungal infections are an important cause of morbidity and mortality in SOT recipients.[36] Immunologic (ie, immunosuppressants, CMV infection), anatomic (ie, tissue ischemia and damage), and surgical (ie, duration of surgery, transfusion requirements) factors contribute to risk for invasive fungal infections. Mucocutaneous candidiasis (ie, oral thrush, esophagitis) is associated with corticosteroids and ALA. KEY CONCEPT Oral nystatin or clotrimazole troches are effective prophylactic options for prevention of thrush. However, clotrimazole inhibits the CYP3A system in the gut and can alter immunosuppressive levels.[7] Use of systemic antifungal prophylaxis, such as oral fluconazole, is controversial due to potential for DDIs and risk of developing resistance. The American Society of Transplantation has recommended antifungal prophylaxis in liver, lung, intestine, and pancreas transplantation.[37,38] Choice of agents depends on fungal risk in that particular population. For example, liver, intestine, and pancreas transplant recipients are at high risk for candidiasis; therefore, use of medications that cover *Candida* spp. is crucial, such as the triazoles (ie, fluconazole, itraconazole) or echinocandins (ie, caspofungin, micafungin, anidulafungin). Lung transplant recipients are at high risk for aspergillosis; therefore, it is imperative to use antifungal prophylaxis that covers *Aspergillus* spp., such as the echinocandins, polyenes (ie, amphotericin B, lipid-based amphotericin B products) or new generation triazoles (ie, voriconazole, posaconazole).[37,38]

Patient Encounter Part 3

Identify your treatment goals for the patient in terms of antimicrobial prophylaxis.

Create a plan for the patient's antimicrobial prophylaxis, making sure to compare and contrast the pros and cons of the different agents in this patient.

Polyomavirus One infection complication seen almost exclusively in renal transplant is polyomavirus. In humans, there are two pathologic polyoma strains, BK and JC. These viruses are rarely associated with disease in immunocompetent individuals. During periods of immunosuppression, the virus is reactivated and can be associated with significant morbidity.[39]

In renal transplant, the major diseases caused by BK virus (BKV) are tubulointerstitial nephritis and ureteral stenosis.[39] Polyomavirus-associated nephropathy (PyVAN) presents with evidence of allograft dysfunction, resulting in either an asymptomatic acute or slowly progressive rise in serum creatinine (SCr) concentrations. Some studies have reported PyVAN may affect up to 10% of renal transplant recipients, frequently resulting in permanent renal dysfunction or allograft loss.[39]

Currently, treatment options for BKV are limited, and management recommendations are generally focused on immunosuppression reductions. There are no directed antiviral interventions; however, some centers have utilized IVIG, cidofovir, or leflunomide to manage BKV infections. All of these agents have been reported to provide some benefit in managing BKV in anecdotal cases.[39]

Hepatitis C With the advent of new antiviral agents, hepatitis C infection can now be cured in most patients. In patients with a history of hepatitis C, antiviral therapy should be initiated prior to transplant, due to complications immunosuppression may play on viral replication.[40] One major avenue opened due to availability of these new agents is use of hepatitis C positive donor organs for transplantation into hepatitis C negative recipients. This allows for use of organs that were often deemed unusable and increases the pool of available organs, possibly reducing wait time for patients and subsequently reducing related morbidity and mortality. In these transplants, antivirals are initiated at time of transplant and given for several weeks following transplant. Viral loads are monitored to ensure hepatitis C infection does not take place.[40]

Vaccination Vaccination is one of the most effective means of preventing infection and related complications.[41] However, there is valid concern that SOT recipients may mount an inadequate response to vaccination due to immunosuppression. Required vaccinations should be administered prior to transplantation so an appropriate antibody response can develop (Table 55–7).[41] If this strategy is pursued, the earlier a vaccine is administered, the more effective it may be, as end-stage organ failure can also contribute to decreased immune response.[41]

In general, the weakest response to vaccine is within the first 6 months posttransplantation due to the intense level of

Table 55–7

Recommended Vaccinations Pre- and Posttransplant[41]

Vaccine	Administration		Additional Information
	Before SOT	After SOT	
Hepatitis A	X		Immunize as soon as possible during course of disease
Hepatitis B	X		Immunize as soon as possible during course of disease (before transplant, administer 40 mcg dose in a series of three to four doses)
Herpes Zoster	X	X	Live[a] virus, can only be administered pretransplant; administer ≥ 14 days before immunosuppressant agents are initiated (experts advise 1 month before) Recombinant herpes zoster vaccine only can be administered after transplantation
Human Papilloma Virus	X		Recommended for men and women ages 9–45, no recommendations for SOT
Influenza	X	X	Annual vaccination with inactivated intramuscular formulation recommended before and after SOT
Measles-Rubella	X		Live[a] virus, administer to patients who are seronegative, *before* transplant, or in women of childbearing age for prevention of congenital rubella syndrome
Meningococcal	X	X	Should be considered in patients at high-risk for antibody-mediated rejection when use of a complement inhibitor may be utilized posttransplant
Pneumococcal	X	X	23-valent polysaccharide vaccine should be given once before transplant and booster at 5 years after initial dose
Tetanus/Diptheria	X		TDaP booster indicated for < 65 years old (may be given ≤ 2 years after last TDaP booster in SOT patients)
Varicella	X		Live[a] virus, administer to patients who are seronegative, *before* transplant

[a] All live vaccines are contraindicated post solid organ transplant (SOT), as they can cause serious infection.

Live vaccines:

- Bacillus Calmette-Guerin
- Herpes zoster
- Live intranasal attenuated influenza
- Live oral typhoid
- Measles-rubella
- Vaccinia (smallpox)
- Varicella

TDaP, tetanus, diphtheria, and pertussis.

immunosuppression during this period.[41] Vaccination within 6 months of transplant may be considered on a case-by-case basis in those patients who are at high risk of developing infection. Use of inactive vaccines is preferred in transplant recipients due to relative risk of infection associated with live vaccines. Healthcare workers and family members who are in close contact with transplant recipients and have received a live vaccine should consider use of respiratory masks for at least 7 days after vaccination and adhere to strict oral and hand hygiene.[41]

▶ *Hypertension*

KEY CONCEPT Cardiovascular disease is the leading cause of death in organ transplant recipients.[42] Posttransplant hypertension is associated with increased cardiac morbidity and patient mortality in transplant patients and is also an independent risk factor for allograft dysfunction. Based on posttransplant morbidity and mortality data, it is imperative that posttransplant hypertension be identified and managed appropriately.[42]

There are several mechanisms responsible for posttransplant hypertension including renal dysfunction, increased sensitivity to endothelin-1 and angiotensin, increased density of glucocorticoid receptors in the vascular smooth muscle, and decreased production of vasodilatory prostaglandins. However, one of the most easily recognized causes of posttransplant hypertension is the use of corticosteroids and CNIs. Corticosteroids cause sodium and water retention, thus increasing blood pressure, whereas CNIs reduce glomerular filtration rate (GFR) and renal blood flow, increase systemic and intrarenal vascular resistance, promote sodium retention, reduce concentrations of systemic vasodilators (ie, prostacyclin, nitric oxide), and increase concentrations of thromboxanes. Compared with cyclosporine, tacrolimus displays significantly less severe hypertension, and patients taking tacrolimus require fewer antihypertensive medications posttransplant.[42]

Treatment **KEY CONCEPT** Controlling hypertension after transplant is essential in preventing cardiac morbidity and mortality and prolonging graft survival. The target blood pressure in transplant recipients should be less than 130/80 mm Hg, consistent with national hypertension guidelines.[42]

Lifestyle Modifications To achieve goal blood pressure, lifestyle modifications including diet, exercise, sodium restriction, and smoking cessation are recommended.[42] Unfortunately, lifestyle modifications alone are often inadequate in high-risk populations, and antihypertensive medications are usually initiated early after transplant.[42]

Immunosuppressive Regimen Modification Because tacrolimus has shown the propensity to cause less severe hypertension compared to cyclosporine, conversion from cyclosporine to tacrolimus may be one way to reduce the severity of hypertension in transplant recipients. **KEY CONCEPT** Conversion to a ToR inhibitor or belatacept, which are not associated with hypertension, may also be an alternative to the CNIs in patients with difficult-to-control hypertension. Corticosteroid taper or withdrawal are effective strategies for lowering blood pressure, but are not warranted in all clinical situations.[42]

Antihypertensive Agents There is no single class of antihypertensive medications recognized as the ideal agent. Numerous factors must be considered when determining appropriate treatment, including the safety and efficacy data of available agents, patient-specific comorbidities, and medication cost.[42] A large majority of patients often require multiple medications to achieve goal blood pressure, and combination therapy is regarded as appropriate first-line therapy.[42]

The limited clinical studies support use of calcium channel blockers (CCB) posttransplantation. Dihydropyridine CCBs have been associated with a higher GFR and lower incidence of allograft loss. Dihydropyridine CCBs have demonstrated an ability to reverse nephrotoxicity associated with cyclosporine and tacrolimus. However, use of diltiazem and verapamil is discouraged for the treatment of hypertension because of potential DDIs and lack of strong evidence in renal and liver transplant recipients. Addition of diltiazem to patients' regimens after cardiac transplant has also been shown to retard progression of cardiac allograft vasculopathy. β-Blockers and thiazide diuretics have proven benefits in reducing cardiovascular disease–associated morbidity and mortality in the general population.[42] Tolerability permitting, these agents are to be considered second and third therapies in most transplant recipients. The angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARB) have definite benefits in patients with nephropathy and are believed to have renoprotective effects in most patients. However, due to their ability to cause an initial increase in SCr, these agents should be used cautiously when combined with the CNIs. In general, antihypertensive therapy should focus on agents with proven benefits in reducing progression of cardiovascular disease and must be tailored to a patient's needs.[42]

▶ *Hyperlipidemia*

KEY CONCEPT Hyperlipidemia is seen in up to 60% of transplant patients.[43] As a result of elevated cholesterol levels, transplant recipients are not only at increased risk of atherosclerotic events, but also allograft vasculopathy. Hyperlipidemia, along with other types of cardiovascular disease, is now one of the primary causes of morbidity and mortality in long-term transplant survivors.[43]

Elevated cholesterol levels in transplant patients are due to age, genetic disposition, renal dysfunction, DM, proteinuria, body weight, and immunosuppressive therapy. Many immunosuppressive agents can produce elevations in serum lipid levels.[43]

Treatment KEY CONCEPT Lowering cholesterol has been shown to significantly decrease severe rejection and transplant vasculopathy and improve 1-year survival in heart transplant recipients.[44] Although these results cannot be extrapolated to other transplant populations, they do demonstrate the potential benefits of aggressive cholesterol lowering in organ transplant recipients. Due to high prevalence of cardiovascular disease among organ transplant recipients, most practitioners consider these patients to be high risk for lipid lowering. Many guidelines state a target calculated low-density lipoprotein cholesterol (LDL-C) level of less than 100 mg/dL (2.59 mmol/L) in high-risk patients.[44] Note: national guidelines for treating hyperlipidemia in the general population are often followed, despite lack of transplant recommendations. Refer to Chapter 13, "Dyslipidemias," for additional information.

Lifestyle Modifications Generally, lowering cholesterol in patients begins with therapeutic lifestyle changes, including reduction in saturated fat and cholesterol intake and increase in moderate physical activity.[43] However, lifestyle modifications alone rarely allow a patient to achieve goal LDL-C level. Modification of the immunosuppressive regimen and use of cholesterol-lowering medications are often warranted.[43]

Immunosuppressive Regimen Modifications Tacrolimus has shown the propensity to cause less severe hyperlipidemia when compared with cyclosporine. Conversion from cyclosporine to tacrolimus may be one way to counteract dyslipidemia in transplant recipients. Also, the ToR inhibitors have been associated with significant changes in lipids and triglycerides; therefore, conversion from a ToR inhibitor to a CNI or belatacept may be warranted in patients with resistant dyslipidemia.[43]

Cholesterol-Lowering Agents 3-Hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, or statins, are considered first-line therapy for hyperlipidemia in the general population.[43] However, there is some uncertainty about the pathogenesis of cardiovascular disease in transplant recipients and whether statin therapy will have similar effectiveness in organ transplant recipients. Statins have shown definite advantages when used in heart transplantation, including reduction in LDL-C and major adverse cardiac events (MACE), as well as an apparent cardioprotective effect. In renal transplant recipients, statins lower LDL-C levels and reduce incidence of some cardiac events; however, the ability to lower MACE has not been seen in this population. Despite these mixed results, statins are still considered the primary therapeutic option for hyperlipidemia in organ transplant recipients. When choosing a statin for management of hyperlipidemia in the transplant patient, a focus on potential DDIs is warranted. Use of cyclosporine in conjunction with simvastatin is considered a contraindication due to risk of skeletal muscle effects.[43]

Proprotein convertase subtilisin kexin type 9 inhibitors are a relatively new class of antihyperlipidemics that promote clearance of LDL-C through increased LDL-C receptors.[7] This class has proven effective in cholesterol lowering and prevention of primary and secondary adverse coronary events in the general population; however, their safety and efficacy in organ transplant recipients is unknown. Fibric acid derivatives are an excellent choice for lowering triglycerides, but are not as effective as statins at lowering LDL-C.[43] These agents play a role in conjunction with statins in patients with both elevated cholesterol and triglycerides. Nicotinic acid is very effective at improving the lipid panel, with excellent results in lowering LDL-C, as well as increasing high-density lipoprotein cholesterol (HDL-C). However, patient tolerability is a concern with this agent. The bile acid sequestrants should be avoided in transplant recipients due to their high incidence of GI adverse events, as well as their propensity for pharmacokinetic DDIs with MPA. Ezetimibe has proven safe and effective in lowering LDL-C in renal transplant recipients. Future studies are needed to establish ideal regimens involving antihyperlipidemic and immunosuppressive medications to decrease morbidity and mortality and ultimately prevent cardiovascular events.[43]

▶ *New-Onset DM after Transplantation*

KEY CONCEPT New-onset DM after transplantation (NODAT) is a serious complication that is often underestimated by transplant practitioners.[45] The incidence of NODAT has been reported as 4% to 25% after renal transplant, 2.5% to 25% after liver transplant, 4% to 40% after heart transplant, and 30% to 35% after lung transplant.[46] Even more alarming is that recent studies have revealed an overwhelming prevalence of impaired glucose tolerance, which is also accepted as a risk factor for long-term morbidity and mortality. NODAT is associated with a 22% higher risk of mortality. Patients with NODAT are also more likely to suffer acute rejection episodes and infectious complications.[45]

Prevention KEY CONCEPT NODAT prevention mainly consists of identifying patients at risk before transplant and controlling modifiable risk factors both before and after transplantation.[45] The major modifiable risk factors are choice of immunosuppressive therapy and body mass index (BMI). For example:

- Immunosuppressive medications: Steroid minimization and possibly withdrawal are effective strategies for preventing NODAT. Also, patients with worsening blood glucose who are receiving tacrolimus may benefit from conversion to cyclosporine or belatacept.[45]
- BMI: A reduction in body weight is recommended in obese patients prior to transplant to lower their NODAT risks.[45]

Treatment KEY CONCEPT Lifestyle modifications are recommended in patients who have developed or those who are at increased risk of developing NODAT.[45] Insulin therapy and oral hypoglycemic agents are often utilized in those patients in whom lifestyle modifications alone have not controlled blood glucose. Refer to Chapter 44, "Diabetes Mellitus," for proper instruction on choosing the appropriate treatment regimens in patients with DM.

▶ *Neoplasia*

Cancer Screening in Transplant Patients Transplant recipients are at increased risk for malignancies (Table 55–8).[47,48] The risk of developing Kaposi sarcoma following transplantation is over 200 times that in the general population. In addition, the risk of nonmelanocytic and melanocytic skin cancer is 10 to 20 times higher compared with the nontransplanted population. Transplant recipients are at greatest risk for the types of cancers associated with viral infections, such as PTLD, cervical, and vulvovaginal cancers. Solid organ tumors like colorectal and lung cancers are two to three times higher in transplant recipients when compared with the general population. The American Cancer Society and American Transplant Society recommend cancer screening for most adults who have undergone transplantation (Table 55–9).[47,48] Although clinical research has not yet proven potential benefits of testing outweigh the harms of testing in transplant recipients, most believe transplant recipients should be tested and screened very closely.[47]

Table 55–8

Overall Risk of Different Types of Cancer in Transplant Patients[47,48]

Cancer	Cumulative Incidence (per 100,000)	Male	Female
Kaposi sarcoma	140	17.4	62
Kidney/ureter	1010	14.1	14.6
Lymphoma	80	6.9	29.1
Bladder	126	1.6	3.6
Esophagus	70	2.4	2.8
Cervix	180	–	5.7
Liver	220	4.2	4.5
Melanoma	320	6.9	5.2
Lung/bronchus/trachea	690	2.3	3.6
Colorectal	510	1.6	2.8
Breast	1050	4	1.1
Prostate	1740	1.6	–

Skin Cancer Skin cancer remains the most common malignancy after transplantation. Incidence of these types of cancers increases with time posttransplant, with one study showing a prevalence rate of 35% among patients within 10 years after transplant. Also, skin cancers in transplant recipients tend to grow more rapidly and are more likely to metastasize.[47]

The most common risk factors for skin cancer development after transplant include increased age; excessive ultraviolet (UV) light exposure; high degree of immunosuppression; Fitzpatrick skin types I, II, and III; history of skin cancers; and infection by human papillomavirus.[47] KEY CONCEPT Many believe that ToR inhibitors in place of CNIs in transplant recipients can reduce risk of nonmelanoma skin carcinomas.[49]

Transplant practitioners must educate their patients about excessive exposure to the sun.[47] Patients should be warned about the risk of skin cancer and advised on simple methods to limit risk:

- Wear protective clothing (ie, long-sleeved shirts, pants, dark-colored clothing).
- Apply sunscreen, sun protection factor (SPF) 30 or higher, daily to all sun-exposed skin.

The ToR inhibitors have activity against basal and squamous cell carcinoma and should be considered in patients with a history of these malignancies or those that develop these malignancies de novo posttransplant.

▶ *Posttransplant Lymphoproliferative Disorders (PTLDs)*

KEY CONCEPT PTLDs are a major complication following organ transplantation.[47] Large series of case reports have demonstrated the incidence of PTLD is 1% for renal patients, 1.8% for cardiac patients, 2.2% for liver patients, and 9.4% for heart–lung patients. The risk of developing non-Hodgkin lymphoma is nearly 50-fold higher in organ transplant recipients compared with the general population. Another risk factor is presence of EBV. Lymphomas are the most common form of PTLD.[47,48]

Disease incidence depends on certain factors including the type of organ transplanted, age of the transplant recipient, type and degree of immunosuppression, and exposure to EBV. Mortality rate in these patients is 50%, with most dying shortly after diagnosis. It has also been demonstrated that risk of developing PTLD is greater in EBV seronegative patients.[47,48] Belatacept has a black-box warning outlining an increased risk of PTLD, especially of the CNS. Patients who are EBV seronegative or have an unknown immunity to EBV should not receive belatacept. Also, immunosuppressive regimens utilizing the ALAs have been proven to increase risk of PTLD.[47,48]

Treatment KEY CONCEPT Treatment for PTLD is still controversial; however, the most common treatment options include reduction of immunosuppression, chemotherapy, and anti–B-cell monoclonal antibodies.[47,48] PTLD continues to be a long-term complication of prolonged immunosuppression. Current treatment options are all associated with certain risks. Prevention is the most effective treatment for PTLD. A better understanding of the disease process and risk factors involved will aid in prophylaxis and treatment of this disorder.[47,48]

▶ *Pregnancy*

Women of childbearing age require adequate education on family planning and preferred forms of birth control.[50] The optimal

Table 55–9

Cancer Screening Recommendations in Transplant Patients[47,48]

Cancer Type	General Populations	Transplant Populations
Breast	Mammography every 1–2 years for all women ≥ 50 years old Clinical breast examination every 3 years in women 20–39 years old, yearly after age 40 Monthly self-examination	Mammography every 1–2 years for all women ≥ 50 years old May undergo screening between 40 and 49 years old but no evidence for or against screening in this age group
Cervical	Annual Pap smear and pelvic examination once sexually active; after three or more tests with normal results, may decrease frequency of examinations	Annual Pap smear and pelvic examination once sexually active
Colorectal	Annual FOBT plus flexible sigmoidoscopy every 5 years for all patients ≥ 50 years old or colonoscopy and DRE every 10 years	Annual FOBT plus flexible sigmoidoscopy every 5 years for all transplant patients ≥ 50 years old
Prostate	Annual DRE and PSA for men ≥ 50 years old with 10-year life expectancy or younger men at high risk	Annual DRE and PSA measurement in all males ≥ 50 years old
Hepatocellular	Not recommended for average-risk individuals α-Fetoprotein and ultrasound every 6 months in high-risk patients (no firm supporting data)	α-Fetoprotein and ultrasound every 6 months in high-risk patients (no firm supporting data)
Skin	Skin examination every 3 years between ages 20 and 40, annually thereafter	Monthly self-examination Total body skin examination every 6–12 months by dermatologists
Renal	Insufficient evidence to support routine screening	No firm recommendations Regular ultrasound of native kidneys
Lung	Insufficient evidence to support routine screening	No firm recommendations
Ovarian	Insufficient evidence to support routine screening	No firm recommendations
Testicular	Insufficient evidence to support routine screening	No firm recommendations
Endometrial	Insufficient evidence to support routine screening	No firm recommendations

DRE, digital rectal examination; FOBT, fecal occult blood test; PSA, prostate-specific antigen.

method of birth control in this population is barrier method (eg, condom, diaphragm). Use of intrauterine devices and progestin-based oral contraceptives is controversial and associated risks must be considered. Intrauterine devices may be less effective in the setting of immunosuppression and predispose patients to increased risk of infection. Progestin-based contraceptives are considered a less effective form of birth control, but may be a safe option in patients without hypertension.[50]

Those considering pregnancy after transplantation should be educated extensively regarding the potential impact of pregnancy on renal function and the risks transplantation and medical immunosuppression may present a fetus.[50] Risks to the infant include premature birth (50%) and intrauterine growth restriction (20%), which may result in death or long-term complications, including cerebral palsy, blindness, deafness, and learning deficiencies. Patients should wait at least 1 year after transplantation to ensure reconstitution of gonadal function posttransplant, as well as demonstrate 1-year freedom from acute rejection.[50]

Understanding the associated risk of immunosuppressives while pregnant is paramount considering their ability to cross the placenta, as well as enter breast milk.[50] Tacrolimus and cyclosporine, both pregnancy category C, are the backbone of immunosuppressive therapy and have been used safely and effectively in pregnancy posttransplant. Side effects associated with CNIs such as hypertension, diabetes, and nephrotoxicity should be monitored closely in the pregnant population. The ToR inhibitors are also pregnancy category C and have not been associated with fetal malformation but should be used cautiously in pregnant patients. Corticosteroids, pregnancy category B, are recognized as relatively safe and have been used extensively in pregnancy after transplantation. However, they carry a risk of premature membrane rupture and newborn adrenal insufficiency. More common side effects associated with corticosteroids that may cause complications in pregnancy include hypertension, diabetes, weight gain, and poor wound healing. Due to teratogenic effects in animal studies, azathioprine is considered pregnancy category D; however, it has been used extensively as an antimetabolite in pregnant transplant patients without extensive evidence of harm to the fetus. 6-Mercaptopurine does not cross the placental barrier.[50]

Currently, the MPA derivatives, both pregnancy category D, are not considered optimal immunosuppressive agents for patients who become pregnant, and alternative therapies should be pursued.[50] These agents have a FDA-approved risk evaluation and minimization strategy to help minimize fetal exposure to MPA, prevent unplanned pregnancies in patients using MPA, collect data on MPA use in pregnancy via the Mycophenolate Pregnancy Registry, and educate patients about the risks associated with the use of this medication. A less teratogenic antimetabolite, azathioprine, should be substituted for MPA products in patients who plan on becoming pregnant. Both belatacept and everolimus are pregnancy category C but are not recommended for use in pregnant patients due to inadequate human data.[50]

▸ *Immunosuppressant Therapy Adherence*

Transplant recipients require strict adherence to medications to ensure optimal outcomes. Nonadherence in this population is attributed to the regimen's complexity, coupled with the variability in drug dosing, need for therapeutic drug monitoring, potential DDIs, infectious risks, and drug toxicities. The incidence of nonadherence to immunosuppressant therapy in the first year posttransplant has been estimated to be as high as 23%.[51] This is alarming when 35% of all graft failures are directly attributed to nonadherence. Risk factors associated with immunosuppressant therapy nonadherence include a history of substance abuse,

Patient Encounter Part 4

The patient continues to have his posttransplant care at your cardiac transplant ambulatory care clinic. He returns to your clinic 1 month after transplant.

Labs:

Na: 142 mEq/L (mmol/L)

Medications:

- Tacrolimus 6 mg by mouth twice daily (goal 8-12 ng/mL [mcg/L]; 9.9-14.9 nmol/L)
- Mycophenolate mofetil 1000 mg by mouth twice daily
- Prednisone 10 mg by mouth once daily
- Atovaquone 1500 mg by mouth once daily
- Valganciclovir 900 mg by mouth once daily
- Nystatin 500,000 units swish and swallow four times daily
- Aspirin 81 mg by mouth once daily
- Pravastatin 20 mg by mouth once daily
- Furosemide 20 mg by mouth twice daily
- Levothyroxine 50 mcg by mouth once daily
- Sertraline 50 mg by mouth once daily
- Allopurinol 100 mg by mouth once daily
- Insulin glargine inject subcutaneously 20 units every night
- Insulin aspart 8 units inject subcutaneously three times daily with meals

Identify why the patient is taking each agent listed.

What are some treatment options for the patient's elevated blood pressure?

What are some treatment options for the patient's elevated cholesterol?

What are some treatment options for the patient's elevated potassium?

Design a monitoring plan for the patient's therapy.

personality disorders, and lack of social support. The role of healthcare providers in educating patients on the importance of their medication regimens and stressing the need for adherence is paramount to optimize patient and allograft survival. Previous reports have suggested intervention by a pharmacist posttransplant improves adherence.[51]

OUTCOME EVALUATION

- Successful outcomes in solid-organ transplantation are measured in terms of: (a) preventing rejection, (b) preventing drug complications, and (c) improving long-term survival.
- By accomplishing the goals listed above, transplant clinicians hope to attain good allograft function to allow for improved quality of life. These goals can be achieved through appropriate use of medical immunosuppression and scrutinizing the therapeutic and toxic monitoring parameters associated with each medication employed. In addition, transplant recipients should be monitored for adverse drug reactions, DDIs, and adherence with their therapeutic regimen.
- Long-term goals after organ transplant are to maximize functionality of the allograft and prevent the complications of immunosuppression, which lead to improved patient survival. Clinicians must play multiple roles in the long-term care of transplant recipients, as not only must the patient be followed from an immunologic perspective, but practitioners must be focused on identifying and treating adverse sequelae associated with lifelong immunosuppression including cardiovascular disease, malignancy, infection, and osteoporosis, among others. Again, limiting drug misadventures and ensuring adherence with the therapeutic regimen are important and should be stressed.

Patient Care Process

Collect Information:

- Perform a pretransplant evaluation, including taking a medication history for use of prescription, nonprescription, and complementary and alternative medications. Identify allergies to medications and other substances.
- Review all available diagnostic and laboratory data, and patient history and comorbidities to evaluate patient for transplant.
- Speak with the patient and review records to identify lifestyle habits, preferences and beliefs, health goals, and socioeconomic factors that affect medication access and adherence and other aspects of care.

Assess the Information:

- Document current medications that should be addressed prior to a surgical procedure (eg, anticoagulation, antiplatelet therapies).

(Continued)

Patient Care Process (*Continued*)

- Identify comorbidities and how they may impact patient and allograft survival, and medication adherence.
- Review relevant laboratory tests (eg, PRA, infectious serologies of the recipient and donor).
- Evaluate current medications that will be continued posttransplant such as drugs to treat concomitant disease states (eg, hypertension, DM, dyslipidemia).
- For medications likely to be continued posttransplant, assess efficacy, safety, adherence, and any significant drug interactions with potential immunosuppressants or other medications following transplant. Are there any financial issues surrounding medications or access?
- Determine whether patient is taking any substance that could adversely affect transplant outcomes.
- Based on allergy history, determine whether the patient has compelling reasons to avoid center-specific immunosuppressants (eg, macrolide antibiotic allergy and tacrolimus) or antimicrobial prophylaxis (eg, sulfa allergy and SMZ-TMP).

Develop a Care Plan:

- Develop patient-specific short-term and long-term therapeutic goals.
- Evaluate patient-specific immunogenic risk based on donor and recipient characteristics and tissue typing at the time of transplant (eg, donor-specific antibodies, crossmatch).
- Propose an immunosuppressive regimen following transplantation, including:
  - Induction therapy (see Table 55–2):
    - Determine if patient requires induction therapy based on type of organ being transplanted and patient's immunogenic or infectious risk.
    - If induction therapy is warranted, assess for appropriate drug choice, dose, and duration of therapy and develop a monitoring plan.
  - Maintenance immunosuppressive agents (see Tables 55–2, 55–3, 55–4, and 55–5, and Figure 55–2):
    - Assess for appropriate choice, dose, and duration of therapy considering center-specific maintenance immunosuppressive policies and need for individualization based on patient's immunogenic or infectious risks.
    - Assess for eligibility to utilize a steroid withdrawal regimen, or a CNI-sparing regimen considering comorbidities or medication intolerance.
    - Assess the need for therapeutic drug monitoring and allograft function surveillance.
  - Antimicrobial prophylaxis (see Table 55–6):
    - Assess suitability of chosen prophylactic agents (eg, drug allergies, CMV donor and recipient serostatus, need for antifungal prophylaxis).
  - Medications used for comorbidities:
    - Assess appropriate selection of medications for pharmacokinetic and pharmacodynamic DDIs, need, efficacy, and side effects.
    - Determine if patient has insurance coverage and what agents are on formulary.

Implement the Care Plan:

- Educate the patient and caregiver about the organ transplant, complications associated with transplantation, need for lifestyle modifications to reduce risk of complications (eg, wear sunscreen, low-sodium diet, precautions to prevent contracting infection), drug therapy (including importance of adherence to therapeutic regimen and insurance/payer information), changes in drug therapy, medication administration, potential adverse effects, and how to manage and report adverse effects that occur.
- Address patient concerns about management of comorbidities, including medication adherence and lifestyle modifications.
- Determine whether the patient has insurance coverage or whether recommended agents are included on the institution's formulary.

Follow-up: Monitor and Evaluate:

- General therapeutic monitoring parameters based on organ transplanted and toxic monitoring parameters for medications prescribed.
- Continually evaluate the patient for presence of adverse drug reactions, drug allergies, or DDIs.
- In outpatient transplant clinic:
  - Monitor therapeutic parameters for allograft function and signs and symptoms of over- or under-immunosuppression by reviewing physical examination, lab tests, and results of other diagnostic tests.
  - Obtain a thorough history of prescription, nonprescription, and complementary and alternative medication use.
  - Monitor the patient's maintenance immunosuppression, including adherence.
  - Assess for appropriate dose, duration of therapy, and toxic monitoring parameters for all prescribed medications.
- Antimicrobial prophylaxis:
  - How long does the patient need to continue prophylaxis therapy?
- Medications used for comorbidities:
  - Assess appropriate selection of medications for pharmacokinetic and pharmacodynamic DDIs, need, and efficacy.
  - Assess for new or worsening comorbid disease and whether new medications are needed for existing comorbidities or new diagnoses.
- Reassess patient-specific short- and long-term therapeutic goals.
- Continue with patient education regarding complications associated with transplantation, need for lifestyle modifications to reduce risk of complications (eg, wear sunscreen, low-sodium diet), and drug therapy.
- Reemphasize the importance of adherence with therapeutic regimen.
- Assess improvement in quality-of-life measures such as physical, psychological, and social functioning, and well-being.

Abbreviations Introduced in This Chapter

6-MP	6-Mercaptopurine
ACE	Angiotensin-converting enzyme
aHUS	Atypical hemolytic uremic syndrome
ALA	Antilymphocyte antibodies
AMR	Antibody-mediated rejection
APC	Antigen-presenting cell
ARB	Angiotensin receptor blocker
AUC	Area under the curve
BKV	BK virus
BMI	Body mass index
BUN	Blood urea nitrogen
C_0	Trough concentration
CCB	Calcium channel blocker
$CD4^+$	Helper T-cells
$CD8^+$	Cytotoxic T-cells
CKD	Chronic kidney disease
CMV	Cytomegalovirus
CNI	Calcineurin inhibitor
CNS	Central nervous system
CXR	Chest x-ray
CYP	Cytochrome P-450
DC	Dendritic cell
DDI	Drug–drug interaction
DM	Diabetes mellitus
DOE	Dyspnea on exertion
DRE	Digital rectal examination
DS	Double strength
DSA	Donor-specific antibody
e-ATG	Antithymocyte globulin equine
EBV	Epstein-Barr virus
ESRD	End-stage renal disease
FBS	Fasting blood sugar
FDA	Food and Drug Administration
FEV	Forced expiratory volume
FOBT	Fecal occult blood test
G6PD	Glucose-6-phosphate-dehydrogenase
GFR	Glomerular filtration rate
GI	Gastrointestinal
HDL-C	High-density lipoprotein cholesterol
HLA	Human leukocyte antigen
HMG-CoA	3-Hydroxy-3-methylglutaryl coenzyme A
Ig	Immunoglobulin (A, G, etc.)
IL-2	Interleukin-2
IV	Intravenous
IVIG	Intravenous immunoglobulin
LC-MS/MS	Liquid chromatography coupled to tandem mass spectrometry
LDL-C	Low-density lipoprotein cholesterol
LFT	Liver function test
MAC	Membrane attack complex
MACE	Major adverse cardiac events
MHC	Major histocompatibility complex
MPA	Mycophenolic acid
MPAG	MPA-glucurinide
NK	Natural killer
NODAT	New-onset diabetes mellitus after transplantation
NYHA	New York Heart Association
P-gp	P-glycoprotein
PRA	Panel-reactive antibodies
PSA	prostate-specific antigen
PTLD	Posttransplant lymphoproliferative disorders
PyVAN	Polyomavirus-associated nephropathy
r-ATG (RATG)	Antithymocyte globulin rabbit
SCr	Serum creatinine
SL	Sublingual
SMZ-TMP	Sulfamethoxazole-trimethoprim
SOB	Shortness of breath
SOT	Solid organ transplant
SPF	Sun protection factor
SPK	Simultaneous pancreas-kidney
SS	Single strength
TCR	T-cell receptor
TDaP	Tetanus, diphtheria, and pertussis
ToR	Target of rapamycin
TPMT	Thiopurine methyltransferase
UV	Ultraviolet

56 Systemic Lupus Erythematosus

Cassandra Dolecki, Marisha Okpala,
and Jessica Farrell

LEARNING OBJECTIVES

Upon completion of the chapter, the reader should be able to:

1. Discuss the incidence and risk factors for systemic lupus erythematosus (SLE).
2. Describe key events in the pathogenesis of SLE including contributions of genetics, hormonal, and environmental factors to the immune dysfunction.
3. Explain symptoms and signs of the disease and tissue damage associated with SLE.
4. List diagnostic criteria for SLE.
5. Recommend nonpharmacologic therapies including cognitive behavioral therapy, sun protection and smoking cessation.
6. Compare and contrast pharmacologic treatment options for SLE by their mechanisms of action, side effects, contraindications, and effectiveness.
7. Discuss the clinical manifestations and appropriate therapy used to treat the corresponding disease manifestations associated with SLE.
8. Provide a counseling plan for adjunct therapies used to treat clinical manifestations of SLE.

INTRODUCTION

Often difficult to diagnose, systemic lupus erythematosus (SLE) is a heterogeneous autoimmune disease in which the immune system attacks the body's own tissue, causing inflammation and tissue damage. A delay in definitive diagnosis can lead to delays in organ-saving treatment. SLE often involves multiple organs and is characterized by flares and periods of quiescence.

EPIDEMIOLOGY AND ETIOLOGY

The incidence and prevalence of SLE is highest in North America, with estimates at 23.2 per 100,000 person-years, and 241 cases per 100,000 people.[1] Known risk factors for SLE include demographics, genetics, and interactions with environmental triggers. **KEY CONCEPT** The strongest risk factor for SLE is gender. Nine of 10 people living with a lupus diagnosis are women,[2] and women of color are disproportionately affected. On average, women of color are two to three times more likely to have SLE and more severe disease.[2] Women of childbearing age are also most likely to be affected, with most diagnoses occurring between 15 and 44 years of age.[2] Genetics may predispose some individuals to the development of SLE after interactions with certain triggers. Normal variations in a variety of genes can increase the risk of developing SLE, and in most cases, multiple genes are involved. Environmental triggers include exposure to sunlight, infections, or exposure to certain medications (see Table 56–1).[3-5]

Lupus Phenotypes

Lupus can be characterized by three major phenotypes: chronic cutaneous lupus, SLE, and drug-induced lupus. Nearly 70% of lupus cases are categorized as SLE, a condition in which symptoms may affect any organ. Approximately 10% of persons living with lupus have chronic cutaneous lupus erythematosus, a type of lupus that only involves the skin. Another 10% of lupus cases can be characterized as drug-induced lupus, which typically resolves after withdrawal of the offending agent. Finally, the remaining 10% of cases are characterized as neonatal lupus. Neonatal lupus is often a term used to describe neonates born to mothers with SLE due to exposure to antibodies in utero and is not considered a true type of lupus. Symptoms of neonatal lupus often resolve in 6 months after birth. The term "lupus" most often refers to SLE, which is the main focus of this chapter.

PATHOPHYSIOLOGY

SLE is a chronic autoimmune disease characterized by a dysfunctional immune system as the result of autoantibody production leading to a systemic inflammatory response.[4] Autoantibodies are produced by B-cells that have lost self-tolerance and may be driven by T-cell dysfunction. Autoantibodies can form immune complexes, which are deposited into tissues causing inflammation and subsequent damage (Figure 56–1). These deposits can also be comprised of immunoglobulin (Ig) M, IgG, IgA, and complement (C). Of autoantibodies identified in patients with autoimmune diseases, antinuclear antibodies (ANA) are the most characteristic of SLE and are found in more than 95% of patients. While a positive ANA can occur in healthy individuals, titers and patterns can be used to identify various types of autoimmune conditions. SLE-specific antibodies include double-stranded DNA (dsDNA), Sjögren syndrome antigen A (SSA; Ro), Sjögren syndrome antigen B (SSB; La), Sm, DNA-histone and

Table 56–1

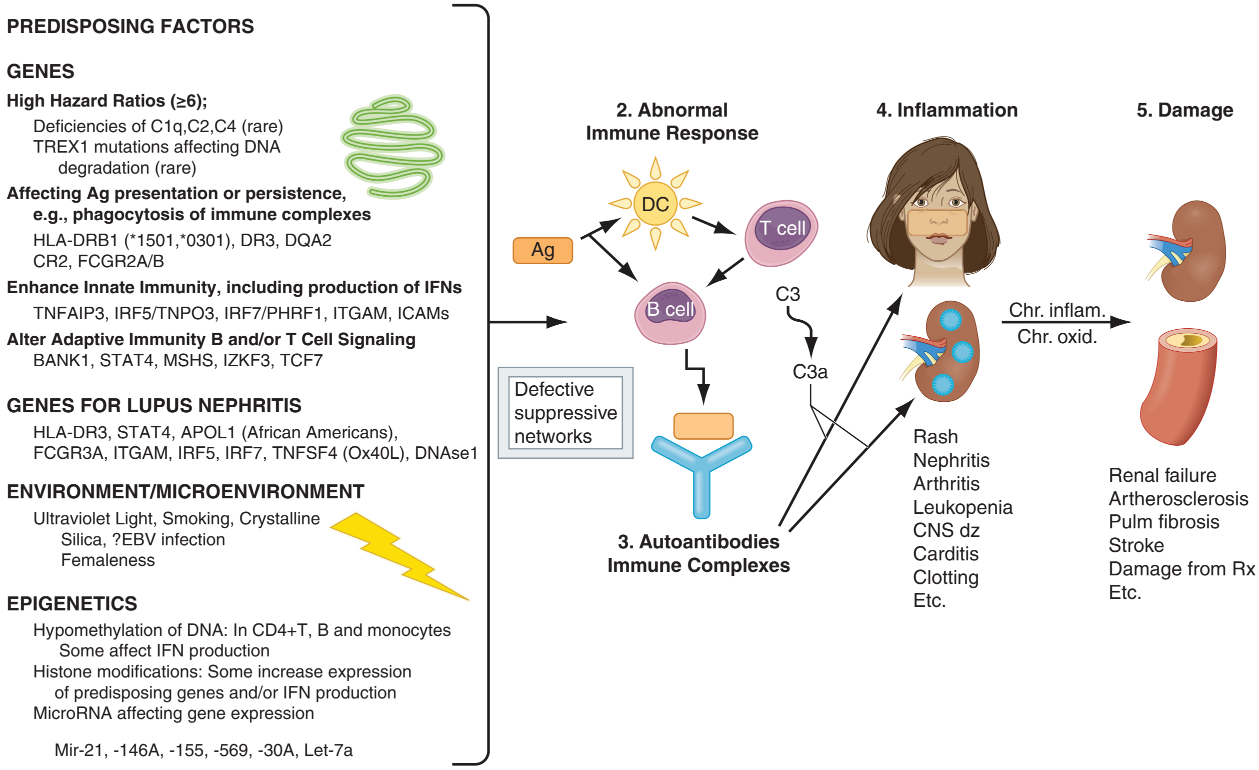
Medications Associated with Drug-Induced Lupus[3-5]

Definite (> 1% incidence)	Procainamide, hydralazine, D-penicillamine, minocycline, quinidine, isoniazid, methyldopa, TNFi, interferon-alpha, diltiazem (subacute cutaneous lupus rash), chlorpromazine, and practolol
Probable (incidence < 1% or > 4 case reports)	Anticonvulsants (phenytoin, carbamazepine, valproic acid, others), ethosuximide, captopril, propylthiouracil (PTU), β-adrenergic blocking agents, sulfasalazine, antimicrobials (sulfonamides, nitrofurantoin), lithium, docetaxel, hydrochlorothiazide, glyburide, amiodarone, interferon gamma, simvastatin, terbinafine, oral contraceptives, acebutolol
Possible (3–4 case reports)	Statins, clozapine, griseofulvin, mesalazine, methimazole, ticlopidine, gemfibrozil
Case reports	Aminoglutethimide, aminosalicylic acid, cefuroxime, celiprolol, chlorprothixene, cimetidine, cinnarizine, clonidine, danazol, dapsone, diclofenac, efalizumab, enalapril, futamide, fluvastatin, granulocyte colony-stimulating factors, hepatitis B vaccination, hydrazine, ibuprofen, interleukin-11, labetalol, lamotrigine, levodopa, mephenytoin, minoxidil, nafcillin, nalidixic acid, nifedipine, olanzapine, olsalazine, paclitaxel, phenelzine, phenobarbital, primidone, propafenone, quinine, rifamycin, streptomycin, sulindac, tamoxifen, verapamil, zafirlukast

TNFi, tumor necrosis factor inhibitors.

ribonucleoprotein (RNP). Autoantibody titers can fluctuate with disease activity and may be present for many years prior to clinical symptoms.

The pathologic findings of SLE can affect every organ system and manifest as inflammation, blood vessel abnormalities, and the autoantibody/immune complex deposition. Genetic predispositions paired with environmental exposures lead to immune dysregulation and subsequent autoantibody formation and deposits, along with cytokine release resulting in a chronic inflammatory state ultimately leading to irreversible organ damage over time. Inflammation can affect and damage many organs, particularly the kidneys, blood vessels, and joints, and also the heart and lungs.



PREDISPOSING FACTORS
GENES
High Hazard Ratios (≥6);
Deficiencies of C1q,C2,C4 (rare)
TREX1 mutations affecting DNA degradation (rare)
Affecting Ag presentation or persistence, e.g., phagocytosis of immune complexes
HLA-DRB1 (*1501,*0301), DR3, DQA2
CR2, FCGR2A/B
Enhance Innate Immunity, including production of IFNs
TNFAIP3, IRF5/TNPO3, IRF7/PHRF1, ITGAM, ICAMs
Alter Adaptive Immunity B and/or T Cell Signaling
BANK1, STAT4, MSHS, IZKF3, TCF7
GENES FOR LUPUS NEPHRITIS
HLA-DR3, STAT4, APOL1 (African Americans), FCGR3A, ITGAM, IRF5, IRF7, TNFSF4 (Ox40L), DNAse1
ENVIRONMENT/MICROENVIRONMENT
Ultraviolet Light, Smoking, Crystalline Silica, ?EBV infection
Femaleness
EPIGENETICS
Hypomethylation of DNA: In CD4+T, B and monocytes
Some affect IFN production
Histone modifications: Some increase expression of predisposing genes and/or IFN production
MicroRNA affecting gene expression
Mir-21, -146A, -155, -569, -30A, Let-7a
2. Abnormal Immune Response
Ag
DC
T cell
B cell
Defective suppressive networks
C3
C3a
3. Autoantibodies Immune Complexes
4. Inflammation
Rash
Nephritis
Arthritis
Leukopenia
CNS dz
Carditis
Clotting
Etc.
Chr. inflam.
Chr. oxid.
5. Damage
Renal failure
Artherosclerosis
Pulm fibrosis
Stroke
Damage from Rx
Etc.

FIGURE 56–1. Pathogenesis of Systemic Lupus Erythematosus. Pathogenesis is related in large part to production of increased quantities and immunogenic forms of nucleic acids and other self-antigens, which drive autoimmune-inducing activation of innate immunity, autoantibodies, and T-cells. Interactions between genes, environment, and epigenetic changes drive increased autophagy, Ag presentation, neutrophil NETosis, autoantibody formation with increased plasma cells, and production of pathogenic effector T-cells in Th1, Th17, and Tfh subsets, with ineffective regulatory networks. (Ag, antigen; C1q, complement system; C3, complement component; chr, chronic; CNS, central nervous system; DC, dendritic cell; dz, disease; EBV, Epstein-Barr virus; HLA, human leukocyte antigen; IFN, interferon; inflam, inflammation; oxid, oxidation; Pulm, pulmonary; Rx, medications.) Systemic Lupus Erythematosus. In: DiPiro JT, Yee GC, Posey M, Haines ST, Nolin TD, Ellingrod V, eds. Pharmacotherapy: a pathophysiologic approach. 11th ed. New York: McGraw-Hill; c2020.

CLINICAL PRESENTATION AND DIAGNOSIS

SLE is a multi-organ, multi-system heterogeneous (meaning symptoms vary by patient) disease. The variability in clinical presentation and onset of symptoms often results in a delay in diagnosis. The "Clinical Presentation by Organ System and Diagnosis of SLE" textbox outlines a multitude of symptoms commonly seen as part of the clinical presentation in SLE.

Diagnosis

KEY CONCEPT Diagnosis is often difficult, as there is not one specific test for SLE. Diagnosis is made based on clinical signs and symptoms, immunologic signs and symptoms, and laboratory and other tests. The 2019 European League Against Rheumatism/American College of Rheumatology (EULAR/ACR) Classification Criteria for SLE are outlined in Table 56–2.[6] While this

Table 56–2

Comparison of EULAR/ACR 2019 and SLICC 2012 SLE Classification Criteria

EULAR/ACR 2019 Criteria[6]		SLICC Criteria[7]
Entry criterion: ANA at a titer of ≥ 1:80 on HEp-2[a] cells or an equivalent positive test; if present, apply additive criteria		**Immunological Criteria** 1. ANA above laboratory reference range 2. Anti-dsDNA above laboratory reference range, except ELISA: twice the laboratory reference range 3. Anti-Sm 4. Antiphospholipid antibody: any of the following: lupus anticoagulant, false-positive RPR, medium or high titer anticardiolipin (IgA, IgG, or IgM), anti-β2 glycoprotein (IgA, IgG, or IgM) 5. Low complement (C): low C3, low C4, low CH50 6. Direct Coombs test in the absence of hemolytic anemia
Additive Criteria	Score	Clinical Criteria
Constitutional		N/A
Fever	2	
Hematologic		1. Hemolytic anemia
Leukopenia	3	2. Leukopenia (< 4000/mm^3 [4 × 10^9/L] at least once), or Lymphopenia (< 1000/mm^3 [1 × 10^9/L] at least once) in the absence of other causes
Thrombocytopenia	4	
Autoimmune hemolysis	4	3. Thrombocytopenia (< 100,000/mm^3 [100 × 10^9/L] at least once), in the absence of other causes
Neuropsychiatric		4. Neurologic: seizures, psychosis, mononeuritis multiplex in the absence of other causes, myelitis, peripheral or cranial neuropathy in the absence of other causes, acute confusional state
Delirium	2	
Psychosis	3	
Seizure	5	
Mucocutaneous		5. Acute cutaneous lupus including lupus malar rash, bullous lupus, toxic epidermal necrolysis variant of SLE, photosensitive rash, or subacute cutaneous lupus
Nonscarring alopecia	2	
Oral ulcers	2	6. Chronic cutaneous lupus including classical discoid rash, localized or generalized, hypertrophic lupus, lupus panniculitis, mucosal lupus, lupus erythematosus tumidus, chilblains lupus, discoid lupus/lichen planus overlap
Subacute cutaneous or discoid lupus	4	
Acute cutaneous lupus	6	7. Oral ulcers: palate, buccal, tongue, or nasal ulcers in the absence of other causes 8. Nonscarring alopecia
Serosal		9. Serositis: typical pleurisy for more than 1 day, or pleural effusions, or pleural rub; typical pericardial pain for more than 1 day, or pericardial effusion, or pericardial rub, or pericarditis by ECG in the absence of other causes
Pleural or pericardial effusion	5	
Acute pericarditis	6	
Musculoskeletal		10. Synovitis involving two or more joints, characterized by swelling or effusion OR tenderness in two or more joints and 30 minutes or more of morning stiffness
Joint involvement	6	
Renal		11. Renal: urine protein/creatinine (or 24-hour urine protein) representing 500 mg protein/24 hours, or red blood cell casts
Proteinuria > 0.5 g/24 hours	4	
Renal biopsy class II or V lupus nephritis	8	
Renal biopsy class III or IV lupus nephritis	10	
Total Score	A score of 10 or more plus fulfilling the entry criterion meets a classification of SLE	Meets four of the above criteria, including at least one clinical and one immunologic criterion, OR biopsy-proven nephritis compatible with SLE and with ANA or anti-dsDNA antibodies

ACR, American College of Rheumatology; ANA, antinuclear antibody; dsDNA, double-stranded DNA; ELISA, enzyme-linked immunoassay; ECG, electrocardiogram; EULAR, European League Against Rheumatism; Ig, immunoglobulin; RPR, rapid plasma reagin; SLE, systemic lupus erythematosus; SLICC, Systemic Lupus International Collaborating Clinics

[a] HEp-2: a cell that is a substrate for ANA testing that aids in the detection of ANA; ANA screening using HEp-2 cells is considered the gold standard for screening.

Clinical Presentation by Organ System and Diagnosis of SLE[6]

Constitutional	fever, fatigue, weight loss, nausea
Hematologic	thrombocytopenia, leukopenia, hemolytic anemia
Dermatologic	malar rash ("butterfly"), alopecia, oral/nasal ulcers, photosensitivity
Musculoskeletal	joint swelling, tenderness, effusions
Central nervous system	vasculitis, psychosis, seizures, memory impairment
Pulmonary	pleurisy, diffuse alveolar hemorrhage
Cardiovascular	pericarditis, endocarditis, myocarditis, Raynaud disease, vasculitis
Renal	proteinuria, nephritis

DIAGNOSIS: refer to Table 56–2 for 2019 European League Against Rheumatism/American College of Rheumatology (EULAR/ACR) Classification Criteria for Systemic Lupus Erythematosus as well as the classification system of the Systemic Lupus International Collaborating Clinics (SLICC).[6,7]

classification criteria provide a guide for clinicians, they are designed for research purposes and may not be sensitive enough for diagnosis in mild cases. An additional classification system exists, the Systemic Lupus International Collaborating Clinics (SLICC); however, this system is often used in clinical trials and less commonly used to guide routine patient care.[7] For each system, the criteria need not be present concurrently. Renal biopsies are often done to aid in diagnosis of renal involvement.

Differentiating SLE from other rheumatologic conditions can be difficult, and overlap with other conditions may occur. This may delay diagnosis and therefore treatment. A stepwise approach may assist with applying symptoms, laboratory tests, and diagnostic criteria (Figure 56–2).

TREATMENT

Desired Outcomes

There is no cure for SLE. KEY CONCEPT Goals of therapy include reducing or eliminating flares, preventing and reducing organ damage, minimizing treatment-related adverse events, and maintaining and improving quality of life.

Nonpharmacologic Therapy

Nonpharmacologic treatments for SLE include sun protection, smoking cessation, exercise, and minimization of environmental risk factors including exposure to sunlight, infection risk, and predisposing medications. SLE causes an increase in sensitivity to ultraviolet exposure, which may worsen skin manifestations of the disease. Avoidance of exposure is ideal, although not always feasible. Sunscreen with at least 30 sun protection factor (SPF) is recommended,

Patient Encounter Part 1

A 34-year-old African American woman presents to the rheumatology clinic as a new patient consult with a chief complaint of intermittent bilateral hand pain accompanied with swelling, morning stiffness lasting an average of 45 minutes to an hour and a malar/butterfly rash. She reports working as a software engineer in a high stress environment where she sits at a desk for extended periods of time.

PMH: Hypertension, hyperlipidemia, anemia, anxiety

FH: Mother (age 62): chronic anemia secondary to ulcerative colitis, major depressive disorder; father (age 68): osteoarthritis of knees, osteoporosis, and rheumatoid arthritis; paternal aunt (age 57): SLE

SH: Married w/no children, denied alcohol and illicit drug use, current smoker (less than 1 pack per day), sedentary lifestyle

Allergies: NKDA

Medications: Lisinopril 10 mg daily, nifedipine ER 60 mg daily, atorvastatin 10 mg daily, women's multivitamin 1 tab daily

Vitals: Height 65.5 in (166.4 cm), weight 180 lb (82 kg), pulse rate 77 bpm, blood pressure (BP) 132/82 mm Hg, body mass index (BMI) 29.5 kg/m^2

Relevant Labs:

Complete blood count (CBC): WNL

Comprehensive metabolic panel (CMP): WNL (SCr 0.67 mg/dL [59 μmol/L])

Urinalysis: Protein urine levels WNL

Thyroid-stimulating hormone (TSH), triiodothyronine (T$_3$), thyroxine (T$_4$): WNL

Low C3, Low C4

(+) anti SSA/B, high titer ANA (1:160 speckled pattern), rheumatoid factor (RF), antiphospholipid antibodies, anti-dsDNA 3x upper limit of normal (ULN)

ROS:

Constitutional: (+) Fatigue

Integumentary: (+) Hair loss, photosensitivity, malar rash, skin lesion / (–) hives, nail changes, pruritus, psoriasis, and scalp tenderness

Musculoskeletal (MSK): (+) Joint pain, joint tenderness, morning stiffness, neck pain

Physical Examination:

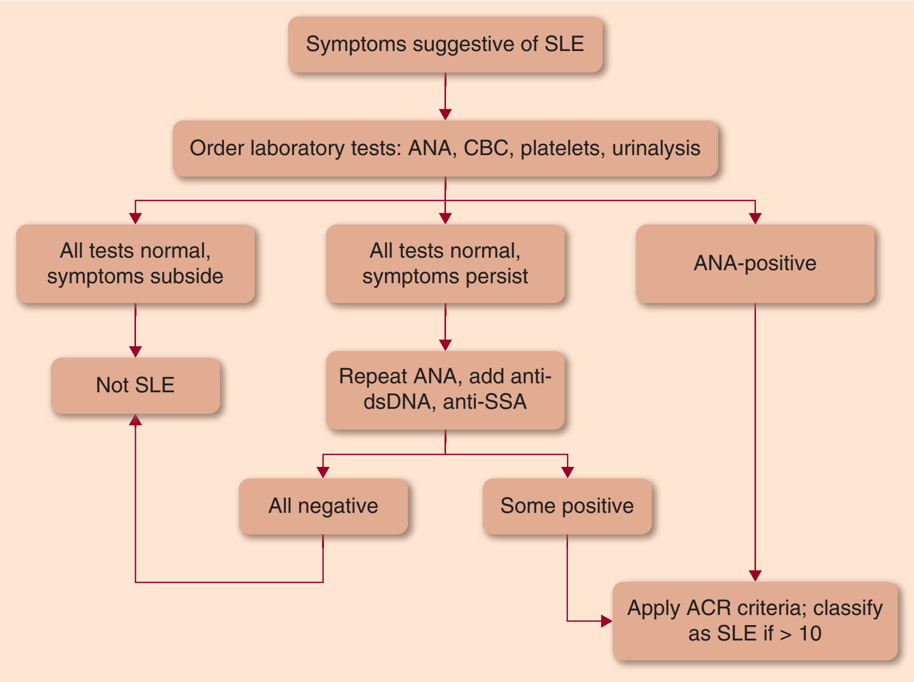
MSK: Shoulders/elbows/knees/hips/feet, and ankles—no tenderness, swelling, effusion, or limited range of motion

Hands—Tenderness, effusion and limited range of motion in the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints

What risk factors does the patient have for SLE?

Are there any medications the patient is taking associated with drug-induced lupus? What is the incidence of drug-induced lupus associated with any identified agent(s) (definite, probable, possible, or case reports)?

What clinical manifestations presented meet SLICC Criteria for Classification of SLE versus what clinical manifestations presented meet ACR/EULAR Criteria for Classification SLE?



Symptoms suggestive of SLE
Order laboratory tests: ANA, CBC, platelets, urinalysis
All tests normal, symptoms subside
All tests normal, symptoms persist
ANA-positive
Not SLE
Repeat ANA, add anti-dsDNA, anti-SSA
All negative
Some positive
Apply ACR criteria; classify as SLE if > 10

FIGURE 56–2. Decision Assistance for Diagnosing SLE. (ACR, American College of Rheumatology; anti-dsDNA, antibody directed against double-stranded DNA; ANA, antinuclear antibody; CBC, complete blood count; SLE, systemic lupus erythematosus; SSA, Sjögren syndrome antigen A). Adapted from Hahn BH. Systemic lupus erythematosus. In: Jameson J, Fauci AS, Kasper DL, Hauser SL, Longo DL, Loscalzo J, eds. Harrison's Principles of Internal Medicine. 20th ed. New York: McGraw-Hill; 2018; and Aringer at al. 2019 EULAR/ACR classification criteria for SLE. Arthritis Rheumatol. 2019;17(9):1400-1412.

along with lip balm with at least 15 SPF.[8] Smoking has been shown to increase the risk of developing SLE,[9] and is also associated with a twofold decrease in the proportion of patients achieving improvement with antimalarials with cutaneous lupus.[10] Therefore, smoking cessation interventions should be offered to all patients with SLE. Additionally, exercise has been shown to reduce fatigue in patients with SLE[11] and has also been shown to not induce disease flares.

SLE can affect all aspects of daily life. Persons living with SLE often experience significant economic and social burdens. This can include absenteeism from work, complete inability to work, higher rates of disability, higher rates of anxiety and depression, and chronic pain.[12] Further, the impact of SLE on mental health is often overlooked. Persons with SLE are much more likely to experience depression, anxiety, and psychological impacts, and should be screened and appropriately treated for anxiety and depression as part of a multifaceted approach to care. For example, cognitive behavioral therapy has been shown to reduce daily stress, psychological symptoms, and improve quality of life.[13] Patient education and connecting patients to support groups are important aspects of nonpharmacologic treatment in SLE.

Pharmacologic Therapy

KEY CONCEPT In general, treatment of SLE is guided by organ involvement, disease severity, and childbearing potential. Fatigue is a very common symptom in SLE; however, it is important to identify and address comorbidities and/or overlapping conditions that can contribute to fatigue such as hypothyroidism, depression, and fibromyalgia. Infections are common in patients with SLE due to immune dysfunction and immunosuppressive therapies, and therefore staying up to date on immunizations such as influenza and pneumococcal can help minimize risk. Due to the increased risk of premature cardiovascular disease (CVD) in patients with SLE, reducing modifiable risk factors such as hypertension (see Chapter 6, "Hypertension"), dyslipidemia (see Chapter 13, "Dyslipidemias"), and obesity is a vital part of the treatment plan.

▶ *Acute Treatment*

Glucocorticoids are the mainstay of treatment for acute symptoms due to fast onset of anti-inflammatory action and are used in times of organ-threatening disease. Glucocorticoids exert anti-inflammatory effects by reduction of B and T lymphocyte proliferation and activation, immunoglobulin production, mononuclear cell and neutrophil migration and adhesion, and reduction of proinflammatory prostaglandins.[14] Typically oral or intravenous glucocorticoids are utilized depending on the severity of the flare, characterized by worsening of symptoms (flares can range from mild to severe and life-threatening). Intravenous steroids are the mainstay of treatment for severe, life-threatening disease flares; however, they should not be used chronically due to negative effects of long-term therapy.[15]

Adverse effects of acute glucocorticoid use include elevated blood glucose and neuropsychiatric events (insomnia, psychosis), while chronic exposure can increase the risk of osteoporosis, elevated blood pressure, weight gain, cataract development, and increased infection risk.[14] Long-term glucocorticoid use in SLE has also been associated with irreversible organ damage; prednisone daily dosages above 6 mg have been shown to increase the risk of future organ damage by 50%.[14] The optimal formulation and dose has not been identified. The lowest effective dose and duration should be used. Patients on glucocorticoids should be continually monitored for toxicities.

▶ *Nonrenal SLE*

Systemic Lupus Erythematosus Disease Activity Index 2000 (SLEDAI-2K)[16] is a validated assessment tool used to measure SLE

Table 56–3

Classification of Nonrenal SLE[15-17]

	Clinical Presentation	Disease Activity Score
Mild	Constitutional symptoms, mild arthritis, rash covering ≤ 9% of BSA, platelets 50,000 to 100,000 cells/mm^3 (50 × 10^9/L to 100 × 10^9/L)	SLEDAI-2K score ≤ 6; BILAG C or ≤ 1 BILAG B manifestation
Moderate	RA-like arthritis, rash covering 9% to 18% of BSA, cutaneous vasculitis ≤ 18% of BSA, platelets 20,000 to 50,000 cells/mm^3 (20 × 10^9/L to 50 × 10^9/L), serositis	SLEDAI-2K score 7–12, or ≥ 2 BILAG B manifestations
Severe	Major organ threatening disease (nephritis, cerebritis, myelitis, pneumonitis, mesenteric vasculitis, platelets < 20,000 cells/mm^3 [20 × 10^9/L], TTP-like disease or acute hemophagocytic syndrome)	SLEDAI-2K score > 12, or ≥ 1 BILAG A manifestation

BILAG, British Isles Lupus Assessment Group; BSA, body surface area; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; SLEDAI-2K, SLE disease activity index 2000; TTP, thrombotic thrombocytopenic purpura.

disease activity. Additionally, the British Isles Lupus Assessment Group (BILAG)[17] disease activity index assesses disease activity in a single organ and also provides information on multiple systems and therefore can be used as a composite score. These scoring indices are used to aid in classification of SLE disease activity as mild, moderate, and severe (Table 56–3).[15-17]

KEY CONCEPT First-line treatment of nonrenal SLE regardless of disease severity includes hydroxychloroquine with or without glucocorticoids. See Figure 56–3. Decision between the agents is based on side effect profile, comorbidities, and childbearing potential. First-line treatment for moderate nonrenal SLE may also include methotrexate or azathioprine. If refractory to the

Patient Encounter Part 2

After receiving the official diagnosis of SLE during her initial visit, the patient was prescribed hydroxychloroquine 200 mg twice daily which she has been taking consistently since then. Today, she presents 11 months later for routine follow up. Her chief complaint is right elbow pain, and she is requesting a steroid joint injection. She also complains of fatigue, dry mouth, worsening arthralgias, anxiety, and stiffness. She is not interested in having children at this time, but may consider it in the next few years.

PMH: Hypertension, hyperlipidemia, anemia, anxiety

Medications: Lisinopril 10 mg daily, nifedipine ER 60 mg daily, atorvastatin 10 mg daily, women's multivitamin 1 tab daily, hydroxychloroquine 200 mg twice daily

Allergies: NKDA

Physical Examination: All normal except MSK mild swelling right elbow. Hands—Worsened tenderness, effusion and limited range of motion in the MCP and PIP joints

Vitals: Weight 185 lb (84 kg), pulse rate 73 bpm, BP 127/75 mm Hg, BMI 30.3 kg/m^2

Relevant Labs:

CBC: WNL

CMP: WNL (SCr 0.67 mg/dL [59 µmol/L])

Liver function tests (LFTs): WNL

Urinalysis: Protein urine levels 650 mg/24 hours

TSH, T_3, T_4: WNL

Low C3, low C4

Elevated C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), and RF

Intermediate thiopurine S-methyltransferase (TPMT) activity

What are the goals of therapy for this patient? What are the targets for remission and low disease activity?

What nonpharmacological lifestyle modifications can the patient be counseled on?

Develop an immunomodulator-specific treatment plan for first-line therapy for moderate nonrenal refractory SLE. Identify appropriate dosing, including considerations for renal or hepatic function, laboratory monitoring, and patient counseling regarding common side effects?

What form(s) of contraception should be considered?

combination of hydroxychloroquine plus methotrexate or azathioprine, belimumab may be added. Third-line options include a calcineurin inhibitor or mycophenolate mofetil. First-line treatment for severe nonrenal SLE includes hydroxychloroquine plus oral or intravenous (IV) glucocorticoids, mycophenolate mofetil, or cyclophosphamide. If refractory to mycophenolate mofetil, second-line treatment includes cyclophosphamide. If refractory to cyclophosphamide, third-line treatment includes rituximab.

▶ *Lupus Nephritis*

Lupus nephritis (LN) is defined as persistent proteinuria greater than 0.5 g/day or greater than 3+ by urine dipstick, and/or cellular casts including red blood cells (RBCs), hemoglobin, granular, tubular, or mixed.[18] LN is categorized into six classifications, depending on the location and degree of nephron involvement, according to the International Society of Nephrology/Renal Pathology Society (Table 56–4).[18] Class of LN guides treatment.

According to the 2012 ACR lupus nephritis guidelines,[18] treatment of LN is separated into induction therapy and maintenance therapy. Induction typically involves cyclophosphamide or mycophenolate mofetil, with or without steroids. Maintenance typically involves azathioprine, mycophenolate mofetil, or rituximab.

Classes I and II generally do not require immunosuppressive treatment. Treatment includes hydroxychloroquine with glucocorticoids at doses required to suppress activity.[18] Hydroxychloroquine is recommended for all classes of LN unless contraindicated. For classes III or IV LN (Figure 56–4), if improvements are made with induction therapy of mycophenolate mofetil, it is then continued for maintenance therapy. If improvement is not seen with mycophenolate mofetil induction, cyclophosphamide induction may be attempted. If cyclophosphamide induction leads to clinical improvement, mycophenolate mofetil or azathioprine are used for maintenance therapy. If these options do not result in clinical improvement, glucocorticoids plus rituximab or a calcineurin inhibitor may be utilized.

For class V LN (Figure 56–5), induction is first attempted with mycophenolate mofetil. If clinical improvement results, then mycophenolate mofetil or azathioprine is utilized for maintenance therapy. If improvement does not occur, then cyclophosphamide induction is attempted.

▶ *Immunomodulators*

Immunomodulators are almost always required for management of SLE. Applicable immunomodulators include antimalarial agents, immunosuppressants, and biologic agents. Choice of agent is guided by organ involvement and disease severity. Currently, the only agents that are Food and Drug Administration (FDA) approved for

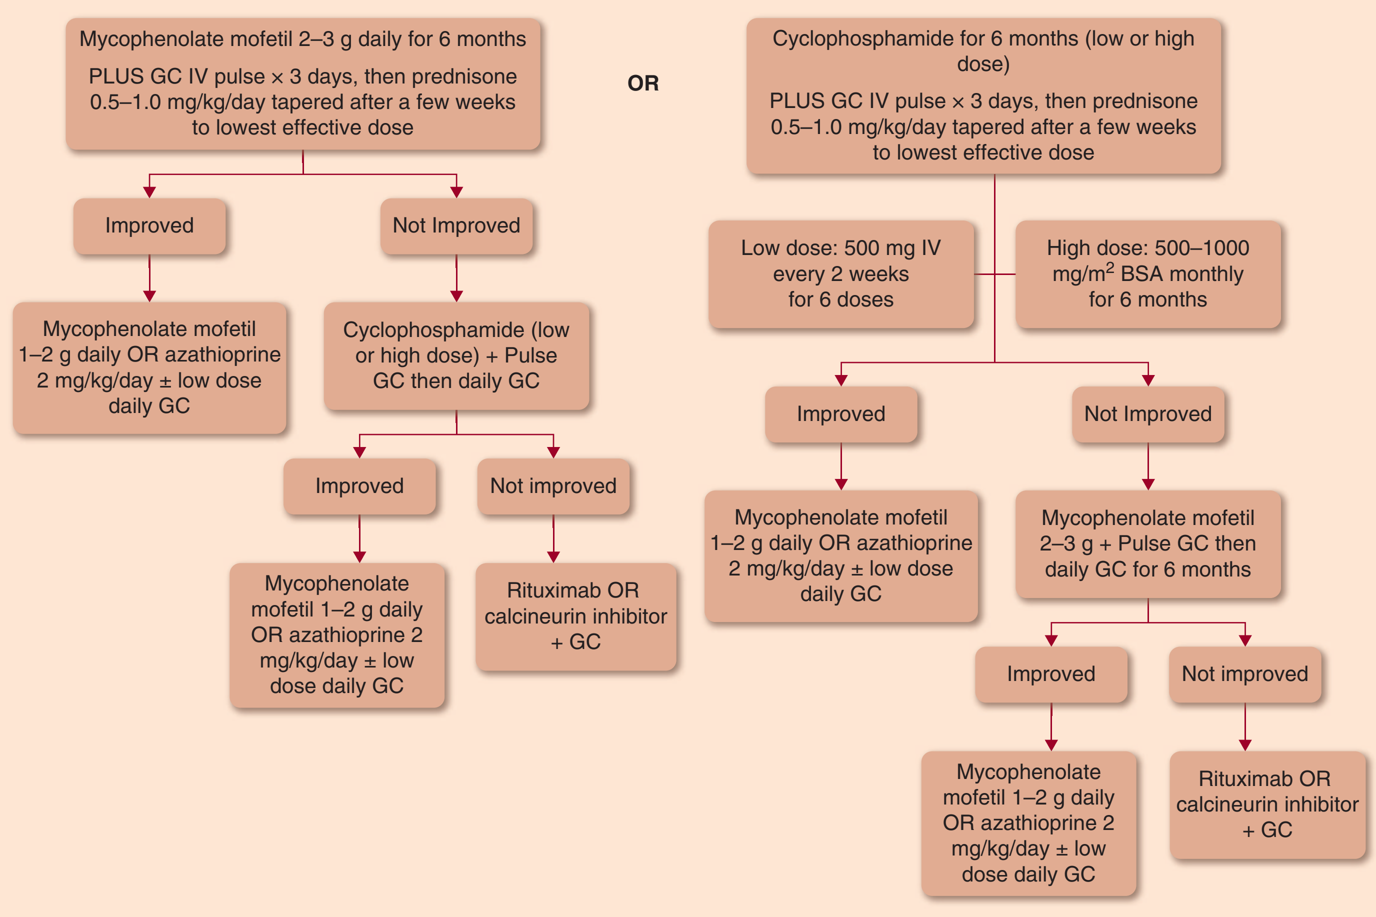
Table 56–4

Lupus Nephritis (LN) Classifications[18]

Class I	Minimal mesangial LN[a]
Class II	Mesangial proliferative LN[b]
Class III	Focal LN involving < 50% of glomeruli; further subcategorized based on presence of active and/or chronic lesions
Class IV	Diffuse LN involving 50% or more of glomeruli; further subcategorized based on presence of active and/or chronic lesions
Class V	Membranous LN; may occur in combination with class III or IV
Class VI	Advanced sclerosing LN with 90% or more globally sclerosed glomeruli without residual activity

[a] Mesangial LN, mesangial cells are specialized cells that make up the mesangium of the glomerulus.

[b] Mesangial proliferative LN, also called mesangial proliferative glomerulonephritis; a form of glomerulonephritis associated primarily with the mesangium portion of the kidney.

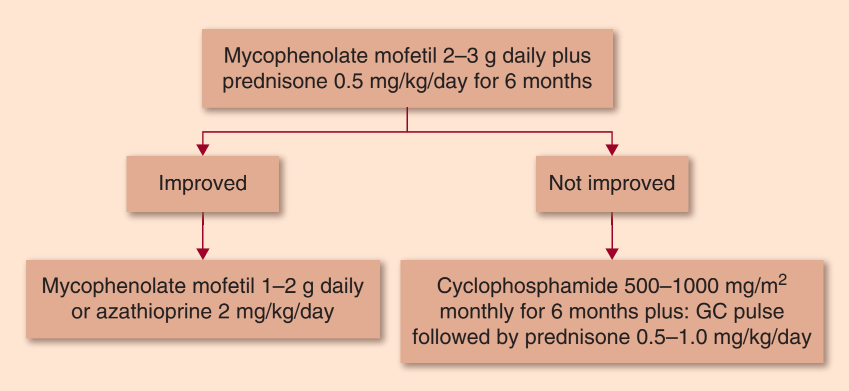


Mycophenolate mofetil 2–3 g daily for 6 months
PLUS GC IV pulse × 3 days, then prednisone 0.5–1.0 mg/kg/day tapered after a few weeks to lowest effective dose
OR
Cyclophosphamide for 6 months (low or high dose)
PLUS GC IV pulse × 3 days, then prednisone 0.5–1.0 mg/kg/day tapered after a few weeks to lowest effective dose
Improved
Not Improved
Mycophenolate mofetil 1–2 g daily OR azathioprine 2 mg/kg/day ± low dose daily GC
Cyclophosphamide (low or high dose) + Pulse GC then daily GC
Improved
Not improved
Mycophenolate mofetil 1–2 g daily OR azathioprine 2 mg/kg/day ± low dose daily GC
Rituximab OR calcineurin inhibitor + GC
Low dose: 500 mg IV every 2 weeks for 6 doses
High dose: 500–1000 mg/m2 BSA monthly for 6 months
Improved
Not Improved
Mycophenolate mofetil 1–2 g daily OR azathioprine 2 mg/kg/day ± low dose daily GC
Mycophenolate mofetil 2–3 g + Pulse GC then daily GC for 6 months
Improved
Not improved
Mycophenolate mofetil 1–2 g daily OR azathioprine 2 mg/kg/day ± low dose daily GC
Rituximab OR calcineurin inhibitor + GC

FIGURE 56–4. Induction treatment for class III or IV Lupus Nephritis. (BSA, body surface area; GC, glucocorticoid; IV, intravenous). (Adapted from Hahn BH, McMahon MA, Wilkinson A, et al. American College of Rheumatology guidelines for screening, treatment, and management of lupus nephritis. Arthritis Care Res (Hoboken). 2012 Jun;64(6):797–808.)

treatment of SLE are hydroxychloroquine and belimumab. Duration of therapy varies depending on disease severity, but most patients require chronic immunomodulator therapy. Table 56–5 includes dosing and administration considerations, adverse drug reactions, contraindications, interactions, pharmacogenomics, and monitoring parameters for immunomodulators used for SLE.

Hydroxychloroquine The mechanism of hydroxychloroquine in inflammatory diseases differs from its antimalarial properties. Hydroxychloroquine accumulates in lysosomes and increases the pH, inhibiting the enzymatic degradation of proteins and organelles obtained via endocytosis, phagocytosis, or autophagy.[19] This prevents downstream presentation of autoantigens by class II major histocompatibility complexes (MHC) seen in autoinflammatory diseases. Further, hydroxychloroquine accumulates in endosomes and alters the pH of endosomes causing inhibition of Toll-like receptor (TLR) signaling, and inhibits activity of the



Mycophenolate mofetil 2–3 g daily plus prednisone 0.5 mg/kg/day for 6 months
Improved
Not improved
Mycophenolate mofetil 1–2 g daily or azathioprine 2 mg/kg/day

FIGURE 56–5. Treatment of class V Lupus Nephritis. (GC, glucocorticoid). (Adapted from Hahn BH, McMahon MA, Wilkinson A, et al. American College of Rheumatology guidelines for screening, treatment, and management of lupus nephritis. Arthritis Care Res (Hoboken). 2012 Jun;64(6):797–808.)

Table 56–5

Immunomodulators Used in Treatment of SLE[21-22]

Drug Name	Dosing/ Administration	Dose Adjustments for Renal or Hepatic Impairment	Adverse Drug Reactions	Contraindications	Select Drug–Drug, Drug–Food Interactions	Pharmacogenomics	Monitoring
Hydroxychloroquine	Weight Based–5 mg/kg/day actual body weight 200 mg to 400 mg PO daily; may take in divided doses	N/A	Common: retinal toxicity, N/V/D, exacerbation of psoriasis Less common/rare: hypoglycemia, QTc prolongation, abnormal LFTs, hemolysis in G6PD deficiency	Hypersensitivity	Consider therapy modification with: citalopram, cyclosporine, dapsone, digoxin, antiepileptics, haloperidol, tamoxifen Avoid concomitant use with: artemether, lumefantrine, mefloquine, remdesivir	G6PD	Retinal examination at baseline or within first year, then annually after 5 years of use, CBC, LFTs, renal function, blood glucose, ECG if at risk for Torsades de Pointes
Chloroquine	Weight-based Maximum dose of 2.3 mg/kg/day actual body weight	GFR < 10 mL/min (0.17 mL/s): administer 50% of dose	Common: retinal toxicity, hypotension, alopecia, exacerbation of psoriasis, N/V/D, pancytopenia Less common/rare: AV block, cardiac arrhythmias and failure, cardiomyopathy, Torsades de Pointes, hypoglycemia, agranulocytosis, aplastic anemia, hemolytic anemia in G6PD deficiency, hepatitis, hearing loss, tinnitus, visual disturbances	Hypersensitivity	Consider therapy modification with: ampicillin, antacids, bacampicillin, digoxin, cyclosporine, dapsone, domperidone, haloperidol, kaolin, lanthanum, QT prolonging agents Avoid concomitant use with: agalsifase, artemether, cimetidine, fexinidazole, lumefantrine, mefloquine, pimozide, remdesivir, strong CYP 3A4 inhibitors	G6PD; Substrate of CYP2C8, CYP2D6, CYP3A4	Retinal examination at baseline or within first year, then annually after 5 years of use, ECG, cardiomyopathy, blood glucose
Quinacrine	100 mg daily No longer commercially available	Unknown	Common: yellowish skin discoloration, rash, N/V/D, psychosis, restlessness, insomnia Less common/rare: hepatotoxicity, cardiac toxicity, mutagenicity, carcinogenicity, aplastic anemia, porphyria, retinopathy	Pregnancy	Unknown	N/A	CBC, LFTs, ECG, pregnancy status

(Continued)

Table 56–5

Immunomodulators Used in Treatment of SLE[21-22] (*Continued*)

Drug Name	Dosing/ Administration	Dose Adjustments for Renal or Hepatic Impairment	Adverse Drug Reactions	Contraindications	Select Drug–Drug, Drug–Food Interactions	Pharmacogenomics	Monitoring
Mycophenolate Mofetil	Induction: 2–3 g/day orally for 6 months in combination with IV pulse glucocorticoid for 3 days followed by oral prednisone Maintenance: 1–2 g/day orally	Lower doses may be required in renal impairment, though no specific adjustments have been identified Increased monitoring may be necessary in patients with hyperbilirubinemia and/or hypoalbuminemia Reduce or interrupt dose for ANC $< 1.3 \times 10^3/\text{mm}^3$ (1.3×10^9/L)	Common: hypertension, edema, hypotension, tachycardia, hyperglycemia, hypercholesterolemia, hypomagnesemia, hypokalemia, hypocalcemia, hyperkalemia, increased LFTs, infections, pain, constipation, N/V/D, dyspepsia, flatulence, cytopenias, leukocytosis, headache, insomnia, dizziness, rash, increased serum creatinine and BUN Less common/rare: thrombosis, fatigue, acne vulgaris, pruritis, gingival hyperplasia, urinary retention, malignancy, myalgias, renal insufficiency	Hypersensitivity to any mycophenolate formulation; pregnancy	Consider therapy modification with: antacids, other immunosuppressants, echinacea, estrogens, metronidazole, penicillins, probenecid, progestins, PPIs, quinolones, roflumilast, sevelamer, tolvaptan Avoid concomitant use with: BCG, bile acid sequestrants, cholestyramine, cladribine, pimecrolimus, rifamycin derivatives, upadacitinib	HPRT1; Substrate of OAT1/3, OATP1B1/1B3 (SLCO1B1/1B3), UGT1A10, UGT1A8, UGT1A9, UGT2B7	CBC, renal function, LFTs, s/sx infection, pregnancy status
Azathioprine	1.5 to 2 mg/kg/day orally in 2–3 divided doses.	CrCl 10–50 mL/min (0.17–0.83 mL/s): administer 75% of normal dose; CrCl <10 mL/min (0.17 mL/s): administer 50% of normal dose; hemodialysis: administer 50% of normal dose and supplement 0.25 mg/kg; CRRT: administer 75% of normal dose No adjustments for hepatic impairment Consider 50% dose reduction or discontinuation for persistent cytopenias	Common: N/V/D, leukopenia, thrombocytopenia, stomatitis, myalgias, hepatotoxicity, fever, infection Less common/rare: anemia, alopecia, pancreatitis, malignancy, rash, hypotension, bone marrow suppression	Hypersensitivity; concurrent use of alkylating agents	Consider therapy modification with: allopurinol, other immunosuppressants, baricitinib, echinacea, leflunomide, ribavirin, roflumilast, sulfamethoxazole, tofacitinib, warfarin Avoid concomitant use with: BCG, cladribine, febuxostat, mercaptopurine, natalizumab, pimecrolimus, upadacitinib	TPMT; NUDT15	CBC with differential weekly during first month, twice monthly for months 2–3, and monthly thereafter; T Bili, CrCl, LFTs, s/sx infection and malignancy

Cyclophosphamide	High dose: 500–1000 mg/m^2 BSA IV monthly × 6 months Low Dose: 500 mg IV every 2 weeks × 6 doses *cycles can be repeated every 3 months at provider discretion	No adjustments noted in the product labeling; however, alternative sources suggest adjustments	Common: alopecia, abdominal pain, N/V/D, anorexia, stomatitis, amenorrhea, oligospermia, sterility, cytopenias, bone marrow suppression, infection Less common/rare: confusion, blurred vision, dizziness, rash, hemorrhagic cystitis	Hypersensitivity, urinary outflow obstruction	Consider therapy modification with: allopurinol, amiodarone, anthracyclines, azathioprine, baricitinib, clozapine, other immunosuppressants, dabrafenib, deferiprone, echinacea, filgrastim, fingolimod, leflunomide, lenograstim, lipegfilgrastim, palifermin, roflumilast, succinylcholine, tofacitinib Avoid concomitant use with: abametapir, BCG, belimumab, cladribine, dipyrone, etanercept, natalizumab, pimecrolimus, tacrolimus, upadacitinib	Substrate of CYP2A6, CYP 2B6, CYP 2C19, CYP 2C9, CYP 3A4	CBC with differential, BUN, urinalysis, BMP, pregnancy status, s/sx hemorrhagic cystitis, toxicities
Methotrexate	Initial: 7.5 mg once weekly, can be increased by 2.5 mg every 2–4 weeks to a maximum of 25 mg weekly. Take with daily folic acid	No dose modifications for renal or hepatic impairment recommended in manufacturer labeling; alternative sources suggest dose reductions in patients with renal dysfunction	Common: increased liver enzymes, alopecia, skin photosensitivity, rash, N/V/D, stomatitis, oligospermia, thrombocytopenia, infection Less common/rare: leukopenia, pancytopenia, dizziness, headache, blurred vision, tinnitus	Hypersensitivity; breastfeeding; pregnancy; alcoholism; chronic liver disease; preexisting bone marrow suppression, leukopenia, thrombocytopenia, or anemia	Consider therapy modification with: alcohol, baricitinib, clozapine, other immunosuppressants, deferiprone, dexketoprofen, echinacea, fingolimod, lenograstin, levetiracetam, lipegfilgrastim, loop diuretics, nivolumab, palifermin, penicillins, probenecid, PPIs, roflumilast, salicylates, sulfonamide antibiotics, tofacitinib, tolvaptan, trimethoprim Avoid concomitant use with: acitretin, BCG, cladribine, dichlorphenamide, dipyrone, foscarnet, natalizumab, nitrous oxide, pimecrolimus, tacrolimus	Substrate of BCRP/ ABCG2, OAT1/3, OATP1B1, Pg-P	Pregnancy status, CBC with differential, serum creatinine, BUN, LFTs, Hepatitis B and C serology, TB testing

Table 56–5

Immunomodulators Used in Treatment of SLE[21-22] (*Continued*)

Drug Name	Dosing/ Administration	Dose Adjustments for Renal or Hepatic Impairment	Adverse Drug Reactions	Contraindications	Select Drug–Drug, Drug–Food Interactions	Pharmacogenomics	Monitoring
Tacrolimus	2–8 mg/day, may be taken once or twice daily Take with or without food, just be consistent	N/A Lower starting doses may be required in severe hepatic impairment	Common: cardiac arrhythmias, DVT, ECG abnormalities, flushing, hypertension, hypotension, orthostatic hypotension, edema, agitation, anxiety, depression, fatigue, headache, hallucination, psychosis, alopecia, rash, pruritus, acne vulgaris, urticaria, photosensitivity, hyperglycemia, altered electrolytes, new onset diabetes mellitus, weight gain, N/V/D, GERD, cystitis, anemia, cytopenias, hepatotoxicity, infections, myalgias, tremor Less common/rare: hemorrhage, hot flashes, skin hyperpigmentation, neuropathy, pancreatitis, cardiomyopathy, weight loss	Hypersensitivity	Consider therapy modification with: alcohol, ACE inhibitors, ARBs, baricitinib, chloramphenicol, clozapine, colchicine, CYP3A4 inducers, CYP3A4 inhibitors, dabratenib, deferiprone, dronedarone, echinacea, enzalutamide, fingolimod, fluconazole, haloperidol, itraconazole, ketoconazole, leflunomide, mitotane, nivolumab, posaconazole, PPIs, ritonavir, roflumilast, St John's wort, stiripentol, tofacitinib Avoid concomitant use with: abametapir, BCG, cladribine, conivaptan, cyclosporine, dipyrone, eplerenone, foscarnet, fusidic acid, grapefruit juice, idelalisib, lasmiditan, mifamurtide, mifepristone, natalizumab, nelfinavir, protease inhibitors, pimecrolimus, saquinavir, sirolimus, temsirolimus, upadacitinib	Substrate of CYP 3A4 and P-gp	Renal function, LFTs, serum magnesium, BMP, BP; Trough whole blood concentrations (optimal level for SLE unknown)
Belimumab	Initial: 10 mg/kg IV every 2 weeks × 3 doses, or 200 mg SC weekly Maintenance: 10 mg/kg IV every 4 weeks, or 200 mg SC weekly	N/A	Common: N/V/D, hypersensitivity reaction, infection, psychiatric disturbances, infusion reactions, injection site reactions, anxiety, depression, headache, insomnia, leukopenia, fever Less common/rare: bradycardia, myalgia, angioedema, anaphylaxis	Hypersensitivity	Consider therapy modification with: echinacea, fingolimod, leflunomide, nivolumab, roflumilast Avoid concomitant use with: BCG, biologic DMARDs, cladribine, cyclophosphamide, natalizumab, pimecrolimus, tacrolimus, upadacitinib	N/A	s/sx hypersensitivity and infusion reactions; s/sx infections; mood changes, worsening of depression, suicidal thoughts

Rituximab	375 mg/m^2 BSA IV weekly × 4 doses OR 1000 mg IV on days 0 and 15 OR 500–1000 mg IV on days 1 and 15	N/A	Common: flushing, hypertension, peripheral edema, night sweats, pruritis, rash, hypophosphatemia, weight gain, N/V/D, pain, cytopenias, increased LFTs, angioedema, infections, fatigue, headache, insomnia, neuropathy, arthralgia, asthenia, cough, epistaxis, pulmonary toxicity, fever, PML, infusion reactions (premedicate with acetaminophen and antihistamine) Less common/rare: anemia, hepatotoxicity, hypogammaglobulinemia	None listed in labeling	Consider therapy modification with: clozapine, deferiprone, echinacea, fingolimod, leflunomide, nivolumab, roflumilast Avoid concomitant use with: BCG, belimumab, biologic DMARDs, cladribine, dipyrone, natalizumab, pimecrolimus, tacrolimus	MS4A1 (CD20 antigen)	CBC with differential, BMP, renal function, BP, fluid/hydration status, s/sx hypersensitivity and infusion reactions, HBV and HCV screening prior to initiation

ACE, angiotensin-converting enzyme; ANC, absolute neutrophil count ; ARB, angiotensin receptor blocker; AV, atrioventricular; BCG, Bacille Calmette Guerin; BMP, basic metabolic panel; BP, blood pressure; BSA, body surface area; BUN, blood urea nitrogen; CBC, complete blood count; CrCl, creatinine clearance; CRRT, complete renal replacement therapy; CYP, cytochrome P450; DMARD, disease-modifying antirheumatic drugs; DVT, deep vein thrombosis; ECG, electrocardiogram; G6PD: glucose 6 phosphate dehydrogenase; GERD, gastroesophageal reflux disease; GFR, glomerular filtration rate; HBV, hepatitis B virus; HCV, hepatitis C virus; IV, intravenous; LFT, liver function test; NUDT15, nucleotide diphosphatase; N/V/D, nausea/vomiting/diarrhea; PO, per oral; P-gp, P-glycoprotein; PML, progressive multifocal leukoencephalopathy; PPI, proton pump inhibitor; QTc, corrected QT interval; SC, subcutaneous; SLE, systemic lupus erythematosus; s/sx, signs and symptoms; TB, tuberculosis; T Bili, bilirubin test; TPMT, thiopurine S-methyltransferase.

nucleic acid sensor cGMP-AMP synthase (cGAS) by interfering with its binding to cytosolic DNA. By preventing TLR signaling and inhibiting cGAS-stimulator of interferon genes signaling, the production of proinflammatory cytokines is reduced.

Hydroxychloroquine is considered first-line for all degrees of SLE disease severity. It has been shown to significantly reduce disease activity, prevent flares, and allows for reduction of corticosteroid doses.[20] Notably, hydroxychloroquine also is the only therapy that has been shown to prolong survival. It may also protect against irreversible organ damage, although evidence is not definitive. It is also safe to use during pregnancy, and has been shown to reduce transmission of autoantibodies to the fetus, therefore reducing risk of neonatal heart block. It is well tolerated with the most common adverse event being nausea and mild gastrointestinal upset which usually subsides after a few weeks of therapy.

Long-term (> 20 years) and high-dose hydroxychloroquine use may be limited by risk of retinal toxicity, which may lead to permanent vision loss (Table 56–5).[21,22] The mechanism of retinopathy is thought to be due to impaired lysosomal degradation of photoreceptor outer segments by the retinal pigment epithelium.[23] Predictors of retinopathy from hydroxychloroquine include doses above 5 mg/kg of actual body weight, long-term use, concurrent tamoxifen use, and preexisting kidney disease.[23,24] In one study, the risk of retinal toxicity remained less than 2% within the first 10 years of use, but rose to almost 20% after 20 years of use.[24] Baseline fundal examinations and annual visual field testing with spectral domain optical coherence tomography (SD-OCT) after 5 years of use are recommended for patients using hydroxychloroquine.[25] If definitive signs of retinopathy are found, hydroxychloroquine should be discontinued.

In patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, use of hydroxychloroquine is cautioned due to risk of hemolytic anemia.[21] Strong evidence for this association, however, is lacking. Screening for G6PD deficiency is not routinely completed prior to hydroxychloroquine initiation.

Chloroquine Chloroquine, also an antimalarial, is a 4-aminoquinoline.[21] The exact mechanism of action in SLE is unknown; however, it may exert its effect by lowering the production of proinflammatory cytokines, specifically interleukin (IL)-6, IL-18, and tumor necrosis factor (TNF)-α, significantly after 4 months of use.[26] It has been shown to reduce required prednisone doses and prevent disease flares by approximately 4.6 times compared to prednisone alone.[27]

Chloroquine use is limited by retinal and cardiovascular toxicities and has largely been replaced by hydroxychloroquine due to superior safety profile. It is associated with more retinal toxicities than hydroxychloroquine. In a study comparing retinopathy in users of chloroquine versus hydroxychloroquine, six of 31 (19%) persons on chloroquine developed retinopathy while none of the 66 hydroxychloroquine users did.[28] Risk factors identified for retinal toxicity in chloroquine use include renal impairment, age, and chloroquine dose.[28,29] As with hydroxychloroquine, patients using chloroquine should undergo baseline fundal examinations and annual visual field testing with SD-OCT after 5 years of use.[25] If definitive signs of retinopathy are identified, chloroquine should be permanently discontinued.

Long-term use of chloroquine is also known to cause cardiac toxicities, including cardiomyopathy and conduction disorders.[21] Chloroquine use is cautioned in persons with G6PD deficiency due to risk of hemolytic anemia.

Quinacrine Quinacrine, also known as mepacrine, is an acridine derivative with a long history of treatment for malaria. The exact mechanism of action in SLE is unknown. Quinacrine has shown some benefit in treating SLE, but is no longer commercially available in the United States. In rare cases, it is compounded. Given its use is limited by availability, quinacrine is replaced by other commercially available antimalarials. However, it may be used at 100 mg per day as add-on therapy to lower doses of hydroxychloroquine or chloroquine to maximize effect of antimalarial drugs while minimizing the risks of retinopathy, particularly in skin manifestations of lupus.[22]

Quinacrine is not without toxicities. No formal pharmacologic safety studies have been performed, although quinacrine has shown possible cardiac and hepatic toxicities in rats, and cancers of the female reproductive tract when used intrauterinely for female sterilization.[22] It is also known to cause fetal demise, aplastic anemia, and psychosis. Quinacrine has been associated with yellow discoloration of the skin.

Mycophenolate Mofetil Mycophenolate inhibits inosine monophosphate dehydrogenase, which inhibits de novo guanosine nucleotide synthesis.[21] B and T lymphocytes are dependent on this pathway for proliferation. Mycophenolate is available as mycophenolate mofetil (trade name: CellCept) and mycophenolate sodium (trade name: Myfortic). These formulations are not equivalent and are not interchangeable. Mycophenolate mofetil is more commonly used and studied in SLE compared to mycophenolate sodium. However, better gastrointestinal tolerability is seen with mycophenolate sodium compared to mycophenolate mofetil.

Mycophenolate mofetil is useful as induction therapy or maintenance in LN, subacute cutaneous disease, and disease refractory to other agents, although has not shown benefit in neuropsychiatric disease. Comparative data of mycophenolate mofetil and azathioprine are conflicting. Mycophenolate has been shown to be superior to azathioprine at reducing flares and achieving remission with lower rates of adverse events.[30] Despite these differences, another trial found no significant differences in time to renal flare.[31] Azathioprine, however, is often preferred in women of childbearing age due to the risk of teratogenicity with mycophenolate mofetil. Mycophenolate mofetil is preferred over cyclophosphamide due to its safety profile and ease of administration. Mycophenolate mofetil has lower incidence of anemias compared to cyclophosphamide; however, mycophenolate mofetil requires dose titration due to gastrointestinal tolerability, specifically diarrhea.

Rates of response to LN induction therapy with mycophenolate mofetil or IV cyclophosphamide were compared based on race.[32] Response rates were similar in Asian and White patients, but differed in Black and Hispanic groups. Black and Hispanic patients had better treatment response to induction with mycophenolate mofetil compared to IV cyclophosphamide.

Azathioprine Azathioprine is an imidazolyl derivative of mercaptopurine; metabolites are incorporated into replicating DNA, halting DNA replication, and blocking the pathway for purine synthesis.[21] Azathioprine is a prodrug that is metabolized to 6-mercaptopurine (6-MP). Activation of 6-MP occurs via hypoxanthine-guanine phosphoribosyltransferase (HGPRT) and a series of processes involving kinases to form 6-thioguanine nucleotides (6-TGN) as major metabolites. 6-TGN incorporation into DNA is at least partly responsible for azathioprine's cytotoxicity. 6-MP is inactivated by two major routes: methylation by thiopurine S-methyltransferase (TPMT) to form an inactive metabolite methyl-6-MP, and oxidation by xanthine oxidase (XO) to form 6-thiouric acid (6-TG). The nucleotide diphosphatase (NUDT15) enzyme converts 6-TGN to inactive monophosphates.

Genetic polymorphisms in TPMT and NUDT15 causing reduced activity may lead to significant exposure to 6-TGN, and therefore increased risk of toxicities at usual doses of azathioprine or mercaptopurine. Pharmacogenomic testing is available to determine TPMT and NUDT15 activity. Patients with low or intermediate TPMT activity are at risk for significant bone marrow suppression due to potentially toxic 6-TGN levels on standard doses of azathioprine or mercaptopurine; lower doses or alternative therapies may be required. Prior to use of azathioprine, testing of TPMT and NUDT15 activity should be considered to guide dosing and treatment decision making.

Inhibition of XO may cause increased plasma concentration of azathioprine and metabolites. If a patient does not have detectable levels of the active metabolites, a xanthine oxidase inhibitor may be added to drive metabolism of 6-MP through the HGPRT and TPMT pathways. Alternatively, xanthine oxidase inhibitor use may potentiate toxicities. Historically, it was recommended to decrease the azathioprine dose by half or one-third when used in combination with a xanthine oxidase inhibitor; however, this may not be necessary with close monitoring of metabolites and symptoms of toxicities (hematologic toxicities, nausea, and vomiting). Once metabolite levels are stable, periodic monitoring of CBC to identify myelosuppression should occur.

Azathioprine is often considered for use in SLE patients with poor symptomatic control with glucocorticoids and hydroxychloroquine, or when hydroxychloroquine alone is unlikely to be sufficient. It can also be used to treat severe disease in pregnancy. Azathioprine is used for maintenance treatment of nephritis after induction with cyclophosphamide or mycophenolate mofetil.

Cyclophosphamide Cyclophosphamide is an alkylating agent that prevents cell division by cross-linking DNA strands and decreasing DNA synthesis, leading to cell death.[21] Cyclophosphamide is administered by IV infusion for SLE. Cyclophosphamide is typically reserved for use in severe organ-threatening disease or as rescue therapy for refractory nonmajor organ manifestations due to toxicities. Toxicities include hemorrhagic cystitis, bone marrow suppression, gonadal toxicities causing male and female infertility, teratogenicity, hyponatremia, and increased risk of malignancy.

Hydration before, during, and after IV infusion of cyclophosphamide, and use of mesna may help lower the risk of hemorrhagic cystitis. Shorter courses of cyclophosphamide may not cause infertility. A major risk factor for toxicities is the cumulative dose. Dosing approaches have been developed to minimize overall exposure.

A multicenter, prospective, randomized trial (Euro-Lupus Nephritis Trial) compared outcomes after low- and high-dose cyclophosphamide induction dosing in 90 patients with SLE and glomerulonephritis.[33] Patients assigned to the high-dose group received monthly infusions of cyclophosphamide for 6 months followed by two quarterly infusions. The initial dose was 0.5 g/m^2 body surface area (BSA), and was increased to a maximum of 1500 mg per dose depending on white blood cell (WBC) nadir (lowest point) on day 14. Patients assigned to the low-dose group received fixed-dose infusions of 500 mg every 2 weeks for a cumulative dose of 3 g. In both treatment arms, azathioprine was initiated 2 weeks after the last cyclophosphamide dose for maintenance treatment. After a median of 41 months, 20% of patients in the high-dose group and 16% in the low-dose group experienced treatment failure. Reasons for failure were defined as an absence of primary response, emergence of a glucocorticoid-resistant flare, and doubling of the serum creatinine level. Outcomes were comparable between groups, while rates of infection were lower in the low-dose group, although not statistically significant. Based on this trial and concerns with toxicities, some clinicians prefer to use low-dose cyclophosphamide.

Methotrexate Methotrexate irreversibly binds to and inhibits dihydrofolate reductase and thymidylate synthestase, inhibiting the formation of reduced folates, purine, and thymidylic acid, resulting in inhibition DNA synthesis, repair, and cellular replication.[21] Methotrexate use is often limited to joint or mucocutaneous involvement, as it is not particularly helpful for SLE with major organ involvement. A systematic review found that methotrexate has been shown to reduce disease activity and average dose of corticosteroids.[34] Similar to utilization in other rheumatic diseases, methotrexate is administered once weekly either orally or subcutaneously, along with daily folic acid supplementation to minimize toxicities, such as anemia, elevated liver function test, nausea, and mucositis.

Tacrolimus Tacrolimus inhibits T lymphocyte activation, although the exact mechanism in SLE is unknown.[21] Use of tacrolimus is typically reserved for patients with LN that is refractory to mycophenolate and cyclosporine. When added to prednisolone for induction therapy, response to tacrolimus was noninferior to mycophenolate mofetil.[35] Over time, the tacrolimus group had numerical trends toward more renal flares and renal function decline. Tacrolimus requires frequent laboratory monitoring due to adverse events, such as electrolyte disturbances, anemia, hyperglycemia, renal abnormalities, and hepatotoxicity.

Belimumab Belimumab is an IgG1-lambda monoclonal antibody that prevents the survival of B lymphocytes by blocking the binding of soluble B lymphocyte stimulator protein (BLyS) to receptors on B lymphocytes. This reduces the activity of B-cell–mediated immunity and the autoimmune response.[21] It was FDA approved for treatment of SLE in 2011, and in 2021 for treatment of LN. Belimumab is indicated for use in seropositive SLE in combination with other immunomodulatory medications. Belimumab is well tolerated as an infusion or injection therapy with the most common side effects being mild leukopenia and risk of worsening depression.

Belimumab was studied as add-on therapy to stable immunosuppressive or antimalarial treatment in a randomized, multicenter, placebo-controlled, phase 3 trial and a corresponding continuation study in patients with anti-ANA or anti-dsDNA positivity.[36,37] Patients who received belimumab had improvements in disease severity, reduction in flares, and improvement in physician global assessment compared to placebo. Rates of severe adverse events were comparable. Notably, LN patients who were pregnant were excluded from these studies. Additionally, Black Americans represented only about 4% of study participants.

Subsequently, belimumab was studied as add-on therapy specifically in patients with autoantibody positive, biopsy-confirmed active LN.[38] Significantly more patients in the belimumab group met the primary endpoint of primary efficacy renal response, a composite defined as estimated glomerular filtration rate (eGFR) greater than or equal to 60 mL/min/1.73 m^2 BSA or no decrease in eGFR from preflare of greater than 20%, urinary protein to creatinine ratio of greater than or equal to 0.7, and not defined as a treatment failure.[38] Adverse events were similar between groups.

Finally, due to previous underrepresentation of Black Americans in belimumab trials, a randomized, multicenter, double-blind, placebo-controlled trial was conducted in adults with SLE who self-identified as Black.[39] Patients received standard of care plus either belimumab or placebo. Numerical trends favoring belimumab, although not statistically significant, were observed in disease response. When stratified by disease activity, a significant improvement was seen in patients with high disease activity. Adverse events and study withdrawals were similar between groups.

Rituximab Rituximab is a monoclonal antibody that binds to the CD20 antigen on B-lymphocyte cell surface, activating complement-dependent B-cell cytotoxicity, and to human Fc receptors, mediating cell killing through an antibody-dependent cellular toxicity.[21] Rituximab is not FDA approved for SLE and has shown conflicting results in clinical trials. A trial comparing add-on therapy with rituximab versus placebo in patients with moderate to severe SLE already receiving prednisone plus azathioprine, mycophenolate mofetil, or methotrexate was conducted.[40] No differences were seen between the treatment arms in clinical response. Safety and tolerability were similar between groups. A subgroup analysis comparing pooled African American and Hispanic patients to other ethnic groups found an improvement in clinical response in this group.

Rituximab increases the risk of hypogammaglobulinemia and subsequent infections. In one study, 19.3% of patients who had normal IgG levels prior to rituximab treatment developed mild to severe hypogammaglobulinemia after rituximab, while 22.4% of patients with preexisting mild to moderate hypogammaglobulinemia worsened after rituximab.[41] Additional therapy-limiting safety issues include immunosuppression, progressive multifocal leukoencephalopathy (PML), and infusion reactions. Due to conflicting results and safety issues, rituximab is therefore often reserved for persons refractory or intolerant to conventional therapies.

Dihydroepiandrosterone Dihydroepiandrosterone (DHEA) is an androgenic adrenal steroid available as a supplement and not evaluated by the FDA. Evidence in SLE is conflicting. A multicenter, randomized, double-blind and placebo-controlled trial in adult women with mild to moderate SLE found no significant difference in disease activity scores, but did show a significant difference in numbers of patients that experienced a flare during treatment, and patient global assessment.[42] Adverse events of DHEA included increased testosterone levels and acne. A small, open-label, noncontrolled trial of patients with mild to moderate SLE reported significant improvements in disease activity, patient global assessment, physician global assessment, and reductions in prednisone doses as compared to baseline.[43] Similar adverse events were observed in this trial.

▶ *Drugs in the Pipeline*

Multiple therapies are currently being studied for SLE treatment. Treatment targets include janus kinase, type 1 interferon, BLyS, antiproliferating-inducing ligand (APRIL), CD20, and CD22. In April 2020, the FDA granted fast-track designation to telitacicept, a recombinant transmembrane activator, calcium modulator, and cyclophilin ligand interactor fusion protein that operates by targeting and neutralizing BLyS and APRIL. In July 2020, a New Drug Application was filed for voclosporin, a potential treatment for LN. It was FDA approved for treatment of LN under the trade name Lupkynis in January 2021.

Treatment of Complications

Due to multi-organ involvement, complications of SLE frequently occur. Common complications include cardiovascular, pregnancy, renal impairment, pulmonary, and musculoskeletal. Persons with SLE also experience social and economic complications.

▶ *Cardiovascular Complications*

KEY CONCEPT Approximately 10% to 15% of people diagnosed with lupus will die prematurely due to cardiovascular complications of SLE.[44] Inflammation as well as treatments for SLE contribute to cardiovascular risk factors, including hypertension, hyperlipidemia, elevated blood glucose, and thromboembolic risk.

Treatment targeted to minimize atherosclerotic and cardiovascular complications in SLE are the same as treating that disease state. Interventions are targeted at meeting and maintaining blood pressure and lipid goals, according to the applicable guidelines (refer to Chapter 6, "Hypertension," and Chapter 13, "Dyslipidemias"). Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) may be particularly useful in the setting of hypertension or proteinuria. Hydroxychloroquine has been shown to reduce total cholesterol, very-low-density lipoprotein (VLDL) cholesterol, low-density lipoprotein (LDL) cholesterol, and triglycerides, and increase high-density lipoprotein (HDL) cholesterol, even in patients on corticosteroid therapy.[20]

Antiphospholipid syndrome (APS) is the association of thrombosis and/or pregnancy morbidity with antiphospholipid antibodies (aPL). Approximately 30% to 40% of persons with SLE are positive for aPL.[45] This increases the risk of thromboembolism by twofold compared to persons with SLE without aPL. Warfarin is the recommended treatment of acute venous thromboembolism in SLE patients with APS. When compared to warfarin, rivaroxaban was associated with higher rates of thromboembolism and major bleeding.[46] Exposure to hydroxychloroquine has been associated with the prevention thrombotic events.[20]

Primary thromboprophylaxis in patients with SLE and positive lupus anticoagulant or isolated persistent aPL at medium to high titers receive hydroxychloroquine and low-dose aspirin.[47] Patients with definite APS and a first venous event are recommended to receive oral anticoagulation with warfarin with a target INR of 2 to 3. Consensus on recommendations for patients with definite APS and a first arterial event were not reached. Indefinite anticoagulation therapy is recommended in patients with definite APS and thrombosis. Anticoagulation limited to a duration of 3 to 6 months may be considered in patients with a low-risk aPL profile and a known transient cause.

▶ *Pregnancy Complications*

KEY CONCEPT Women with SLE are at a higher risk of experiencing difficulty conceiving, miscarriage, stillbirth, and preeclampsia. Women who are aPL-positive are more likely to experience thromboemboli during pregnancy that can be life-threatening to the mother and the fetus. Due to fluctuating hormone levels, women often experience a disease flare during pregnancy. It is imperative that high-risk obstetric specialists are involved early and throughout the pregnancy. It is recommended that women work with their rheumatologist and obstetrician to plan pregnancies. Due to risk of teratogenicity and adverse effects on pregnancy associated with some medications used in SLE, careful selection of immunomodulators may need to be considered prior to conception. Pregnancy outcomes are best when conception occurs during a period of remission. Pregnancy morbidity is more common in women with SLE, particularly those with aPL positivity. This makes contraception and pregnancy planning of particular importance.

Contraception Estrogen use is an independent risk factor for cardiovascular events. Use of estrogen-containing

Table 56–6

Effectiveness and Safety of Contraceptive Options in Women with SLE[48]

	Method	Safety in SLE
Highly effective	Copper IUD Progestin IUD	Safe in all women with SLE
	Progestin Implant	Limited data but likely safe in all women with SLE
Effective	Progestin-only pill	Safe in all women with SLE
	Depo medroxyprogesterone acetate	Avoid in positive aPL, or high risk of osteoporosis
	Combined estrogen and progestin pill	Avoid in moderate to severe SLE, or positive aPL
	Transdermal patch Estrogen ring	Avoid in SLE or positive aPL
Less effective	Diaphragm Condom Fertility-awareness tracking Spermicide	Safe in all women with SLE

aPL, antiphospholipid antibody; IUD, intrauterine device; SLE, systemic lupus erythematosus

contraceptives may increase the risk of thromboembolism in an already vulnerable population. Intrauterine devices (IUDs) are the preferred method of contraception in women with SLE, regardless of aPL status. Estrogen should be avoided in aPL-positive women, leaving the alternative options of the progestin-only pill, progestin implant, and IUDs. In women with SLE and negative aPL tests, alternative options are presented in Table 56–6.[48]

Combined oral contraceptives such as ethinyl estradiol and levonorgestrel have drug interactions with mycophenolate mofetil, cyclosporine, and glucocorticoids. Mycophenolate mofetil can decrease the effectiveness of oral contraceptives, while the combined contraceptives may increase the serum concentrations of cyclosporine and glucocorticoids.

Treatment of SLE During Pregnancy KEY CONCEPT Hydroxychloroquine is safe for use during pregnancy and should continue throughout gestation. Hydroxychloroquine is not teratogenic, and does not increase the risk of miscarriage, stillbirth, pregnancy loss, or fetal abnormalities.[21] It has also been shown to reduce the risk of anti-SSA–associated cardiac manifestations of neonatal lupus.

While azathioprine has been shown to cause fetal abnormalities in some case reports, updated guidelines support its use in LN and other rheumatic diseases during pregnancy.[48] It may be used for a severe nephritis flare if benefits outweigh the potential risks. Treatment of LN during pregnancy may include glucocorticoids, with the possibility of adding azathioprine not to exceed 2 mg/kg/day if needed to reduce glucocorticoid doses or maintain disease control.[18] KEY CONCEPT Cyclophosphamide, mycophenolate mofetil, methotrexate, and nonsteroidal anti-inflammatory drugs (NSAIDs) should be avoided during pregnancy due to association with fetal harm.

Tacrolimus crosses the placenta.[21] Miscarriage, preterm delivery, low birth weight, birth defects, renal dysfunction, transient neonatal hyperkalemia, and fetal distress have been reported following in utero exposure to tacrolimus in infants of organ transplant recipients. Pharmacokinetics are also altered during pregnancy. Whole blood concentrations decrease as pregnancy progresses; however, unbound concentrations increase. Measuring unbound concentrations may be preferred, especially in women with anemia or hypoalbuminemia. If unbound concentration measurement is not available, interpretation of whole blood concentrations should account for RBC count and serum albumin concentration. The risk of infection, hypertension, and preeclampsia may be increased in pregnant women who have had a kidney transplant.

KEY CONCEPT Treatment of thromboembolism during pregnancy should include low molecular weight heparins. Warfarin should be avoided in pregnancy. Low-dose aspirin may be considered in low-risk aPL-positive patients without previous venous thromboembolism, while high-risk patients should receive low molecular weight heparin.

Ideally, pregnancies should be planned for conception to occur during periods of disease remission. Pregnancies in patients with SLE are considered high risk.

▶ *Other Complications*

KEY CONCEPT Additional noncardiovascular complications in SLE include renal, pulmonary, musculoskeletal involvement, and glandular involvement. Uncontrolled LN may result in the need for dialysis and/or a renal transplant. A less common pulmonary complication of SLE includes pulmonary hypertension (PH). Osteopenia or osteoporosis may develop as a result of chronic steroid use or due to lack of vitamin D due to sunscreen/sun avoidance. Sjögren syndrome and hypothyroidism often coexist with SLE. Treatment of SLE complications, including PH,

Patient Encounter Part 3

The patient returns to the clinic a year and half later currently flaring with thrombocytopenia, anemia, and rash (burning, pruritus). She has 3+ protein and 2+ blood in the urine and is diagnosed with active LN. Her most recent labs of hemoglobin (9.8 g/dL [98 g/L; 6.1 mmol/L]), hematocrit (29.8% [0.298]), and platelets (31,000/mm^3 [31×10^9/L]) support this diagnosis. She is currently being treated with belimumab and hydroxychloroquine. Methotrexate was previously utilized; however, she did not tolerate treatment due to significant gastrointestinal side effects and continuous fatigue. To treat the flare, she began taking prednisone 60 mg daily 5 days ago. She mentions that she wants to have children this year and wants to discuss prepregnancy planning during this visit.

What pregnancy planning counseling points should be considered regarding preconception planning and assessment of associated risk?

During pregnancy, what pharmacological therapy is considered mainstay treatment if not otherwise contraindicated versus what is absolutely contraindicated?

If prednisone is continued long term, what side effects should she be educated on?

What modifications, if any, need to be made to this patient's pharmacological therapy plan leading up to conception and pregnancy?

Patient Care Process

Collect Information:

- Perform a comprehensive medication reconciliation including prescription, over-the-counter and supplement use.
  - Review for medications associated with drug-induced lupus (see Table 56–1).
  - If applicable, identify both failed and successful SLE pharmacological treatments, noting side effects, adverse effects and therapeutic response in the past.
- Review patient's clinical history and physical assessment findings (see Table 56–2):
  - Joint pain
  - Skin involvement
  - Hematologic abnormalities
  - Constitutional symptoms (eg, fatigue)
  - Cardiovascular involvement
  - Lung involvement
  - Central nervous system involvement
- Review laboratory data in correlation and context to clinical history findings and organ involvement (see Table 56–2).

Assess the Information:

- Identify clinically relevant drug–drug interactions, any patient reported allergies and presence of adverse reactions.
- Classify severity of disease activity (see Table 56–3):
  - Mild
  - Moderate
  - Severe
- Assess frequency of flares, organ involvement, and severity of organ involvement to determine appropriate recommendations for therapeutic intervention(s) (see Table 56–3):
  - Intermittent disease flares
  - Chronic disease flare related to organ involvement
  - Quiescent disease
- Assess use of intravenous "pulse" versus daily oral systemic glucocorticoids (see **Acute Treatment** section).
  - Methylprednisolone versus prednisone
- Screen for presence of comorbid conditions; the following conditions are commonly associated with SLE:
  - Accelerated atherosclerosis
  - Pulmonary hypertension
  - APS
  - Osteopenia or osteoporosis
  - Depression and anxiety
- Assess contraception and pregnancy planning in patients of childbearing age (see **Pregnancy Complications, Contraception, and Treatment of SLE During Pregnancy** sections).
- Based on the following baseline laboratory findings, determine if any findings need to be brought to the attention of supervising rheumatology provider when collaborating on initiating, modifying, or stopping pharmacological therapy:
  - ESR/CRP
  - CBC/CMP
  - TSH
  - Hepatitis B virus (HBV) and hepatitis C virus (HCV) testing
  - Infection (eg, tuberculosis)

Develop a Care Plan:

- Considering disease activity, organ involvement, severity of organ involvement, and laboratory findings, determine appropriate pharmacological treatment.
  - Determine insurance authorization, if applicable.
- Establish personalized monitoring frequency of laboratory findings and therapeutic response based on disease activity, medication(s) selected, and severity of organ involvement.
  - CRP, ESR, C4, C3
  - Additional testing dependent on symptoms and organ involvement which may include ECG, lung function testing, chest x-ray, renal or skin biopsies, CT scan
- Determine necessity of steroid treatment.
- If appropriate, address preconception planning and assessment of associated risk.

Implement the Care Plan: (See Treatment section)

- Counsel patient on significance of reporting side effects and therapeutic response to pharmacological treatment.
  - Adherence is dependent on the safety, effectiveness, and tolerability of medications
- Provide education on:
  - Modifiable risk factors, lifestyle modifications, and nonpharmacologic interventions
  - Drug therapy including mechanism of action, benefits of medication, common and serious adverse effects, expected time to response

Follow-up: Monitor and Evaluate: (See Outcome Evaluation section)

- Follow up approximately every 3 to 4 months on patient's response to medication, disease activity, and nonpharmacological modifiable risk factors.
- Follow up on patient reported disease flares.
- Reverify insurance coverage in case of modification of therapy.
- If applicable, follow up on long-term steroid treatment side effects.
- Assess for comorbidities, such as cardiovascular complications.

hypothyroidism, Sjögren syndrome, and osteopenia and osteoporosis, follows the same treatment recommendations for non-SLE patients who have these disease states (refer to Chapter 45, “Thyroid Disorders,” and Chapter 57, “Osteoporosis”).

Pulmonary hypertension due to SLE is treated as World Health Organization group I PH, also called pulmonary arterial hypertension (PAH). Therapy options aimed at inducing vasodilation of the pulmonary vasculature include prostacyclin analogues and agonists, endothelin receptor antagonists, phosphodiesterase-5 inhibitors, and soluble guanylate cyclase stimulators.[49] Sjögren syndrome is a chronic autoimmune condition characterized by antibodies directed against salivary and lacrimal glands, although other organs may be affected. Common symptoms include dry eyes, dry mouth, and poor salivation. Although there is no cure, treatments are aimed at symptomatic improvement. Nonpharmacologic treatments include increased fluid intake, artificial saliva and tears, and plugging lacrimal ducts with collagen plugs. Topical pharmacologic treatments include cyclosporine and lifitegrast. Lastly, systemic pharmacologic treatments include corticosteroids and cholinergic agonists such as pilocarpine or cevimeline.

OUTCOME EVALUATION

- Multiple disease activity indices exist (SLEDAI-2K, BILAG), but are rarely used outside of clinical trials.
- In practice, assess disease activity and severity with history taking, physical examination, and laboratory testing. Laboratory evaluation is typically done every 3 to 6 months, but can be done more frequently if a patient had a recent flare.
- Complete additional testing as symptoms arise and organ involvement is suspected. This may include electrocardiogram (ECG), lung function testing, chest x-ray, renal or skin biopsies, computed tomography (CT) scan.
- Appropriately monitor drug-induced adverse effects and toxicities (Table 56–5).

6-MP	6-Mercaptopurine
6-TG	6-Thiouric acid
6-TGN	6-Thioguanine nucleotides
ACE	Angiotensin-converting enzyme
ACR	American College of Rheumatology
ANA	Antinuclear antibody
ANC	Absolute neutrophil count
aPL	Antiphospholipid antibody
APRIL	Antiproliferating-inducing ligand
APS	Antiphospholipid syndrome
ARB	Angiotensin receptor blocker
AV	Atrioventricular
BCG	Bacille Calmette Guerin
BILAG	British Isles Lupus Assessment Group
BLyS	B lymphocyte stimulator protein
BMI	Body mass index
BMP	Basic metabolic panel
BP	Blood pressure
BSA	Body surface area
BUN	Blood urea nitrogen
C (C3, C4)	Complement
CBC	Complete blood count
cGAS	Cyclic GMP-AMP synthase
CMP	Comprehensive metabolic panel
CrCl	Creatinine clearance
CRP	C-reactive protein
CRRT	Complete renal replacement therapy
CT	Computed tomography
CVD	Cardiovascular disease
CYP	Cytochrome P450
DHEA	Dihydroepiandrosterone
DMARD	Disease-modifying antirheumatic drugs
dsDNA	Double-stranded DNA
DVT	Deep vein thrombosis
ECG	Electrocardiogram
eGFR	Estimate glomerular filtration rate
ELISA	Enzyme-linked immunoassay
ESR	Erythrocyte sedimentation rate
EULAR	European League Against Rheumatism
FDA	Food and Drug Administration
G6PD	Glucose-6-phosphate dehydrogenase
GERD	Gastroesophageal reflux disease
HBV	Hepatitis B virus
HCV	Hepatitis C virus
HDL	High-density lipoprotein
HGPRT	Hypoxanthine-guanine phosphoribosyltransferase
Ig	Immunoglobulin
IL	Interleukin
IUD	Intrauterine device
IV	Intravenous
LDL	Low-density lipoprotein
LN	Lupus nephritis
LFT	Liver function test
MCP	Metacarpophalangeal
MHC	Major histocompatibility complex
MSK	Musculoskeletal
NSAID	Nonsteroidal anti-inflammatory drug
NUDT15	Nucleotide diphosphatase
N/V/D	Nausea/vomiting/diarrhea
P-gp	P-glycoprotein
PAH	Pulmonary arterial hypertension
PH	Pulmonary hypertension
PIP	Proximal interphalangeal
PML	Progressive multifocal leukoencephalopathy
PPI	Proton pump inhibitor
PTU	Propylthiouracil
QTc	Corrected QT interval
RA	Rheumatoid arthritis
RBC	Red blood cell
RF	Rheumatoid factor
RNP	Ribonucleoprotein
RPR	Rapid plasma reagin
SC	Subcutaneous
SD-OCT	Spectral domain optical coherence tomography
SLE	Systemic lupus erythematosus
SLEDAI-2K	SLE disease activity index 2000
SLICC	Systemic Lupus International Collaborating Clinics
SPF	Sun protection factor
SSA	Sjögren syndrome antigen A
SSB	Sjögren syndrome antigen B
T_3	Triiodothyronine
T_4	Thyroxine
TB	Tuberculosis
T Bili	Bilirubin test
TLR	Toll-like receptor
TNFi	Tumor necrosis factor inhibitors
TPMT	Thiopurine S-methyltransferase
TSH	Thyroid-stimulating hormone
TTP	Thrombotic thrombocytopenic purpura
ULN	Upper limit of normal
VLDL	Very-low-density lipoprotein
WBC	White blood cell
XO	Xanthine oxidase

Osteoporosis

Beth Bryles Phillips and Morgan K. Moulton

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the association between osteoporosis and morbidity and mortality.
2. Identify risk factors that predispose patients to osteoporosis.
3. Describe the pathogenesis of fractures in patients with osteoporosis.
4. List the criteria for diagnosis and screening of osteoporosis.
5. Recommend appropriate lifestyle modifications to prevent bone loss.
6. Compare and contrast the effect of available treatment options on reducing fracture risk.
7. Recommend an appropriate treatment regimen for a patient with osteoporosis, and develop a monitoring plan for the selected regimen.
8. Educate patients about osteoporosis and drug treatment, including appropriate use, administration, and adverse effects.

INTRODUCTION

Osteoporosis is a common and often silent disorder causing significant morbidity and mortality and reduced quality of life. It is characterized by low bone density and loss of strength in bone tissue resulting in an increased risk and rate of bone fracture. Osteoporosis is responsible for more than 2 million fractures in the United States annually. Approximately 10 million Americans have osteoporosis, and an additional 43 million are classified as having low bone density.[1,2] The cost of care is expected to rise to $25.3 billion by 2025. The risk of developing an osteoporosis-related fracture varies according to age, sex, and race/ethnicity.[1] Common sites of fracture include the spine, hip, and wrist, although almost all sites can be affected.

The fractures associated with osteoporosis have an enormous impact on individual patients, not only causing initial pain, but also chronic pain, loss of mobility, depression, nursing home placement, and death. Patients with vertebral fractures may also experience height loss, kyphosis, and decreased mobility due to limitations in bending and reaching. These patients are also at greater risk of having a future vertebral fracture. Multiple vertebral fractures may lead to restrictive lung disease and altered abdominal anatomy, while patients with hip fractures have added risks associated with surgical intervention to repair the fracture. More than 50% of patients never fully recover or regain preinjury independence, and death may occur in up to 20% of patients within 2 years after fracture.[2]

EPIDEMIOLOGY AND ETIOLOGY

Osteoporosis is the most common skeletal disorder, but only a fraction of patients are evaluated and diagnosed, and less than one in four receives treatment after a fracture.[2,3] Osteoporosis can be classified as either primary (no known cause) or secondary (caused by drugs or other diseases). Primary osteoporosis is most often found in postmenopausal women and aging men, but it can occur in other age groups as well.[1,2]

The prevalence of osteoporosis varies by age, sex, and race/ethnicity and increases exponentially after age 50.[4] As a group, African Americans have the highest BMD, while Asian Americans have the lowest.[4] In the United States most hip fractures occur in postmenopausal White women, who also have the highest incidence of fracture when adjusted for age. The frequency of fracture in African American and Hispanic women trail far behind that of Caucasians, although hip fracture-related mortality may be higher.[5] Although both men and women lose bone as they age, postmenopausal women have accelerated bone loss due to loss of estrogen. Men have some protection from osteoporosis due to their larger initial bone mass and size and lack of accelerated bone loss associated with menopause.[6] Secondary causes of osteoporosis, such as hypogonadism, are found more commonly in men with low trauma fractures.[6]

PATHOPHYSIOLOGY

The human skeleton contains both cortical and trabecular bone. Cortical bone comprises approximately 80% of the skeleton, and its density and compactness account for much of bone strength. It is generally found on the surfaces of long and flat bones. Trabecular (or cancellous) bone has a sponge-like appearance and is found along the inner surfaces of long bones and throughout the vertebrae, pelvis, and ribs. This type of bone is more susceptible to osteoporotic fractures.

Under normal circumstances, the skeleton undergoes a dynamic and constant process of bone remodeling, responding to stress and injury through continuous replacement and repair. This process is completed by the basic multicellular unit, including both osteoblasts and osteoclasts. Osteoclasts are involved with

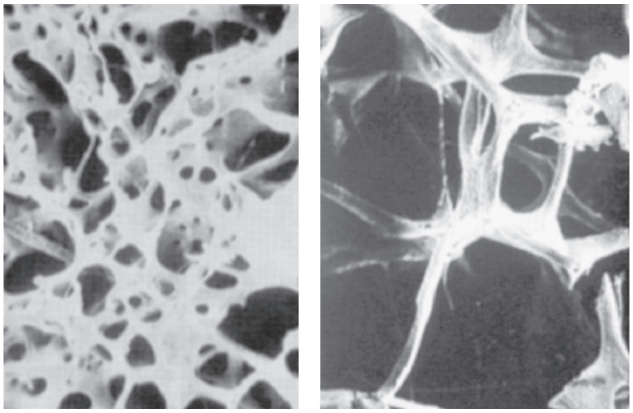

FIGURE 57–1. Normal trabecular bone (*left*) compared with trabecular bone from a patient with osteoporosis (*right*). The loss of mass in osteoporosis leaves bones more susceptible to breakage. (From Barrett KE, Barman SM, Brooks HL, Yuan JJ, eds. Ganong's Review of Medical Physiology, 26e. New York: McGraw-Hill; 2016: Figure 21–12; with permission. http://www.accesspharmacy.com.)

Table 57–1

Risk Factors for Osteoporosis and Osteoporotic Fractures[1,2]

Risk Factors for Osteoporosis	Risk Factors for Falling and Fractures
Low bone mineral density	Poor health/frailty
Female sex[a]	Impaired gait or balance
Age 65 and over	Recent falls
Race/ethnicity[a]	Cognitive impairment
History of previous low trauma (fragility) fracture after age 50	Impaired vision
Osteoporotic fracture in a first-degree relative (especially parental hip fracture)[a]	Environmental factors (eg, stairs, throw rugs, pets, poor lighting)
Low BMI or body weight (under 57.6 kg)	Medications (eg, opioids, psychotropics, anticonvulsants)
Premature menopause (before 45 years old)	
Secondary osteoporosis[b]	
Rheumatoid arthritis[a]	
Oral glucocorticoid therapy[a]	
Current cigarette smoking[a]	
Alcohol intake (three or more drinks daily)	
Loss of height	

[a] Risk factors included in FRAX risk assessment calculator.

[b] Secondary causes in the FRAX tool: type 1 diabetes, adult osteogenesis imperfecta, longstanding untreated hyperthyroidism, hypogonadism, premature menopause (before age 45), chronic malnutrition, malabsorption, and chronic liver disease.

BMI, body mass index.

resorption or breakdown of bone and continuously create microscopic cavities in bone tissue. Osteoblasts are involved in bone formation and continuously mineralize new bone in the cavities created by osteoclasts. Until peak bone mass is achieved between the ages of 25 and 35, bone formation exceeds bone resorption for an overall increase in bone mass. Figure 57–1 illustrates the difference between normal and osteoporotic bone.

In osteoporosis, an imbalance in bone remodeling occurs. Most commonly, osteoclastic activity is enhanced, resulting in overall bone loss. However, a reduction in osteoblastic activity and bone formation also occurs in certain types of osteoporosis. Due to a decrease in endogenous estrogen, bone remodeling accelerates during menopause, and a substantial amount of bone is lost during the first 5 years after menopause compared to men of the same age. The resultant bone loss and change in bone quality predispose patients to low impact (or low trauma) fractures.

CLINICAL PRESENTATION AND DIAGNOSIS

See accompanying text box for the clinical presentation of osteoporosis.

KEY CONCEPT All postmenopausal women and men older than 50 years should be evaluated for osteoporosis risk and need for further diagnostic assessment.[1,2] Many risk factors for osteoporosis and osteoporotic fractures are predictors of low bone mineral density (BMD) (Table 57–1). The risk for osteoporosis generally increases as the number of risk factors increases, and the risk of fractures increases as BMD decreases. Because osteoporosis is commonly caused by secondary factors (Table 57–2), medical history, medication history, and laboratory values should be evaluated to determine if further workup is needed.

Clinical Presentation of Osteoporosis

General

Many patients with osteoporosis are asymptomatic unless they experience a low trauma fracture.

Symptoms of Low Trauma Fracture

Pain at the site of the fracture or immobility.

Signs

Height loss (> 2 cm), spinal kyphosis ("dowager's hump"), low trauma fracture especially of the hip or spine.

Diagnostic Assessment

The diagnostic assessment for osteoporosis may include an assessment of BMD, vertebral imaging, laboratory workup, and other factors for secondary causes of osteoporosis, and biochemical markers of bone turnover. **KEY CONCEPT** Osteoporosis may be diagnosed by low bone density as determined by BMD or established history of low-trauma hip or vertebral fracture (resulting from a fall from standing height or less) in adulthood.[1]

▶ *Measurement of Bone Mineral Density*

Osteoporosis is characterized by weakened bone tissue, and BMD is the best measure of bone strength, predicting approximately 70% of bone strength.[7] Low BMD is associated with an increased risk of fractures. BMD can be measured at various sites throughout the skeletal system and by various methods. Dual-energy x-ray absorptiometry (DXA) can be used to measure central (hip and/or spine) and peripheral (heel, forearm, or hand) sites. Quantitative ultrasound, peripheral quantitative computed

Table 57–2

Medical Conditions and Drugs Associated with Osteoporosis or Low Bone Mass (Secondary Osteoporosis)[1,2]

Medical Conditions	Drugs
Alcoholism	Anticoagulants (heparin, warfarin)
Chronic kidney disease	Anticonvulsants (phenytoin, phenobarbital, primidone, valproate, carbamazepine)
Chronic obstructive pulmonary disease	Aromatase inhibitors (anastrozole, exemestane, letrozole)
Cushing syndrome	Cytotoxic drugs (eg, methotrexate, cisplatin)
Cystic fibrosis	Glucocorticoids (5 mg or more of prednisone daily or equivalent for at least 3 months)
Diabetes mellitus	Gonadotropin-releasing hormone analogs (leuprolide acetate, nafarelin, goserelin)
Eating disorders	Immunosuppressants (eg, tacrolimus)
GI disorders (eg, gastrectomy, malabsorption syndromes)	Lithium
Hematologic disorders (eg, hemophilia)	Medroxyprogesterone acetate
Hyperparathyroidism	Proton pump inhibitors
Hyperthyroidism	Selective serotonin reuptake inhibitors
Hypogonadal states	Sodium-glucose cotransporter 2 (SGLT2) inhibitors
Immunologic Diseases (eg, AIDS/HIV, rheumatoid arthritis)	Thiazolidinediones
Organ transplantation	Thyroid supplements (due to over-replacement)
Renal failure	Total parenteral nutrition
Skeletal cancer (eg, myeloma)	
Vitamin D deficiency	

Table 57–3

World Health Organization (WHO) Definition of Osteoporosis

Classification	T-Score[a]
Normal	–1 or greater
Osteopenia	Between –1 to –2.5
Osteoporosis	Less than –2.5

[a] *T*-score is the number of standard deviations above or below the mean bone mineral density in young adults.

tomography, radiographic absorptiometry, and single-energy x-ray absorptiometry are used to measure peripheral sites.

The World Health Organization (WHO) recommends a standardized approach to measuring BMD for diagnosis of osteoporosis using central measurement of BMD by DXA.[2] Preferred sites for central measurement include the total hip, femoral neck, and lumbar spine. Additionally, the American Association of Clinical Endocrinologists (AACE) states that the mid-third radius (also called 33% or 1/3 radius) of the forearm may be used when other data are not available.[2] Some instruments used for peripheral bone densitometry are portable, allowing bone density to be measured in pharmacies and health-fair screening booths. In addition to accessibility, peripheral measurement of BMD is generally less expensive than central DXA, making it an attractive option for many patients. Peripheral BMD testing is useful in identifying patients who are candidates for central DXA and who are at increased risk of fracture, but it should not be used for diagnosis.

Once the BMD report is available, *T*-scores and *Z*-scores are used to interpret the data. The *T*-score is the number of standard deviations from the mean BMD in healthy, young, White women. Osteoporosis is defined as a *T*-score more than –2.5 standard deviations below the mean BMD in young adults (Table 57–3). Osteopenia, or low bone mass, is defined as a *T*-score between –2.5 and –1.0. The *Z*-score, defined as the number of standard deviations from the mean BMD of age- and sex-matched controls, is similar to the *T*-score but is corrected for both age and sex of the patient. *Z*-scores may be more clinically relevant in evaluating BMD in premenopausal women, men younger than the age of 50, and patients who may have secondary causes for low BMD.

▶ *Screening and Risk Factor Assessment*

The National Osteoporosis Foundation (NOF) and AACE recommend BMD measurements in the following groups: women age 65 and older, men age 70 and older, perimenopausal women and men age 50 to 69 with risk factors, anyone with a fracture after age 50, and adults with a secondary cause for osteoporosis.[1,2]

FRAX (see *www.shef.ac.uk/FRAX*) is an additional tool developed by the WHO to evaluate an individual's 10-year probability of developing hip and major osteoporotic fractures based on femoral neck BMD *T*-score, age, and other risk factors.[1] The intended use is for men and women older than 40 years. The FRAX tool has not been validated for patients with previous or current use of pharmacotherapy to treat osteoporosis. Although the *T*-score is helpful in calculating risk of fracture with FRAX, fracture risk may be calculated without it.

▶ *Vertebral Imaging*

Vertebral fractures cause significant morbidity and mortality among patients with osteoporosis. They are often clinically silent, widespread, frequently recur, and commonly go undiagnosed. For these reasons, vertebral imaging is recommended in patients with a central T-score –1.0 or less and at least one other factor: (a) women age 70 and older and men age 80 and older; (b) reported decrease in height of 4 or more centimeters; (c) reported or documented prior vertebral fracture; and (d) glucocorticoid therapy of at least 5 mg daily of prednisone (or equivalent) for at least 3 months.[2]

▶ *Laboratory Evaluation*

Laboratory assessment has little value in diagnosing osteoporosis but can be beneficial in identifying or excluding secondary causes of bone loss, or for monitoring drug therapy. Screening laboratory tests for the most common causes of secondary osteoporosis include complete blood cell count, serum chemistries (electrolytes with calcium, phosphorus, and liver enzymes), vitamin D, and urinalysis. For monitoring, bone turnover markers (BTMs) may be used: C-terminal telopeptide (CTX) for bone resorption, and serum carboxy-terminal propeptide of type I collagen (PINP) for bone formation. CTX should be drawn in the fasting state and at the same time in the morning due to potential variability. The clinical utility of BTMs include a more rapid measure of drug therapy response (3–6 months) compared to DXA (1–2 years), detecting presence of drug malabsorption or nonadherence, and assisting in determining length of a bisphosphonate drug holiday.[2] Other considerations for use of BTMs include high cost and lack of reliable results in patients with chronic kidney disease.[2,8]

Patient Encounter Part 1: Patient History

HPI: A 76 -year-old White woman presents to the clinic with her daughter for follow-up on her bone mineral density test results. She currently takes no prescription medication to prevent osteoporotic fracture. She takes calcium carbonate (Tums) approximately once a week for heartburn in addition to omeprazole daily. Milk upsets her stomach, so she usually drinks tea or diet soda (occasionally fruit juice), and she is unable to eat much cheese or dairy products. She reports occasional gardening for exercise. She has longstanding uncontrolled diabetes, although it has been under good control after her hospitalization 6 months ago. She has thought about quitting smoking but is not ready to do so at this time. She reports tolerating her medications well and reports no problems. She lives alone in her own home in a rural community.

PMH: DM type 2, HTN, hyperlipidemia, coronary heart disease S/P myocardial infarction with stent placement 6 months ago, CKD stage IV, GERD, lactose intolerance, osteoarthritis.

FH: Father died at age 76 with Alzheimer disease; mother died at age 92 with history of breast cancer and osteoporotic fracture of the hip; sister alive and well at age 69

SH: Homemaker; smoked 2 packs a day for 40 years, now smokes ½ pack daily; denies alcohol use

Meds: Acetaminophen 1000 mg 3 times daily as needed for joint pain, insulin glargine 40 units at bedtime, lisinopril 10 mg daily, atorvastatin 40 mg daily, omeprazole 20 mg daily, calcium carbonate (Tums) 500 mg as needed, aspirin 81 mg daily, clopidogrel 75 mg daily

Do any symptoms suggest the presence of osteoporosis?

What risk factors for osteoporosis does this patient have as defined by the World Health Organization?

What diseases or medications could contribute to osteoporosis in this patient?

What are the recommended daily intakes for calcium and vitamin D?

How could she incorporate more calcium into her diet?

TREATMENT

Desired Outcomes

KEY CONCEPT Treatment goals for osteoporosis include: (a) preventing fractures; (b) maintaining or increasing BMD; (c) preventing secondary causes of bone loss; and (d) reducing morbidity and mortality associated with osteoporosis. Strategies to prevent fractures include maximizing peak bone mass, reducing bone loss, and using precautions to prevent falls leading to low trauma fractures.

Nonpharmacologic Therapy

▸ *Modification of Risk Factors*

Some osteoporosis risk factors (see Tables 57–1 and 57–2) are nonmodifiable, including family history, age, ethnicity, sex, and concomitant disease states. Other risk factors for bone loss may be minimized by early intervention, including smoking, low calcium intake, poor nutrition, inactivity, heavy alcohol use, and vitamin D deficiency. To avoid certain risk factors and maximize peak bone mass, efforts must be directed toward osteoporosis prevention at an early age.

▸ *Nutrition*

A healthy diet is essential to ensure sufficient nutrient intake and appropriate weight maintenance. Dietary calcium intake is important for achieving peak bone mass and maintaining bone density. Good dietary sources of calcium include dairy products, fortified juice, cruciferous vegetables (eg, broccoli, kale), salmon, and sardines (Table 57–4). Dietary intake generally provides 600 to 700 mg/day of calcium for men and women 50 and older. Supplementation to achieve recommended intake not attained by diet alone is important for primary prevention, as well as for those with a diagnosis of osteoporosis.

Adequate dietary intake of vitamin D is essential for calcium absorption. The most common source of vitamin D comes from exposure to sunlight. Ultraviolet rays from the sun promote synthesis of vitamin D_3 (cholecalciferol) in the skin, generally occurring within 15 minutes of direct sunlight exposure to bare skin without sunscreen. Ideally, individuals should receive twice weekly sun exposure to ensure optimal synthesis, but adequate exposure may not be possible during winter months in northern climates. Vitamin D may also be found in some dietary sources, including fortified milk, egg yolks, saltwater fish, and liver.

Table 57–4

Foods Containing Approximately 300 mg of Elemental Calcium

1 cup[a] skim milk
1 cup soy milk (calcium-fortified)
1 cup yogurt
1½ oz[b] cheddar cheese
1½ oz jack cheese
1½ oz Swiss cheese
1½ oz part-skim mozzarella
4 tablespoonfuls[c] grated Parmesan cheese
8 oz tofu
1 cup greens (collards, kale)
2 cups broccoli
4 oz almonds
2 cups low-fat cottage cheese
3 oz sardines with bones
5 oz canned salmon
1 cup orange juice (calcium-fortified)

[a] One cup = 240 mL.

[b] One ounce (1 oz) = 28 g.

[c] One tablespoon ≈ 15 mL.

▶ *Exercise*

Exercise can help prevent low trauma fractures. Weight-bearing exercise such as walking, jogging, dancing, and climbing stairs can help build and maintain bone strength. Muscle-strengthening or resistance exercises can help improve and maintain strength, agility, and balance, which can reduce falls.[1] It is important to develop and maintain a lifelong routine of weight-bearing and resistance exercise, because the benefits on bone can be lost after cessation of the exercise program.[1]

▶ *Falls Prevention*

The threshold at which individual patients develop a fracture varies, and other factors, such as fall risk, may play a role in fracture susceptibility. For this reason, fall history and evaluation of risk factors for falling should also be included in the initial evaluation. Patients with frailty, poor vision, hearing loss, or those taking medications affecting balance are at higher risk for falling and subsequent low trauma fractures.[1,2]

Many medications are associated with an increased risk of falling, such as antipsychotics, benzodiazepines, tricyclic antidepressants, sedative/hypnotics, anticholinergics, and glucocorticoids. Some cardiovascular and antihypertensive drugs can also contribute to falls, especially those causing orthostatic hypotension.[1] Efforts to decrease the risk of falling include balance training, muscle strengthening, removal of hazards in the home, installation of fall reduction measures such as handrails, and discontinuation of predisposing medications.[1,2] Patients with underlying physical and functional deficits may also benefit from physical and occupational therapy intervention to augment fall prevention strategies.[1,2]

Pharmacologic Treatment

KEY CONCEPT All men and women older than 50 years should be considered for pharmacologic treatment if they meet **any** of these criteria: (a) history of hip or vertebral fracture, (b) *T*-score –2.5 or less at femoral neck or spine, or (c) osteopenia and at least a 3% 10-year probability of hip fracture or at least a 20% 10-year probability of major osteoporosis-related fracture as determined by FRAX.[1,2]

▶ *Pharmacologic Therapy Guideline Recommendations*

Several guidelines for treating osteoporosis in men and women have been published.[1,2,4,9-11] The AACE guidelines provide the most comprehensive approach to evaluation and treatment of postmenopausal women.[2] The Endocrine Society's recommendations for treating postmenopausal women differ in some areas from the AACE guidelines. A treatment algorithm for managing osteoporosis referencing the guidelines is provided in Figure 57-2.

▶ *Calcium and Vitamin D*

KEY CONCEPT Calcium and vitamin D supplements to meet requirements should be added to all drug therapy regimens for osteoporosis to increase BMD and decrease the risk of hip and vertebral fractures.

Calcium plays an important role in maximizing peak bone mass and decreasing bone turnover, thereby slowing bone loss. When the calcium supply is insufficient, calcium is taken from bone stores to maintain the serum calcium level. Adequate calcium consumption is proposed to prevent this from occurring and may also correct secondary hyperparathyroidism in older adults.

The NOF recommends a daily calcium intake of 1000 mg for men between the ages of 51 and 70 and a higher intake of 1200 mg for women older than age 51 and men older than age 71.[1] When these requirements cannot be achieved by diet alone, appropriate calcium supplementation is recommended. Intakes over 1200 to 1500 mg/day may increase the risk of developing kidney stones,[1] and supplementation greater than 2500 mg/day may lead to hypercalciuria and hypercalcemia. Additionally, excessive calcium supplementation may be associated with an increased risk of cardiovascular events.[12,13]

Calcium supplements are available in a variety of calcium salts and dosage forms. Daily calcium requirements are reported as elemental calcium. However, many product labels list calcium content in the salt form, so the percentage of elemental calcium must be known to calculate the elemental calcium content per tablet. There is a lack of data supporting one salt form over another for reducing fracture risk or BMD stabilization.[2] However, a number of factors, including a single large intake of calcium, can limit calcium absorption, and special consideration must be given to calcium dosing to maximize absorption. Supplement doses should be limited to 500 to 600 mg of elemental calcium per dose, and absorption parameters, elemental calcium content, and adherence should be considered when choosing an appropriate supplement. Similar to other over-the-counter (OTC) products, various formulations may be included under the same general brand name (eg, Tums), so product labeling is very important in determining the amount of calcium in the product. Table 57–5 lists several common OTC products with their calcium and vitamin D content.

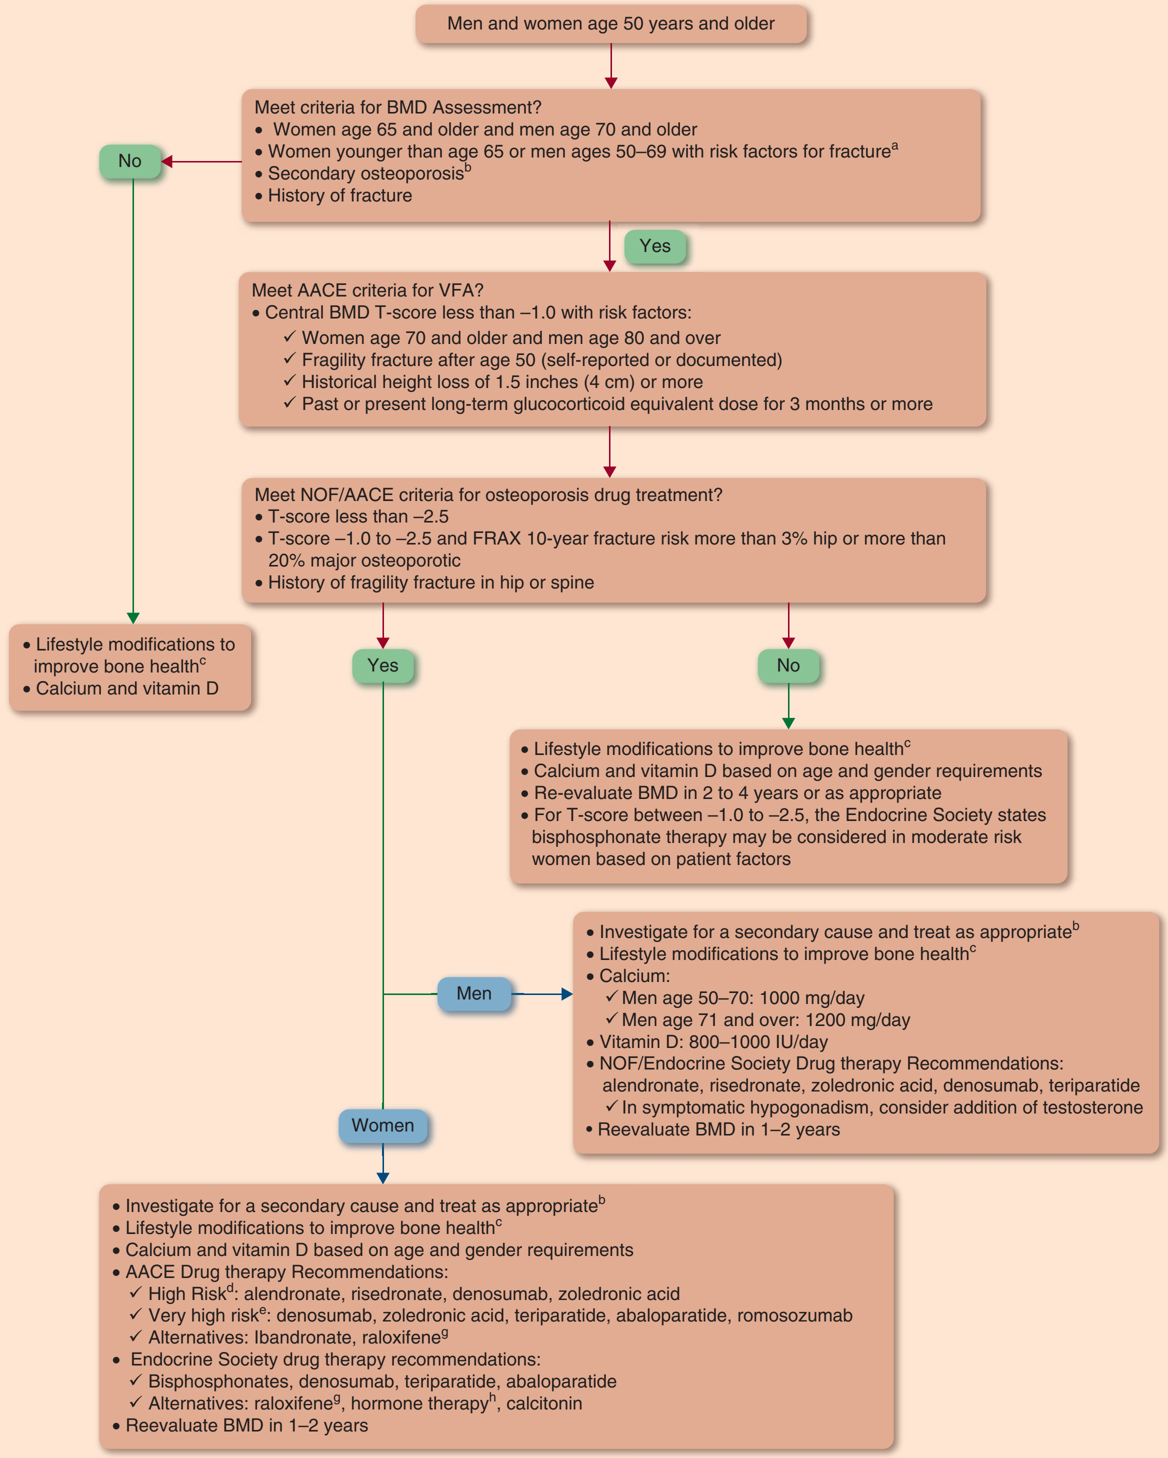
Calcium carbonate should be taken with food to maximize absorption. Older adults or patients receiving proton pump inhibitors or H_2-receptor antagonists may have difficulty absorbing calcium supplements due to reduced stomach acidity. Calcium citrate may be better absorbed in these situations because an acid environment is not needed for absorption; it may be taken with or without food.

Common adverse effects include constipation, bloating, cramps, and flatulence, especially with calcium carbonate. Changing to a different salt form may alleviate symptoms for some patients. Calcium salts may reduce the absorption of iron and some antibiotics, such as tetracycline and fluoroquinolones. To mitigate absorption issues, calcium supplements should be administered 2 hours prior to or 4 hours after antibiotic or iron therapy.

Vitamin D is crucial for bone health. It is needed for calcium absorption and may aid in balance and reduce fall risk, enhance bisphosphonate efficacy, improve BMD, and reduce fracture risk.[2] The NOF recommends a daily vitamin D intake of 800 to 1000 IU daily for all adults age 50 and older.[1] Vitamin D is available as a single entity, in combination with varying amounts of calcium salts, and in many multivitamin preparations. To avoid hypercalciuria and hypercalcemia, the maximum recommended dose for chronic use in most patients is 4000 IU/day.[14]

Patients at risk for vitamin D deficiency include older adults with malabsorption syndromes, chronic renal insufficiency, other chronic diseases, and those with limited sun exposure.[1] Frail, older adults in particular are at increased risk of deficiency due to decreased exposure to sunlight and subsequent decreased vitamin D synthesis in the skin, decreased GI absorption of vitamin D, and reduction in vitamin D_3 synthesis.

Many adults have low vitamin D levels, and vitamin D deficiency is an important secondary cause of osteoporosis.[2] Although vitamin levels should only be drawn in patients at risk for deficiency, patients with osteoporosis meet this criterion.[15] Laboratory determination of 25-hydroxyvitamin D



Men and women age 50 years and older

Meet criteria for BMD Assessment?
- Women age 65 and older and men age 70 and older
- Women younger than age 65 or men ages 50–69 with risk factors for fracture[a]
- Secondary osteoporosis[b]
- History of fracture

Meet AACE criteria for VFA?
- Central BMD T-score less than –1.0 with risk factors:
  - ✓ Women age 70 and older and men age 80 and over
  - ✓ Fragility fracture after age 50 (self-reported or documented)
  - ✓ Historical height loss of 1.5 inches (4 cm) or more
  - ✓ Past or present long-term glucocorticoid equivalent dose for 3 months or more

Meet NOF/AACE criteria for osteoporosis drug treatment?
- T-score less than –2.5
- T-score –1.0 to –2.5 and FRAX 10-year fracture risk more than 3% hip or more than 20% major osteoporotic
- History of fragility fracture in hip or spine

- Lifestyle modifications to improve bone health[c]
- Calcium and vitamin D

- Lifestyle modifications to improve bone health[c]
- Calcium and vitamin D based on age and gender requirements
- Re-evaluate BMD in 2 to 4 years or as appropriate
- For T-score between –1.0 to –2.5, the Endocrine Society states bisphosphonate therapy may be considered in moderate risk women based on patient factors

- Investigate for a secondary cause and treat as appropriate[b]
- Lifestyle modifications to improve bone health[c]
- Calcium:
  - ✓ Men age 50–70: 1000 mg/day
  - ✓ Men age 71 and over: 1200 mg/day
- Vitamin D: 800–1000 IU/day
- NOF/Endocrine Society Drug therapy Recommendations: alendronate, risedronate, zoledronic acid, denosumab, teriparatide
  - ✓ In symptomatic hypogonadism, consider addition of testosterone
- Reevaluate BMD in 1–2 years

- Investigate for a secondary cause and treat as appropriate[b]
- Lifestyle modifications to improve bone health[c]
- Calcium and vitamin D based on age and gender requirements
- AACE Drug therapy Recommendations:
  - ✓ High Risk[d]: alendronate, risedronate, denosumab, zoledronic acid
  - ✓ Very high risk[e]: denosumab, zoledronic acid, teriparatide, abaloparatide, romosozumab
  - ✓ Alternatives: Ibandronate, raloxifene[g]
- Endocrine Society drug therapy recommendations:
  - ✓ Bisphosphonates, denosumab, teriparatide, abaloparatide
  - ✓ Alternatives: raloxifene[g], hormone therapy[h], calcitonin
- Reevaluate BMD in 1–2 years

[a] Risk factors: Current smoker, personal history of fracture (after age 50), history of low-trauma fracture in a first-degree relative, low BMD, low body weight/body mass index, excessive alcohol use, early menopause, chronic glucocorticoid use (3 months or longer).

[b] See Table 56–2.

[c] Lifestyle modifications to improve bone health: Tobacco avoidance, weight-bearing/resistance exercise, fall prevention, good nutrition, and limiting alcohol.

[d] High Risk: No history of fragility fracture or meet any of the other criteria listed in “very high risk” category.

[e] Very high risk: Fracture within the past 12 months, fractures while on osteoporosis therapy, multiple fractures, fractures while on glucocorticoid therapy, T-score less than –3.0, high risk of falls or history of falls with injury, or FRAX 10-year fracture risk greater than 4.5% for hip or greater than 30% for major osteoporotic.

[f] Romosozumab: Consider after using more established therapies first.

[g] Raloxifene: Consider for women at high breast cancer risk who are not appropriate for other therapies.

[h] Hormone therapy: Consider for women with a history of hysterectomy who are not appropriate for other therapies.

(AACE, American Association of Clinical Endocrinologists; BMD, bone mineral density; NOF, National Osteoporosis Foundation; VFA, vertebral fracture assessment.)

FIGURE 57–2. Algorithm for the management of osteoporosis in postmenopausal women and men ages 50 and older.

Table 57–5

Calcium and Vitamin D Content of Common Supplements

Product (% Elemental Calcium)	Elemental Calcium per Tablet (mg)	Vitamin D per Tablet (IU)
Calcium Carbonate (40%)		
Tums 500 mg	200	—
Tums E-X 750 mg	300	—
Tums ULTRA 1000 mg	400	—
Os-Cal 500	500	—
Os-Cal 500 + D	500	200
Os-Cal Ultra	600	200
Caltrate 600	600	—
Caltrate 600 + D	600	200
Caltrate 600 + Soy	600	200
One-A-Day Women's Multivitamin	450	400
Rolaids 550 mg	220	—
Viactiv	500	100
Calcium Citrate (24%)		
Citracal	200	—
Citracal 250 mg + D	250	62.5
Citracal + D	315	200
Calcium Phosphate, Tribasic (39%)		
Posture – D	600	125
Calcium Lactate (13%)	85	—
Calcium Gluconate (9%)	60	—

levels should occur prior to the start of pharmacotherapy to determine whether supplementation is adequate or whether treatment of deficiency is needed. The AACE guidelines recommend treatment with vitamin D$_3$ (cholecalciferol, readily available over-the-counter) 5000 IU daily for 8 to 12 weeks.[2] After 25-hydroxyvitamin D levels have risen above 30 ng/mL (75 nmol/L), cholecalciferol doses of 1500 to 2000 IU or more may be needed to maintain 25-hydroxyvitamin D levels between 30 and 60 ng/mL (75–150 nmol/L).[2,15] The AACE no longer recommends high-dose vitamin D$_2$ (ergocalciferol, prescription only) as a preferred option for replacement due to variability in current 25-hydroxyvitamin D assays. These assays have unequal cross-reactivity for vitamin D$_2$, causing inaccurately low total amounts of vitamin D$_2$ to be reported.[2]

▸ *Bisphosphonates*

KEY CONCEPT Bisphosphonates are a first-line option for many men and women due to established efficacy in preventing osteoporotic fractures. They decrease bone resorption by rapidly binding to the bone matrix and inhibiting osteoclast activity. Once attached to bone tissue, bisphosphonates are released very slowly over several years, with alendronate and zoledronic acid having the highest binding affinity to bone.[2] Three of the four available agents (alendronate, risedronate, and zoledronic acid) are considered to be "broad spectrum" due to efficacy in decreasing hip, vertebral and nonvertebral fractures.[2] Alendronate, risedronate, and zoledronic acid are approved for use in men and women, whereas ibandronate is only approved for postmenopausal osteoporosis. Ibandronate is generally considered a second-line bisphosphonate due to lack of documented efficacy in nonvertebral fractures in prospective trials.[2,16] Table 57–6 contains comparative dosing for the bisphosphonates.

Bisphosphonates cause initial increases in BMD by up to 5% to 8% in the lumbar spine and up to 3% to 6% in the hip.[17,18] BMD continues to increase with long-term bisphosphonate therapy of 7 to 10 years.[19,20] Although increases in BMD have been reported at other sites, most of the clinically significant increases occur in the hip or spine and are an important marker of treatment effects. Bisphosphonate therapy can also prevent vertebral and nonvertebral fractures, decreasing the vertebral fracture risk by as much as 40% to 50% with oral bisphosphonates and up to 70% with zoledronic acid.[1,21] IV zoledronic acid has also shown a 28% decrease in mortality associated with hip fracture.[22] Upon discontinuation of therapy, clinical trials with alendronate and zoledronic acid showed sustained benefits in fracture risk reduction up to 5 years after therapy is stopped.[2] Long-term administration of bisphosphonates is considered beneficial in patients at high risk for fracture. However, for women who must discontinue bisphosphonate therapy due to intolerance or adverse events, improvements in BMD may be sustained.[20]

Patients may experience bone, muscle, or joint pain that resolves upon bisphosphonate discontinuation. Upper GI adverse effects occur in up to 20% of patients receiving oral bisphosphonates and are often related to inappropriate administration. These adverse effects range from relatively mild nausea, vomiting, and diarrhea to more severe esophageal irritation and esophagitis. Other common adverse reactions include dyspepsia, abdominal pain, nausea, and esophageal reflux. Esophageal ulceration, erosions with bleeding, perforation, stricture, and esophagitis may also occur. Advanced age, previous upper GI tract disease, and use of nonsteroidal anti-inflammatory drugs also increase the risk for GI adverse events, whereas once-weekly administration of oral bisphosphonates may decrease the risk.

IV zoledronic acid is associated with acute-phase reactions (flu-like symptoms) that can last for days, such as headache, arthralgia, myalgia, and fever.[1,2,22] Acetaminophen may be given to prevent and treat these symptoms.[2] Patients with moderate to severe renal impairment, severe dehydration, or taking concomitant diuretics or nephrotoxic drugs may be at higher risk of developing acute renal failure with zoledronic acid. Laboratory monitoring, including serum creatinine, alkaline phosphatase, phosphate, magnesium, and calcium, is recommended prior to administration of each zoledronic acid dose.

Serious but rare adverse events associated with long-term bisphosphonate use include osteonecrosis of the jaw (ONJ) and atypical femoral fractures (AFF).[23,24] These events may be related to oversuppression of bone turnover causing weakening of bone structure related to inhibition of osteoclastic activity. The incidence of developing ONJ with bisphosphonate therapy ranges from 1/10,000 to 1/100,000 patient treatment years.[25-27] ONJ is less common in patients receiving bisphosphonates for osteoporosis than other indications. Patients should complete major dental work prior to initiation of bisphosphonate therapy.[27,28] The rate of AFF increases with duration of bisphosphonate use, and the risk appears to decline upon discontinuation of therapy.[27,29,30] Patients may experience thigh or groin pain prior to the fracture.

Due to the potential risks of long-term bisphosphonate use and residual beneficial effects after stopping therapy, the AACE recommends a bisphosphonate drug holiday based on initial risk assessment.[2,27] For patients initially at very high risk for fractures (see Figure 57-2), bisphosphonates should be discontinued after 10 years of oral therapy or after 6 years of IV bisphosphonate use. In patients who were initially at high risk for fracture, a drug holiday should be considered after 5 years of oral or 3 years of IV bisphosphonate use.[2] The optimal duration of the drug holiday is unknown, but reinitiation of the same or alternative therapy may be considered in patients who have experienced a fracture,

Table 57–6

Prescription Drug Therapy for Osteoporosis

Drug	Product Size	Indication/Usual Dose	Administration
Bisphosphonates			
Alendronate (Fosamax)	5-, 10-, 35-, 70-mg tablets; 70-mg with cholecalciferol 2800 IU; 70-mg with cholecalciferol 5600 IU; 70-mg oral solution	Prevention of PM osteoporosis: 5 mg orally daily or 35 mg orally once weekly Osteoporosis (men and women): 10 mg orally once daily or 70 mg orally once weekly Glucocorticoid-induced osteoporosis: 10 mg once daily Avoid when CrCl < 35 mL/min (0.58 mL/s)	Take after an overnight fast with 6–8 oz (180–240 mL) plain water while sitting or standing upright at least 30 minutes prior to morning meal. Do not lie down for 30 minutes after administration. Do not take with other medications or fluids. Do not crush, chew, or suck on the tablet.
Ibandronate (Boniva)	150-mg tablets; 3-mg/3 mL injection	PM osteoporosis: 150 mg orally once monthly; 3 mg IV push over 15–30 seconds every 3 months Avoid when CrCl < 30 mL/min (0.5 mL/s)	Same as alendronate except administer at least 1 hour prior to morning meal and refrain from lying down for 1 hour after administration.
Risedronate (Actonel, Atelvia)	5-, 30-, 35-, 75-, 150-mg tablets; 35-mg delayed release tablets	PM osteoporosis: 5 mg orally daily, 35 mg orally once weekly, 75 mg on 2 consecutive days each month, or 150 mg once monthly Male osteoporosis: 35 mg orally weekly or 150 mg orally monthly Glucocorticoid-induced osteoporosis: 5 mg orally daily Avoid when CrCl < 30 mL/min (0.50 mL/s)	Same as alendronate. Delayed release tablets may be taken with food.
Zoledronic acid (Reclast)	5 mg/100 mL IV infusion	Prevention of PM osteoporosis: 5 mg infused IV over 15 minutes or longer every 24 months Treatment of osteoporosis (men and women), glucocorticoid-induced osteoporosis: 5 mg infused IV over 15 minutes or longer every 12 months Avoid when CrCl < 35 mL/min (0.58 mL/s)	Infuse over at least 15 minutes. May premedicate with acetaminophen.
Monoclonal Antibody			
Denosumab (Prolia)	60 mg/mL SC prefilled syringe	PM or male osteoporosis, glucocorticoid-induced osteoporosis: 60 mg SC every 6 months	Inject in the upper arm, upper thigh, or abdomen. Keep refrigerated.
Parathyroid Hormone Analogs			
Abaloparatide (Tymlos)	3120 mcg/1.56 mL pen injector (30 doses)	PM osteoporosis: 80 mcg SC daily	Inject into abdomen. Keep refrigerated.
Teriparatide (Forteo)	250 mcg/mL, 2.4-mL prefilled pen	Osteoporosis (men and women), glucocorticoid-induced osteoporosis: 20 mcg SC daily	Inject into thigh or abdominal wall. Keep pen refrigerated.
Antisclerostin Antibody			
Romosozumab (Evenity)	105 mg/1.17 mL prefilled syringes	PM osteoporosis: 210 mg (two 105-mg prefilled syringes) SC once monthly	Inject into the abdomen, thigh, or upper arm. Keep refrigerated.
Estrogen Agonists/Antagonists			
Raloxifene (Evista)	60-mg tablets	PM osteoporosis: 60 mg daily	May be taken with or without food.
Bazedoxifene/conjugated estrogens (Duavee)	20 mg/0.45 mg	PM osteoporosis + menopausal symptoms: one tablet daily	Only for short duration.
Calcitonin			
Calcitonin salmon (Miacalcin)	200 IU/0.9 mL, 3.7-mL nasal spray	PM osteoporosis: Nasal spray: 200 IU daily	Nasal spray: Alternate nostrils on a daily basis.

CrCl, creatinine clearance; PM, postmenopausal; SC, subcutaneously.

significant BMD loss, or possibly a rise in CTX to pretreatment values. One strategy suggests that for women at low risk of fracture who have been maintained on bisphosphonate therapy for 3 to 5 years, a drug holiday of 2 to 3 years may be considered.[27]

Oral bisphosphonates are poorly absorbed, and administration with food or calcium supplementation further reduces absorption. Proper drug administration is important for adequate absorption and prevention of adverse effects. See Table 57–6 for

Patient Encounter Part 2: Physical Examination and Diagnostic Tests

ROS: 4 cm height loss since middle age; (+) back and knee pain; weight decrease of 7 lb (3.2 kg) in last 6 months

PE:

Gen: Well-developed White woman in no acute distress

VS: BP 134/76 mm Hg, P 76 beats/min, RR 18 breaths/min, T 36.3°C (97.3°F), Wt 64.1 kg (141 lb), Ht 64 in (163 cm), BMI 24.2 kg/m^2

Chest: No crackles or rhonchi

CV: RRR, normal S_1, S_2; no murmurs, rubs, or gallops

Spine: Mild kyphosis present, nontender

Abd: Soft, nontender, nondistended; normal bowel sounds, no hepatosplenomegaly

Ext: No clubbing, cyanosis, or edema

Labs:

Na 139 mEq/L (139 mmol/L)
K 4.0 mEq/L (4.0 mmol/L)
Cl 105 mEq/L (105 mmol/L)
CO_2 26 mEq/L (26 mmol/L)
25(OH)D 21 ng/mL (52 nmol/L)
A1C 6.9% (0.069; 52 mmol/mol Hb)
WBC 4.5 × 10^3/µL (4.5 × 10^9/L)
RBC 4.3 × 10^6/µL (4.3 × 10^{12}/L)
BUN 29 mg/dL (10.4 mmol/L)
SCr 1.86 mg/dL (164 µmol/L)
eGFR 26 mL/min/1.73 m^2
Calcium 8.8 mg/dL (2.2 mmol/L)
Hemoglobin 12.6 g/dL (126 g/L; 7.82 mmol/L)
Hematocrit 37.1% (0.371)
Platelets 298 × 10^3/µL (298 × 10^9/L)

Bone Densitometry by DXA

- BMD of femoral neck: T-score = −1.8
- BMD of lumbar spine: T-score = −2.4

Vertebral Fracture Assessment (VFA): No fracture present

What additional risk factors and signs of osteoporosis are present in this patient?

What are the goals of pharmacologic and nonpharmacologic therapy?

List at least three nonpharmacologic interventions important in her treatment plan.

What factors support pharmacotherapy for osteoporosis in this patient?

What type of supplement(s) would you recommend for this patient to meet her calcium and vitamin D requirements? Why?

recommended administration. Contraindications to bisphosphonates include hypersensitivity, hypocalcemia, pregnancy, and renal impairment (creatinine clearance less than 30–35 mL/min [0.50–0.58 mL/s]), or failure. Patients with esophageal abnormalities delaying swallowing (eg, achalasia, stricture), GI malabsorption (eg, celiac disease, Crohn disease, or gastric bypass), or who cannot remain upright for 30 minutes should avoid oral bisphosphonates; consider IV bisphosphonates for these patients.

▶ *Denosumab*

Denosumab is a broad-spectrum, twice-yearly injectable human monoclonal antibody that prevents nuclear factor-kappa B ligand (RANKL) from binding to its receptor, thereby decreasing osteoclast maturity, function, and survival.[2] It has proven benefit in reducing hip, vertebral, and nonvertebral fractures through its antiresorptive effects.[2] Denosumab decreases hip, vertebral, and nonvertebral fracture risk by up to 40%, 68%, and 20%, respectively.[31] Its use for up to 10 years has been associated with continued increases in lumbar spine and hip BMD as well as sustained reductions in fracture risk.[32] It is a first-line therapy for many women and men, and it can also be considered in patients unable to tolerate bisphosphonates due to GI contraindications or side effects and for patients with malabsorption or adherence issues.[2] In contrast to bisphosphonates, the antiresorptive effects of denosumab are reversible, and decreases in BMD may be seen within months of discontinuation of therapy.[2,9]

Common adverse effects include back pain, arthralgias, fatigue, headache, dermatologic reactions, diarrhea, and nausea. Serious adverse reactions, including hypophosphatemia, hypocalcemia, dyspnea, and skin and other infections, can also occur. Patients should seek medical attention if they experience any signs or symptoms of infection. Denosumab can worsen hypocalcemia, and preexisting hypocalcemia should be corrected before initiating therapy. Suppression of bone turnover has been associated with denosumab therapy, and although rare, ONJ and AFF have occurred.[32] Drug holidays are not recommended because of the rapid reversal of fracture risk reduction after discontinuation of therapy.[2] In patients unable to tolerate denosumab or who experience treatment failure, alternative therapy should be started when the next scheduled dose of denosumab is due.[2,9] Denosumab therapy should not be followed with an anabolic agent (eg, teriparatide) due to potential loss of hip BMD.[2]

Denosumab has a risk evaluation and mitigation strategy (REMS) program, in which the manufacturer is required by the FDA to inform patients and healthcare providers of the risks associated with its use.[33] Denosumab is administered as a subcutaneous injection once every 6 months by a healthcare provider and should be stored in the refrigerator until administration. Once at room temperature, the vial or prefilled syringe must be used within 14 days. Doses can be administered within 1 month of the scheduled dose.[9] Denosumab can be used in chronic kidney disease, but the risk of developing hypocalcemia is higher compared to patients with normal kidney function.[2]

▶ *Parathyroid Hormone Analogs*

Teriparatide (recombinant human PTH [1–34]) and abaloparatide (a synthetic analog of PTH-related protein [PTHrP]) are anabolic therapies that exert beneficial effects on bone through stimulation of the parathyroid hormone (PTH) type 1 receptor. Activation of this receptor promotes osteoblastic activity and bone formation but may also enhance bone resorption.[34] The overall net effect is an increase in BMD. They produced large decreases in vertebral and nonvertebral fractures by up to 86% and 43%, respectively,[35-37] but reduction in hip fractures has not been demonstrated.[2,9] Teriparatide is FDA-approved for treatment of postmenopausal and male osteoporosis, but abaloparatide is approved for treatment of postmenopausal women only. The AACE and Endocrine Society recommend these drugs as a first-line option in patients with prior fractures or those deemed very high risk.[2,9] Both agents are available for self-injection as prefilled pens and administered as daily subcutaneous injections.

Common adverse effects of both drugs include nausea, headache, leg cramps, dizziness, orthostatic hypotension, injection site discomfort, hypercalciuria, and hypercalcemia.[2] Abaloparatide may also be associated with palpitations.[37] Neither drug should be used in patients with preexisting hypercalcemia, hyperparathyroidism, or patients at risk of osteosarcoma including Paget disease, and history of skeletal radiation. Observations of osteosarcoma in animal studies led to the inclusion of a black box warning in product labeling for both drugs, but the risk has not been confirmed in humans.[2]

Patient-related concerns include cost of therapy and need for daily subcutaneous injections. Treatment is not recommended beyond 2 years due to unestablished safety and efficacy with long-term treatment. BMD declines once treatment is stopped, although sustained benefits in fracture reduction may persist for 1 to 2 years after discontinuation.[2] Once the maximum treatment duration has been reached, the patient should be switched to a bisphosphonate or denosumab to prevent these losses and maintain or provide further reduction in fracture risk.[2,9]

▶ *Antisclerostin Antibody*

Romosozumab is a monoclonal antibody that promotes bone formation and reduces resorption by binding to and inhibiting sclerostin, thereby increasing production of mature osteoblasts.[2,38] It has demonstrated reductions in vertebral fracture by as much as 73% when compared to placebo at 1 year.[39] Additionally, romosozumab has demonstrated a greater reduction in vertebral fracture risk than alendronate and denosumab.[38,39] It is indicated for treatment of osteoporosis in postmenopausal women at high risk of fracture (history of fracture or multiple risk factors for fracture) who have failed or are intolerant to other treatment options.[38,39]

Romosozumab 210 mg is administered as two subcutaneous injections once monthly by a healthcare provider and should be stored in the refrigerator until administration. Once at room temperature, the prefilled syringes must be used within 30 days.[38] The effect of romosozumab wanes after 1 year; therefore, treatment is only recommended for a total of 12 months. Upon discontinuation of therapy, a bisphosphonate or denosumab should be started to prevent the loss of benefit, including gains in BMD and reduction in fracture risk.

Common adverse effects include injection site reactions, arthralgias, headache, and skin-related hypersensitivity reactions. ONJ and AFF also occurred in clinical trials. Because of increased cardiovascular events compared to alendronate in a clinical trial, romosozumab carries a black box warning for increased risk of myocardial infarction, stroke, or cardiovascular death.[38] Patients should not take the drug if they have had a stroke or myocardial infarction in the past year.

▶ *Estrogen Agonists/Antagonists*

Raloxifene has estrogen-like activity on bones and cholesterol metabolism and estrogen antagonist activity in breast and endometrium. It reduces bone resorption and decreases overall bone turnover. Raloxifene has demonstrated reductions in vertebral fractures but not hip or nonvertebral fractures.[40] It has been shown to decrease breast cancer risk in patients at risk for osteoporosis.[41] Due to availability of other more effective therapies, its use is generally recommended only in select women with a high risk of breast cancer and inability to take other agents.[2,9]

Adverse effects of raloxifene include hot flushes, leg cramps, and increased risk of venous thromboembolism.[41] A previous history of venous thromboembolism is a contraindication to therapy. Hot flushes are very common and may be intolerable in postmenopausal women who are already predisposed to experiencing them.

Bazedoxifene, a third-generation estrogen agonist/antagonist, has similar effects to raloxifene. It is available in the United States only as a combination product with conjugated estrogens (Duavee) for treatment of moderate to severe vasomotor symptoms associated with menopause and for prevention of postmenopausal osteoporosis.[1] Other therapies should be considered for women who meet criteria for osteoporosis treatment.

▶ *Calcitonin*

Calcitonin is a naturally occurring mammalian hormone that plays a major role in regulating calcium levels. It inhibits bone resorption by binding to osteoclast receptors. Calcitonin reduces vertebral fracture risk by up to 30%, but no benefit has been demonstrated in reducing hip or nonvertebral fractures.[2,42] Only the nasal formulation has demonstrated fracture benefit. This drug is generally reserved for patients unable to tolerate or take other agents. However, it is sometimes used for short-term relief of back pain from vertebral fractures due to data suggesting benefit for this purpose.[2,9]

Adverse effects associated with the intranasal formulation include rhinitis, nasal irritation, and dryness. The safety and effectiveness of calcitonin has been studied for up to 5 years. Once discontinued, benefits of drug therapy are lost within 1 to 2 years.[2]

▶ *Hormone Therapy*

Estrogen, either alone or in combination with a progestin as hormone replacement therapy (HRT), has a long history as an effective treatment for osteoporosis. The Women's Health Initiative (WHI) trial found a 34% reduction in both vertebral and hip fractures and a 23% reduction in other fractures in postmenopausal women receiving conjugated estrogens and medroxyprogesterone.[43] However, significant risks associated with long-term HRT, including breast cancer and venous thromboembolism, limit its use as a first-line option.[2,43,44] The Endocrine Society states that hormone therapy may be considered in women with past hysterectomy intolerant to other therapies who are less than 10 years postmenopause and experiencing vasomotor symptoms.[9]

▶ *Combination Therapy*

Combination therapy is based on the premise that two more antiresorptive therapies with different mechanisms of action may provide more benefit on bone than monotherapy. However, this

Patient Encounter Part 3: Development of a Treatment Plan

Considering all of the information presented, develop a treatment plan for this patient. Include the following information:

a) Recommendations for patient-specific drug therapy including dose and frequency;

b) Patient education about the chosen regimen, including administration directions;

c) Monitoring plan for efficacy and adverse effects;

d) After the first denosumab infusion, the patient complains of intolerable back pain and arthralgias. What are some considerations for alternative treatment options?

Patient Care Process

Collect:

Subjective and objective information:

- Patient characteristics (eg, age, sex, menopausal status)
- Past medical history (eg, secondary causes of osteoporosis)
- Presence of symptoms, if applicable, past fracture history, and history of falls
- Family history (eg, presence of parental hip fracture)
- Social history (tobacco and alcohol use/history, diet, duration and type of physical activity)
- Medication history, including prescription, over-the-counter, and alternative therapies
- Physical examination (eg, signs of previous fractures)
- Laboratory tests (eg, rule out secondary causes)
- Diagnostic test results:
    - Central BMD
    - X-ray
    - Vertebral fracture assessment
- If the patient is already receiving pharmacotherapy, assess efficacy, safety, and patient adherence. How long has the patient been on each agent? Was the patient previously treated with other agents? Has the patient experienced any new fractures?

Assess the Information:

- Assess risk factors for osteoporosis and the presence of secondary causes of osteoporosis. If secondary causes are present, can any be treated or corrected?
- Determine the patient's average daily intake of calcium and sources of vitamin D, and assess whether calcium or vitamin D supplementation (or replacement) is needed.
- Assess physical activity and fall risk. Is the patient taking any medications that could increase fall risk?
- If *T*-score is between –1.0 and –2.5, use FRAX calculator to estimate 10-year fracture risk.
- Medication assessment:
    - Does the patient meet criteria for drug treatment of osteoporosis?
    - Does the patient have any indications for (eg, recent fracture) or contraindications to specific drug therapy?
    - Are there any patient-related factors that influence choice of agent (eg, patient preference, insurance coverage, ability to administer drug therapy, availability of infusion center near patient's home)?
    - Evaluate current therapy for safety, efficacy, and adherence.

Develop a Care Plan:

- Select therapy (including agent and dose) likely to be safe and effective, and consider patient-related factors (see Table 57–6).
- Ensure the regimen includes appropriate calcium and vitamin D supplementation or replacement for the patient.

Implement the Care Plan:

- If pharmacologic therapy is indicated, discuss therapeutic goals and expectations (eg, effect of fracture risk, follow-up laboratory or diagnostic tests to evaluate efficacy).
- Educate the patient on drug therapy selected, including drug name, dose, route and method of administration, common or serious adverse reactions, adherence, and monitoring.
- Educate the patient about nonpharmacologic measures to prevent osteoporotic fractures.

Follow up: Monitor and Evaluate:

- Annually review the need for continued medication. Assess appropriate drug administration, adherence, efficacy, adverse effects, and nonpharmacologic measures to prevent fractures.
- Reassess BMD every 1 to 2 years in patients on pharmacologic agents to treat osteoporosis. Vertebral imaging is appropriate if there is a documented loss in height of 2 cm or greater.

practice is not currently recommended for most patients due to high cost and lack of long-term safety and efficacy data. The AACE states that addition of a bisphosphonate or denosumab to prevent hip fracture may be reasonable in patients using raloxifene to reduce breast cancer risk.[2]

Treatment of Special Populations

▶ *Glucocorticoid-Induced Osteoporosis*

Glucocorticoids (eg, prednisone, hydrocortisone, methylprednisolone, and dexamethasone) play a significant role in bone remodeling, including increasing bone resorption, inhibiting bone formation, and changing bone quality. They promote bone resorption through reduced calcium absorption from the GI tract and increased renal calcium excretion. Bone formation is reduced through inhibition of osteoblasts and decreased estrogen and testosterone production.[45] Up to 40% of patients receiving long-term oral glucocorticoids have evidence of vertebral fracture.[46] Most bone mass is lost during the initial 3 to 6 months of therapy and continues to decline slowly thereafter.[45] Fracture risk is affected by other osteoporotic risk factors, and this risk is largely reversible once glucocorticoids are discontinued.

KEY CONCEPT The American College of Rheumatology (ACR) recommends oral bisphosphonate therapy for all patients age 40 or over at moderate to high risk of fracture (as determined by FRAX) receiving glucocorticoids (prednisone 2.5 mg or more daily or equivalent) for 3 months or longer. For patients younger than 40 years of age, a DXA with Z-score is recommended for evaluation of risk. Nonpharmacologic therapy and optimal calcium and vitamin D intake are also recommended. For patients unable to take oral bisphosphonates, alternative therapy recommendations include IV bisphosphonates, teriparatide, denosumab, and raloxifene in that order.[46] Frequent clinical fracture risk assessment with BMD testing every 1 to 3 years is recommended while receiving glucocorticoids.[46]

OUTCOME EVALUATION

- Evaluate patients for progression of osteoporosis, including signs and symptoms of new low trauma fracture (eg, localized pain), loss of height, and physical deformity (eg, kyphosis). Assess patients on an annual basis or more often if new symptoms present.
- For patients receiving drug therapy, monitor for beneficial effects on bone density. The AACE recommends a follow-up DXA scan every 1 to 2 years to monitor the effects of therapy.
- Assess patients for adverse effects of therapy:
  - Oral bisphosphonates: Dyspepsia, esophageal reflux, esophageal pain, or burning, ONJ and AFF (unusual groin, hip, or thigh pain)
  - Injectable zoledronic acid: Influenza-type symptoms related to infusion, ONJ and AFF (rare)
  - Denosumab: Arthralgias, dermatologic reactions, and hypocalcemia, ONJ and AFF (rare)
  - Abaloparatide and teriparatide: Nausea, headache, leg cramps, hypercalcemia, and orthostatic hypotension; also palpitations with abaloparatide
  - Romosozumab: Hypersensitivity, hypocalcemia (muscle cramps, numbness, seizure), ONJ and AFF (rare)
  - Raloxifene: Hot flushes, signs, or symptoms of thromboembolic disease (eg, pain, redness, or swelling in one extremity, chest pain, and shortness of breath)
  - Calcitonin salmon: Nasal irritation or burning

Abbreviations Introduced in This Chapter

AACE	American Association of Clinical Endocrinologists
ACR	American College of Rheumatology
AFF	Atypical femoral fracture
BMD	Bone mineral density
BMI	Body mass index
CTX	C-terminal telopeptide
DXA	Dual-energy x-ray absorptiometry
FDA	Food and Drug Administration
HRT	Hormone replacement therapy
NOF	National Osteoporosis Foundation
ONJ	Osteonecrosis of the jaw
WHI	Women's Health Initiative
VFA	Vertebral fracture assessment

Rheumatoid Arthritis

Susan P. Bruce

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Identify risk factors for developing adult rheumatoid arthritis (RA) or juvenile idiopathic arthritis (JIA).
2. Describe the pathophysiology of RA, with emphasis on the specific immunologic components.
3. Discuss the comorbidities associated with RA.
4. Recognize the typical clinical presentation of RA or JIA.
5. Create treatment goals for a patient with RA or JIA.
6. Compare the available pharmacotherapeutic options, selecting the most appropriate regimen for a given patient.
7. Propose a patient education plan that includes nonpharmacologic and pharmacologic treatment measures.
8. Formulate a monitoring plan to evaluate the safety and efficacy of a therapeutic regimen designed for an individual patient with RA or JIA.

INTRODUCTION

Rheumatoid arthritis (RA) is a complex systemic inflammatory condition manifesting initially as symmetric swollen and tender joints of the hands and/or feet. Some patients may experience low disease activity, whereas others may present with high disease activity and/or extraarticular manifestations. The systemic inflammation of RA leads to joint destruction, disability, and premature death. Juvenile idiopathic arthritis (JIA) is the most common form of arthritis in children.

EPIDEMIOLOGY AND ETIOLOGY

RA has a prevalence of 0.5% to 1%.[1,2] RA arises from an immunologic reaction, perhaps in response to a genetic or infectious antigen. Risk factors associated with the development of RA include the following:

- Female gender (3:1 females to males)
- Increasing age (peak onset 35–50 years of age)
- Current tobacco smoking. Tobacco users are more likely to have increased disease activity. This risk is reduced when a patient has remained tobacco-free for at least 10 years.
- Family history of RA. Genetic studies demonstrate a strong correlation between RA and the presence of major histocompatibility complex class II **human leukocyte antigens** (HLA), specifically HLA-DRB1 haplotypes.[2] HLA is a molecule associated with the presentation of antigens to T lymphocytes.
- Silica dust inhalation. Occupational exposure to silica is associated with an increased risk of developing RA.[2]
- Emerging evidence suggests that stress may influence RA onset and disease activity. It appears that individual major stressful life events may increase risk of RA. Additionally, chronic presence of minor stressors (daily difficulties, work and relationship stress, financial pressures) may affect the immune response and RA disease activity.[3]
- The prevalence of JIA is approximately 1 in 1000 children.[4] There are no known risk factors for JIA.

PATHOPHYSIOLOGY

The underlying pathogenesis of RA likely begins long before a patient presents with signs and symptoms. The characteristics of a **synovium** affected by RA are: (a) the presence of a thickened, inflamed membrane lining called **pannus**; (b) development of new blood vessels; and (c) influx of inflammatory cells in the synovial fluid, predominantly T lymphocytes. The pathogenesis of RA is driven by T lymphocytes, but the initial catalyst causing this response is unknown. Understanding specific components of the immune system and their involvement in the pathogenesis of RA will facilitate understanding of current and emerging treatment options for RA. The components of most significance are T lymphocytes, cytokines, B lymphocytes, and kinases.[5,6]

T Lymphocytes

The development and activation of T lymphocytes are important to maintain protection from infection without causing harm to the host. Activation of mature T lymphocytes requires two signals. The first is the presentation of an antigen by antigen-presenting cells to the T-lymphocyte receptor. Second, a ligand-receptor complex (ie, CD80/CD86) on antigen-presenting cells binds to CD28 receptors on T lymphocytes.[5]

Once a cell successfully passes through both stages, the inflammatory cascade is activated. Activation of T lymphocytes: (a) stimulates the release of macrophages or monocytes, which

Table 58–1

Cytokines Involved in the Pathogenesis of RA[5,6]

Cytokine	Source	Activity
Proinflammatory		
TNF-α	Macrophages, monocytes, B lymphocytes, T lymphocytes, fibroblasts	Induces IL-1, IL-6, IL-8, GM-CSF; stimulates fibroblasts to release adhesion molecules
IL-1	Macrophages, monocytes, endothelial cells, B lymphocytes, activated T lymphocytes	Stimulates fibroblasts and chondrocytes to release matrix metalloproteinases
IL-6	T lymphocytes, monocytes, macrophages, synovial fibroblasts	Activates T lymphocytes, induces acute-phase response, stimulates growth and differentiation of hematopoietic precursor cells; stimulates synovial fibroblasts
IL-17	T lymphocytes in synovium	Synergistic effect with IL-1 and TNF leading to increased production of proinflammatory cytokines
Anti-Inflammatory		
IL-4	CD4+ type 2 helper T lymphocytes	Inhibits activation of type 1 helper T lymphocytes, decreases production of IL-1, TNF-α, IL-6, IL-8
IL-10	Monocytes, macrophages, B lymphocytes, T lymphocytes	Inhibits production of IL-1, TNF-α, and proliferation of T lymphocytes

subsequently causes the release of inflammatory cytokines; (b) activates osteoclasts; (c) activates release of matrix metalloproteinases or enzymes responsible for the degradation of connective tissue; and (d) stimulates B lymphocytes and the production of antibodies.[5,6]

Cytokines

Cytokines are proteins secreted by cells that serve as intercellular mediators (Table 58–1). An imbalance of proinflammatory and anti-inflammatory cytokines in the synovium leads to inflammation and joint destruction. Some of the proinflammatory cytokines are interleukin 1 (IL-1), tumor necrosis factor-α (TNF-α), IL-6, and IL-17. These proinflammatory cytokines cause activation of other cytokines and adhesion molecules responsible for recruitment of lymphocytes to the site of inflammation. Anti-inflammatory cytokines and mediators (IL-4, IL-10, and IL-1 receptor inhibitor) are present in the synovium, although concentrations are not high enough to overcome the effects of the proinflammatory cytokines.[5,6]

B Lymphocytes

In addition to serving as antigen-presenting cells to T lymphocytes, B lymphocytes may produce proinflammatory cytokines and antibodies. Antibodies of significance in RA are rheumatoid factors (antibodies reactive with the Fc region of IgG) and anticitrullinated protein antibodies (ACPA). Rheumatoid factors are not present in all patients with RA, but their presence is indicative of disease severity and structural progression. ACPA are produced early in the course of disease. High levels of ACPA are indicative of aggressive disease and a greater likelihood of poor outcomes. Monitoring RF and ACPA may be useful to match the intensity of treatment appropriately.[5,6]

Kinases

Kinases are enzymes involved in communication or signaling activities within and between cells. Activated kinases lead to cell activation and proliferation. Examples include Janus-associated kinases (JAKs) and tyrosine kinase. Research is ongoing to identify additional therapeutic targets to interrupt signaling and thereby halt the inflammatory process.[5,6]

Comorbidities Associated with RA

RA reduces a patient's average life expectancy, but RA alone rarely causes death. Instead, specific comorbidities contribute to premature death independent of safety issues surrounding the use of immunomodulating medications. KEY CONCEPT The comorbidities with the greatest impact on morbidity and mortality associated with RA are: (a) cardiovascular disease, (b) infections, (c) malignancy, and (d) osteoporosis.

▶ *Cardiovascular Disease*

More than half of all deaths in RA patients are cardiovascular related. Because a patient with RA experiences inflammation and swelling in joints, it is likely that there is inflammation elsewhere, such as in the blood vessels, termed vasculitis. C-reactive protein (CRP), a nonspecific marker of inflammation, is associated with an increased risk of cardiovascular disease; CRP is elevated in patients with RA. Traditional cardiovascular risk factors alone cannot explain the increased cardiovascular mortality in patients with RA. Increasing evidence suggests that the presence of RA is a cardiovascular risk similar to diabetes. Aggressive management of systemic inflammation and traditional cardiovascular risk factors (eg, blood pressure, cholesterol, tobacco use) may reduce cardiovascular mortality in this population.[7-9]

▶ *Infections*

Patients with RA have an increased risk of infections due to the underlying disease process. Older age, disease activity, and concomitant conditions (ie, renal failure, lung disease) may increase risk of infection. Additionally, prolonged glucocorticoid use may contribute to infection risk. Patients and clinicians must pay close attention to signs and symptoms of infection.[10]

▶ *Malignancy*

Cancer is the second most common cause of death in RA patients. There is an overall increased risk of malignancy and an increased risk of developing lymphoproliferative malignancy (eg, lymphoma, leukemia, multiple myeloma), melanoma, and lung cancer but decreased risk of developing cancer of the breast, prostate, and digestive tract. Research is underway to understand the mechanisms that increase or decrease risk of

Table 58–2

Comparison of RA and Osteoarthritis

Characteristic	RA	Osteoarthritis
Speed of onset	Rapid (weeks to months)	Slow (years)
Gender prevalence (women:men)	3:1	1:1
Usual age of onset	Juvenile or adult (35–50 years)	Greater than 50 years
Most common joints affected	Small joints of hands (MCPs, PIPs), feet	Hands (DIPs), large weight-bearing joints (hips, knees)
Joint symptoms	Pain, swelling, warmth, stiffness	Pain, bony enlargement
Presence of inflammation	Local and systemic	None or mild, local
Duration of morning joint stiffness	Usually 60 minutes or longer	Usually less than 30 minutes
Joint pattern	Symmetric	Symmetric or asymmetric
ESR	Elevated	Normal
Synovial fluid	Leukocytosis, slightly cloudy	Mild leukocytosis
Systemic manifestations	Yes	No

DIPs, distal interphalangeal joints; ESR, erythrocyte sedimentation rate; MCPs, metacarpophalangeal joints; PIPs, proximal interphalangeal joints.

specific cancers, and how medication use independently contributes to individual risk.[11]

▶ *Osteoporosis*

Every patient with RA is at risk for developing osteoporosis. Cytokines involved in the inflammatory process directly stimulate osteoclast and inhibit osteoblast activity. Additionally, arthritis medications such as glucocorticoids can lead to increased bone loss. Bone mineral density should be evaluated at baseline and routinely using dual-energy x-ray absorptiometry.[12]

CLINICAL PRESENTATION AND DIAGNOSIS

See the box on next page for the clinical presentation of RA.

Diagnosis

Both osteoarthritis and RA are prevalent in the US population, but they differ in presentation (Table 58–2). Because management of the two conditions differs significantly, early evaluation and diagnosis are essential to maximize an individual's care.

In 2010, The American College of Rheumatology (ACR) and European League Against Rheumatism (EULAR) released classification criteria for RA (Table 58–3).[1] The goal was to identify a subset of patients with undifferentiated synovitis who were at high risk for chronic and erosive disease. The criteria are intended to help identify patients earlier in the course of disease. This will allow researchers to determine whether earlier introduction of medications alters the disease process. The criteria were developed as a tool for research purposes, but they are also helpful to guide clinical diagnosis. Patients with at least one joint with definite clinical synovitis that is not explained by another disease should be evaluated for RA.

Certain clinical features of RA are considered in diagnosis and treatment decisions because they may be related to rapid disease progression. **KEY CONCEPT** The most clinically important features associated with poor long-term outcomes include: (a) high disease activity, (b) positive autoantibodies (RF or ACPA), and (c) early presence of bony erosions by radiography.[13]

▶ *Diagnosis of Juvenile Idiopathic Arthritis*

Diagnostic criteria for JIA include: (a) age less than 16 years at disease onset, (b) arthritis in one or more joints for more than 6 weeks, and (c) exclusion of other types of arthritis. JIA can be divided into three main types:

1. *Systemic (10%–20% of cases)*: Occurs equally in girls and boys at any age. There are characteristic fever spikes twice daily (> 38.3°C or 101°F) and the presence of a pale, pink, transient rash.
2. *Polyarticular (approximately 35% of cases)*: More likely to affect girls than boys (3:1). Arthritis is present in five or more joints. The disorder resembles adult RA more than the other types of JIA.

Table 58–3

ACR/EULAR 2010 Classification Criteria for Rheumatoid Arthritis1

Criteria	Score
Joint involvement	
1 large joint (hips, knees, ankles, elbows, shoulders)	0
2–10 large joints	1
1–3 small joints (MCPs, PIPs, MTPs, wrists)	2
4–10 small joints	3
More than 10 joints (at least one small joint)	5
Serology (need at least one result for classification)	
Negative RF and negative ACPA	0
Low-positive RF or low-positive ACPA	2
High-positive RF or high-positive ACPA	3
Acute-phase reactants (need at least one result for classification)	
Normal CRP and normal ESR	0
Abnormal CRP or abnormal ESR	1
Duration of symptoms	
Less than 6 weeks	0
More than 6 weeks	1
TOTAL:	6 or greater indicates definite RA

ACPA, anticitrullinated protein antibodies; ACR, American College of Rheumatology; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; EULAR, European League Against Rheumatism; MCPs, metacarpophalangeal joints; MTPs, metatarsophalangeal joints; PIPs, proximal interphalangeal joints; RA, rheumatoid arthritis; RF, rheumatoid factor.

Clinical Presentation of RA

General

- About 60% of patients develop symptoms gradually over several weeks to months.
- Patients may present with systemic findings, joint findings, or both.

Symptoms

- Nonspecific systemic symptoms may include fatigue, weakness, anorexia, and diffuse musculoskeletal pain.
- Patients complain of pain in involved joints and prolonged morning joint stiffness.

Signs

- The metacarpophalangeal (MCP), proximal interphalangeal (PIP), metatarsophalangeal (MTP), and wrist joints are involved frequently.
- Joint involvement is usually symmetric.
- There is often limited joint function.
- **Swan neck** and/or **boutonniere deformities** may be present (see **Figure 58–1**).
- Signs of joint inflammation are present (tenderness, warmth, swelling, and erythema).
- Low-grade fever may be present.
- Extraarticular manifestations:
- *Skin:* Subcutaneous **nodules**
- *Ocular:* **Keratoconjunctivitis sicca**, **scleritis**
- *Pulmonary:* Interstitial fibrosis, pulmonary nodules, **pleuritis**, pleural effusions
- *Vasculitis:* Ischemic ulcers, skin lesions, **leukocytoclastic vasculitis**
- *Neurologic:* Peripheral neuropathy, **Felty syndrome**
- *Hematologic:* Anemia, **thrombocytosis**

Laboratory Tests

- Positive rheumatoid factor (RF) (the test is negative in up to 30% of patients)
- Elevated ESR (Westergren ESR: > 20 mm/hour in men; > 30 mm/hour in women)
- Elevated C-reactive protein (CRP) (> 0.7 mg/dL or 7 mg/L)
- Complete blood count: Slight elevation in WBC count with a normal differential; slight anemia; thrombocytosis
- Positive anticitrullinated protein antibodies (ACPA)

Other Diagnostic Tests

- *Synovial fluid analysis:* Straw colored, slightly cloudy, WBC 5–25 × 10^3/mm^3 (10^9/L), no bacterial growth if cultured
- *Joint x-rays:* To establish baseline and evaluate joint damage
- *MRI:* May detect erosions earlier in the course of disease than x-rays but is not required for diagnosis

Assessing Disease Activity

- Common tools to assess disease activity include Patient Activity Scale, Clinical Disease Activity Index, Simplified Disease Activity Index, and Disease Activity in 28 joints (DAS-28).[14] Components involved in calculating a DAS-28 score are the number of swollen and tender joints, ESR or CRP, and a subjective measure of the patient's general health. A DAS-28 score of 3.2 or less indicates low disease activity, between 3.2 and 5.1 is considered moderate activity, and 5.1 or more is considered to be high activity. Remission as defined by DAS-28 is a score of less than 2.6.[14] An online DAS-28 calculator is available at www.4s-dawn.com/DAS28/.

3. *Oligoarticular (about 40% of cases)*: More likely to affect girls than boys (5:1). Uveitis is more likely to be present. Arthritis is present in four or fewer joints. The age of onset is younger than 8 years.

TREATMENT

Desired Outcomes

KEY CONCEPT The goals of treatment in RA are to: (a) reduce or eliminate pain, (b) reduce disease activity to the lowest possible level, ideally remission, as soon as possible, (c) protect articular structures and function, (d) control systemic complications, and (e) improve/maintain quality of life. The goals for JIA are the same, with the added goals of maintaining normal growth, development, and activity level.[15] It is a common misconception that patients with JIA grow out of the disease. Many children with JIA become adults with JIA. Knowing this, it is essential that early, aggressive treatment is initiated to achieve the goals of therapy.

General Approach to Treatment

The clinician must evaluate patient-specific factors and select appropriate treatment to maximize the care of each patient. Joint damage accumulates over time; therefore, early diagnosis and early aggressive treatment are necessary to reduce disease progression and prevent joint damage. Aggressive treatment is defined as one or more disease-modifying antirheumatic drugs (DMARDs) at effective doses. Delaying treatment will result in more destructive disease that is very difficult to delay or reverse to preserve joint function.

KEY CONCEPT It is imperative that one or more DMARDs be initiated in all patients as soon as possible to reduce disease activity. DMARDs are the mainstay of RA treatment because modifying the disease process can prevent or reduce joint damage. The umbrella term DMARD includes conventional synthetic (csDMARD), biologic (bDMARD), and targeted synthetic (tsDMARD). The drugs in these classes modify the underlying disease process rather than merely providing symptomatic relief. In addition to safety and efficacy data, the initial DMARD choice depends on disease severity, patient characteristics (ie, comorbidities, likelihood of adherence), cost, and clinician experience with the medication.[4,14] Methotrexate is the initial treatment of choice for moderate to high disease activity.[15]

Depending on disease severity, combination therapy may be initiated at the time of diagnosis or after an adequate trial of

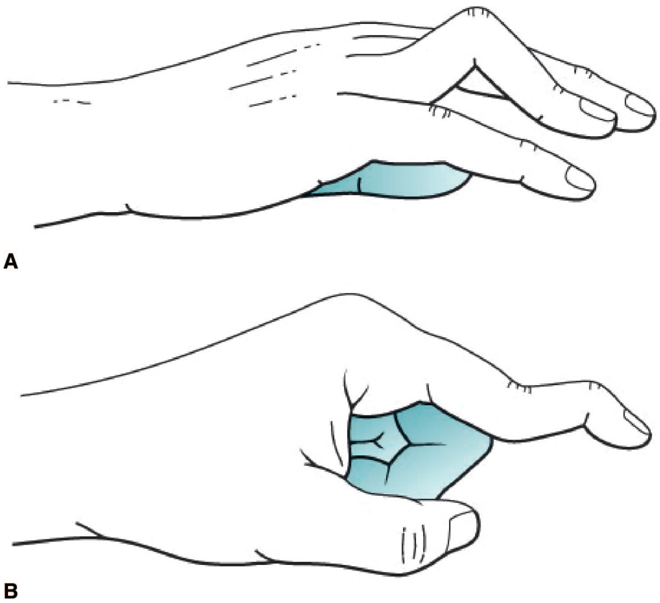

FIGURE 58–1. Boutonnière **(A)** and swan-neck **(B)** deformities. (Reproduced with permission from Toy EC, Patlan Jr JT, Warner MT. Case Files: Internal Medicine, 5th ed; 2017. http://accessmedicine.mhmedical.com/ViewLarge.aspx?figid=140919481.)

DMARD monotherapy. If a patient has evidence of rapid disease progression (eg, worsening radiographic erosions), a more aggressive treatment plan may be warranted with more frequent follow-up to achieve the goal of remission or low disease activity.

Nonsteroidal anti-inflammatory drugs (NSAIDs) and glucocorticoids also have specific roles in the treatment of RA, as discussed below. Agents such as azathioprine, cyclosporine, minocycline, gold salts, and anakinra are used rarely today.[14]

Patient Encounter Part 1

A 64-year-old woman presents to her primary care physician for routine follow-up. She was diagnosed with RA 15 years ago and presents today with concerns of increased morning stiffness (average 90 minutes daily) and symmetrical tenderness/swelling in her hands. She wishes to improve function as soon as possible because she has plans to retire soon and would like to continue her active lifestyle. She follows a low carb diet and consciously strives to maintain a healthy weight. She walks 3 miles every evening with her friends. She does not smoke and consumes alcohol socially. She has been taking medications for RA since diagnosis and sets regular reminders to make sure she does not miss a dose.

What additional information do you need to assess disease activity?

What variables in this scenario may inhibit optimal patient care?

Which features suggest that the patient is experiencing symptoms of RA rather than OA?

What additional information do you need before creating a care plan for this patient?

Figures 58–2 and 58–3 outline the course of treatment for adult RA according to the ACR 2015 and 2021 Recommendations.[14,15] The recommendations are based on the disease activity level and duration of disease activity (early vs established). Figure 58–2 applies to patients with early RA (defined as < 6 months). csDMARD monotherapy includes methotrexate (preferred), hydroxychloroquine, leflunomide, or sulfasalazine. Examples of combination csDMARD therapy include methotrexate/sulfasalazine, methotrexate/hydroxychloroquine, or methotrexate/sulfasalazine/hydroxychloroquine.

Figure 58–3 outlines the course of treatment for patients with established RA (disease duration 6 months or longer). Combination bDMARDs or tsDMARDs should be avoided because of the increased risk of infection due to excessive immunosuppression. There is no evidence that the benefits of any combination of bDMARD or tsDMARD therapy outweigh the potential risks, especially the increased risk of infections.

Nonpharmacologic Therapy

All patients should receive education about the nonpharmacologic and pharmacologic measures to help manage RA and JIA. Empowered patients take an active role in care by participating in therapy-related decisions. Certain forms of nonpharmacologic therapy benefit all levels of severity, whereas others (ie, surgery) are reserved for severe cases only.

Occupational and physical therapy may help patients preserve joint function, extend joint range of motion, and strengthen joints and muscles through strengthening exercises. Patients with joint deformities may benefit from the use of mobility or assistive devices that help to minimize disability and allow continued activities of daily living. When appropriate, patients should also be counseled about stress management. In situations where the disease has progressed to a severe form with extensive joint erosions, surgery to replace or reconstruct the joint may be necessary.

Pharmacologic Therapy

▶ *Bridge Therapy/Symptomatic Relief*

The current standard of care for RA treatment is to initiate disease-modifying therapy immediately. While this step is critical to control the underlying disease activity, it may take weeks to months for the patient to experience relief. It is acceptable to initiate “bridge therapy” or short-term use of certain medications to provide symptomatic relief until the disease-modifying drug reaches its therapeutic effect. The most common classes used for bridge therapy are NSAIDs and glucocorticoids.

NSAIDs These agents provide analgesic and anti-inflammatory benefits for joint pain and swelling. However, they do not prevent joint damage or change the underlying disease. Selecting an NSAID depends on multiple patient-specific factors, including cardiovascular risk, potential for GI-related adverse events, adherence to medication regimens, and insurance coverage or lack thereof. NSAID therapy is conditionally recommended as adjunct therapy in children with JIA. NSAIDs are not recommended for monotherapy.[4] However, they are strongly recommended over no treatment if enthesitis is present. Clinicians must carefully evaluate the potential risks of NSAID therapy against the potential benefits. See Chapter 59 (Osteoarthritis) for additional discussion of NSAID therapy.

Glucocorticoids In contrast to NSAIDs, low-dose glucocorticoid treatment (equivalent to prednisone 10 mg/day or less) effectively reduces inflammation through inhibition of cytokines and inflammatory mediators and prevents disease progression. However, due to the adverse effect profile, the goal of glucocorticoid use is to keep doses low and use the drugs as infrequently as possible. For the purposes of bridge therapy, if necessary, the recommended duration is 3 months or less.[15] Patients taking more than 2.5 mg/day of prednisone or equivalent are at increased risk for clinically significant adverse reactions, especially bone loss leading to osteoporosis. Other glucocorticoid-related adverse reactions include Cushing syndrome, peptic ulcer disease, hypertension, weight gain, infection, mood changes, cataracts, dyslipidemia, and hyperglycemia.[18] Intra-articular administration of glucocorticoids may be considered in RA for rapid control of inflammation if a limited number of joints are affected. Intra-articular glucocorticoid injections are conditionally recommended as bridge treatment of JIA for 3 months or less if moderate to high disease activity is present.[4]

▶ *Conventional Synthetic (cs) DMARDs*

Methotrexate KEY CONCEPT Methotrexate is the csDMARD of choice in RA because of its documented efficacy and safety profile when monitored appropriately. Methotrexate exerts its anti-inflammatory effect through inhibition of dihydrofolate reductase, which causes inhibition of purines and thymidylic acid, and by inhibiting production of certain cytokines. Unless the patient has contraindications to methotrexate or takes other medications that should be

used with caution or avoided in combination with methotrexate, once-weekly doses should be initiated and increased steadily until the patient has symptomatic improvement or a maximum dose of 20 mg/week is reached. It is important to emphasize to patients and healthcare providers that the dosing is once weekly (not once daily) to avoid medication errors resulting in serious complications from profound myelosuppression (eg, infections, bleeding). If oral monotherapy does not produce complete resolution of symptoms, converting to subcutaneous administration may be considered prior to using methotrexate in combination with other csDMARDs or bDMARDs. If a patient experiences intolerable gastrointestinal effects, switching to subcutaneous methotrexate will reduce those effects. Concomitant folic acid is given routinely to reduce the risk of folate-depleting reactions induced by methotrexate therapy (eg, stomatitis, diarrhea, nausea, alopecia, myelosuppression, and elevated liver function tests).

Methotrexate is recommended as initial treatment for JIA in patients with more than four active joints, preferably subcutaneous over oral administration.[4] There are insufficient published data to assess the risk of serious toxicity in children receiving doses greater than 20 mg/m^2/week. Methotrexate therapy in children should be monitored the same way that is recommended in adults.

Hydroxychloroquine and Sulfasalazine The exact mechanism of action of these drugs is unknown, but both agents are fairly well tolerated. Because of their slow onset of action, each drug must be given at therapeutic doses for at least 6 months before it can be deemed a treatment failure. If a patient has low disease activity upon diagnosis, hydroxychloroquine is recommended.[15]

Hydroxychloroquine is not associated with renal, hepatic, or bone marrow suppression and therefore may be an acceptable treatment option for patients with contraindications to other DMARDs because of their toxicities.

Starting sulfasalazine at low doses and titrating slowly will minimize the nausea and abdominal discomfort caused by the drug. Patients with a sulfa or salicylate allergy should not receive sulfasalazine.

In patients with JIA, sulfasalazine is recommended only for patients with the enthesitis-related category with contraindications to TNF inhibitors or mild enthesitis. Enthesitis-related arthritis is a less common form of JIA that affects boys more than girls and is characterized by lower extremity joint involvement, including heel pain and enthesitis. Hydroxychloroquine is not recommended as monotherapy in JIA patients with active arthritis.[4]

Leflunomide This drug inhibits dihydroorotate dehydrogenase, an enzyme within mitochondria that supplies T lymphocytes with the necessary components to respond to cytokine stimulation. Thus, leflunomide inhibits the T-lymphocyte response to various stimuli and halts the cell cycle. Its efficacy is similar to that of moderate doses of methotrexate or sulfasalazine. Because of its extended half-life, leflunomide therapy begins with a loading dose followed by a maintenance dose. Leflunomide may be used in combination with methotrexate, but the added efficacy comes with a dramatic rise in the risk of hepatotoxicity. If therapy requires abrupt discontinuation (eg, due to toxicity or pregnancy), administering cholestyramine will accelerate leflunomide removal from the body.[19]

Leflunomide is recommended as an alternative to methotrexate in patients with JIA experiencing disease activity in five or more joints.[17] However, leflunomide does not have an FDA-approved indication for this use.

▶ *Biologic DMARDs and Associated Biosimilars*

bDMARDs are indicated in patients who have received an adequate trial of csDMARD monotherapy or combination therapy but have failed to achieve treatment goals. These agents may be added to csDMARD monotherapy (eg, methotrexate), or replace ineffective csDMARD therapy.

"Biosimilars" are highly similar to an FDA-approved biologic agent (called the reference product) and have been shown to have no clinically meaningful differences in efficacy or adverse effects from the reference product. They are not completely identical to the originator compound because of molecular complexity and production using recombinant DNA techniques in living organ systems. The FDA will approve a biosimilar product only if it has the same mechanism of action, route of administration, dosage form, and strength as the reference product. Also, a biosimilar can only be approved for indications that were previously approved for the reference product. Biosimilars have a nonproprietary name plus an FDA-designated suffix consisting of four lowercase letters that have no intended meaning. Biosimilars are not considered to be interchangeable with the reference product unless the manufacturer fulfills additional requirements for interchangeability.[20]

Patients with concomitant serious infections, lymphoproliferative disorders, hepatitis, history of malignancy, or heart failure should be evaluated thoroughly to determine if or which biologic DMARD is appropriate, preferred, or contraindicated in their treatment regimen. The 2021 treatment guidelines provide recommendations for those scenarios based on available evidence.[15]

Tumor Necrosis Factor (TNF) Inhibitors There are currently five reference TNF inhibitors approved for the treatment of RA: etanercept, adalimumab, infliximab, golimumab, and certolizumab.

Etanercept is a recombinant form of human T receptor. Etanercept provides a therapeutic effect by binding to soluble TNF and preventing its binding with TNF receptors. Etanercept is very effective as monotherapy or in combination with other csDMARDs. Etanercept has an FDA-approved indication for treatment of JIA.

Adalimumab is a recombinant human IgG1 monoclonal antibody specific for human TNF. Adalimumab binds to soluble and bound TNF-α. It can be administered in combination with methotrexate or other DMARDs. Adalimumab has an FDA-approved indication for JIA.

Infliximab is a chimeric IgG1 monoclonal antibody that binds to soluble and bound TNF-α. Methotrexate is given with it to suppress antibody production against the mouse-derived portion of the molecule. Qualified healthcare personnel must be present during the infliximab infusion to respond to infusion-related reactions, if they occur (rash, urticaria, flushing, headache, fever, chills, nausea, tachycardia, dyspnea). These reactions may be treated by: (a) temporarily discontinuing the infusion, (b) slowing the infusion rate, or (c) administering corticosteroids or antihistamines. Patients may be pretreated with corticosteroids or antihistamines if they continue to experience infusion reactions. Infliximab was shown in clinical trials to be effective for treatment of JIA, but it has not yet received FDA approval for this indication.

Golimumab is a human monoclonal antibody that binds to membrane-bound and soluble TNF. Golimumab can be administered in combination with methotrexate in patients with moderate to severe RA. One advantage of this agent over others in the class may be the once-monthly subcutaneous dosing or every-other-month IV dosing. Golimumab is not FDA approved for use in JIA.

Certolizumab is a humanized antibody Fab fragment conjugated to polyethylene glycol, which delays its metabolism and elimination. Certolizumab can be administered alone or in combination with methotrexate in patients with moderate to severe RA. Certolizumab is not FDA approved for use in JIA.[4]

IL-1 Inhibitors Anakinra is a recombinant form of human IL-1 receptor inhibitor. Anakinra inhibits the activity of IL-1 by binding to it and preventing cell signaling. It is indicated for adults with RA who have failed one or more csDMARDs. Anakinra is not recommended in the ACR treatment guidelines for patients with JIA or RA due to infrequent use and lack of new data. Anakinra is not FDA approved for treatment of JIA.[4]

Canakinumab is a human monoclonal antibody that binds to IL-1 and blocks binding with the IL-1 receptor, thereby neutralizing its activity. Canakinumab is not indicated for treatment of adult RA. Canakinumab is indicated for the treatment of systemic JIA in patients 2 years and older. The recommended dose is 4 mg/kg (maximum 300 mg) subcutaneously every 4 weeks.[22] Canakinumab is not recommended in the ACR treatment guidelines for patients with JIA or adult RA.

T Cell Costimulatory Inhibitor Abatacept interferes with T-cell signaling, ultimately blocking T-cell activation and leading to anergy, or lack of response to an antigen. Abatacept is indicated as monotherapy or in combination with csDMARDs following inadequate response to methotrexate or anti-TNF agents. Abatacept is FDA approved for the treatment of moderate to severe JIA; it is recommended as an option for patients who did not respond to an adequate trial of methotrexate.[4,22]

Anti-CD20 Antibody Rituximab is a genetically engineered chimeric anti-CD20 monoclonal antibody that causes B-lymphocyte depletion in bone marrow and synovial tissue. Rituximab is indicated for patients with moderate to severe RA and a history of inadequate response to one or more TNF inhibitor therapies. Patients with RF-positive RA tend to respond more favorably to rituximab than patients with RF-negative disease. Rituximab carries a black box warning of fatal infusion reactions, severe mucocutaneous reactions, hepatitis B reactivation, and progressive multifocal leukoencephalopathy. The benefits of rituximab must be tempered against the safety concerns reported with use of rituximab in the oncology setting. The role of rituximab in JIA is unclear, and the medication is not FDA approved for this purpose.[4]

Interleukin-6 Inhibitors Interleukin-6 (IL-6) production is increased in patients with RA. Presence of IL-6 shifts inflammation from acute to chronic.[23] In addition, IL-6 plays a significant role in the pathogenesis of anemia associated with RA. Tocilizumab, an anti–IL-6 receptor monoclonal antibody, inhibits the binding of IL-6 to the IL-6 receptor. Tocilizumab is FDA approved for treatment of moderate to severe RA and JIA. In JIA, it is recommended for patients with moderate to high disease activity with an inadequate response to a TNF inhibitor.[7]

Sarilumab is an IL-6 receptor inhibitor that binds to soluble and membrane-bound IL-6 receptors. It is indicated for treatment of moderate to severe RA following inadequate response or intolerance to one or more DMARDs. It is not FDA approved for JIA nor included in the JIA treatment guidelines.[4,23]

▶ *Targeted Synthetic (ts) DMARDs*

Janus-Kinase (JAK) Inhibitors A distinct advantage of JAK inhibitors over biologic DMARDs is that they are given orally because they are synthetic small molecules rather than large proteins produced by recombinant DNA techniques. A JAK inhibitor may be initiated if a patient does not have an adequate response to or is otherwise unable to receive csDMARDS or bDMARDs.[24] Although oral administration is advantageous, consideration of JAK inhibitor use must be assessed in the context of potential adverse reactions (eg, hematologic effects, malignancy, thrombosis risk).

Tofacitinib selectively inhibits JAK, with greatest affinity for JAK3.[24] Tofacitinib is indicated for treatment of moderate to severe RA as monotherapy or in combination with csDMARDs. Baricitinib inhibits JAK1 and JAK2. It is approved as monotherapy or in combination with methotrexate in moderate to severe RA. Upadacitinib is highly selective for JAK1. It is approved as monotherapy or in combination with methotrexate or other csDMARDs.[24-26]

▶ *Selecting Disease-Modifying Therapy*

The decision to select a particular agent generally is based on the prescriber's comfort level with monitoring medication safety and efficacy, severity of disease activity, presence of factors suggestive of poor prognosis, the frequency and route of administration, the patient's comfort level or manual dexterity to self-administer subcutaneous injections, the cost, and the availability of insurance coverage. Table 58–4 highlights dosing, safety, monitoring, and patient counseling information for DMARDs used in the treatment of RA. Together, Figures 58–2 and 58–3 and Table 58–4 can be used to build an individualized treatment plan. While monotherapy is preferred, combination therapy may be necessary to achieve the target of low disease activity or remission. When selecting a treatment plan, cost should also be considered. The expense of biologic DMARDs can limit their use in patients without adequate insurance or other means of covering the drug cost. Cost analyses indicate that the increased expenses associated with biologic DMARDs may be offset by the costs avoided for treatment of advanced RA. It is anticipated that introduction of biosimilars will reduce RA treatment costs because they are expected to be less costly than the reference products.

KEY CONCEPT The risk of infection in patients treated with bDMARDs and tsDMARDs must be considered when selecting and monitoring therapy.[14] Influencing the immune response to reduce symptoms of RA may influence the body's response to pathogens. Of particular concern is use of TNF inhibitors in patients with a history of tuberculosis exposure. TNF is important in the formation of granulomas that wall off tuberculosis infection. In theory, if TNF is inhibited, patients with latent tuberculosis may have a reactivated infection. Patients receiving any bDMARD or tsDMARD should be screened for tuberculosis and other infections (hepatitis B, hepatitis C). Antituberculosis therapy should be initiated in patients with active or latent tuberculosis.[14] Patients with active tuberculosis should receive the full course of antituberculosis treatment prior to initiating biologic DMARDs. If there is latent infection, biologic DMARD therapy may be initiated after at least 1 month of antituberculosis treatment. Biologic DMARDs should not be initiated and should be discontinued temporarily during an acute, serious infection. Biologic DMARD therapy can be continued during

Table 58–4

FDA-Approved DMARDs for Treatment of RA[1,2,21-26]

Drug	Dose[a]	Time to Effect (weeks)	ADRs	Dosing in Hepatic Impairment	Dosing in Renal Impairment	Monitoring	Counseling Points
Conventional Synthetic DMARDs (csDMARDs)							
Methotrexate	Adults: 7.5–20 mg orally, SC or IM once weekly Polyarticular-course JIA: Recommended starting dose: 10 mg/m^2 oral, IM, or SC once weekly; usual max dose: 20 mg/m^2 once weekly	4–8	N, D, hepatotoxicity, alopecia, new-onset cough or SOB, MYL	Contraindicated	CrCl (mL/min)[b]: 61–80: 75% of dose 51–60: 70% of dose 10–50: 50% of dose Less than 10: Avoid use	CBC, creatinine, LFTs every 4–8 weeks; monitor for signs of infection	Use of folic acid concomitantly Avoid alcohol Use contraception if childbearing potential
Hydroxychloroquine	Adults: 200 mg orally twice daily or 400 mg once daily	8–24	N, D, HA, vision changes, skin pigmentation	Use with caution	No change	Specialized retinal eye examination at baseline and at 5 years	
Sulfasalazine	Adults: 1000 mg orally two to three times daily Polyarticular-course JIA: Initial: 10 mg/kg/day orally; increase weekly by 10 mg/kg/day; usual dose: 30–50 mg/kg/day orally in two divided doses; max 2 g/day	8–12	N, D, rash, yellow-orange discoloration of urine or skin, photosensitivity, MYL	Avoid use	CrCl (mL/min)[b]: 10–30: Give twice daily Less than 10: Give once daily	CBC, LFTs, creatinine every 2–4 weeks for 3 months, then every 8–12 weeks	Sunscreen use
Leflunomide (Arava)	Adults: 100 mg orally daily for 3 days; then 20 mg daily	4–12	Hepatotoxicity, D, N, HTN, rash, HA, abdominal pain	Avoid use	Guidelines not available	CBC, LFTs, creatinine every 2–4 weeks for 3 months, then every 8–12 weeks Monitor for signs of infection	Avoid alcohol Use contraception if childbearing potential
Biologic DMARDs (bDMARDs) and Associated Biosimilars							
Tumor Necrosis Factor (TNF) Inhibitors							
Etanercept (Enbrel) Biosimilar: Etanercept-szzs (Erelzi) Etanercept-ykro (Eticovo)	Adults: 25 mg SC twice weekly or 50 mg SC once weekly Children ages 2–17: 0.8 mg/kg SC once weekly; max 50 mg/week	1–4	ISR	No change	No change	Monitor for infection	ISR—topical corticosteroids, antipruritics, analgesics, rotate injection sites Screen for tuberculosis, Hepatitis B
Infliximab (Remicade) Biosimilars: Infliximab-dyyb (Inflectra) Influximab-abda (Renflexis) Infliximab-axxq (Avsola) Infliximab-qbtx (Ixifi)	Adults: 3–10 mg/kg by IV infusion at 0, 2, and 6 weeks; then every 8 weeks	1–4	IR (rash, urticaria, flushing, HA, fever, chills, nausea, tachycardia, dyspnea)	No change	No change	Monitor for infection	Screen for tuberculosis, Hepatitis B

Adalimumab (Humira) Biosimilar: Adalimumab-atto (Amjevita) Adalimumab-adbm (Cyltezo) Adalimumab-afzb (Abrilada) Adalimumab-bwwd (Hadlima) Adalimumab-fkjp (Hulio) Adalimumab-adaz (Hyrimoz)	Adults: 40 mg SC every other week Children older than 4 years and weighing 15–29 kg: 20 mg SC every other week Children weighing 30 kg or more: 40 mg SC every other week	1–4	ISR	No change	No change	Monitor for infection	Screen for tuberculosis, Hepatitis B
Golimumab (Simponi)	Adults: 50 mg SC once monthly 2 mg/kg IV infusion at weeks 0, 4, then every 8 weeks	1–4	ISR, IR	No change	No change	Monitor for infection	Screen for tuberculosis, Hepatitis B
Certolizumab (Cimzia)	Adults: 400 mg SC initially, at 2 weeks, 4 weeks, then 200 mg every other week	1–4	ISR	No change	No change	Monitor for infection	Screen for tuberculosis, Hepatitis B
T Cell Costimulatory Inhibitor							
Abatacept (Orencia)	Adult IV infusion: < 60 kg, 500 mg; 60–100 kg, 750 mg; > 100 kg, 1000 mg IV on days 1, 15 and every 28 days thereafter SC Injection: Weight-based loading dose, then 125 mg SC within 1 day, 125 mg SC once weekly; or 125 mg once weekly in patients unable to receive IV. JIA (> 6 years of age): < 75 kg: 10 mg/kg; 75–100 kg: 750 mg; > 100 kg: 1000 mg IV infusion on days 1, 15, 28, and every 28 days thereafter	2	HA, infection, IR, ISR	No change	No change	Monitor for infection	Screen for tuberculosis, Hepatitis B
Anti-CD20 Monoclonal Antibody							
Rituximab (Rituxan) Biosimilars: Rituximab-pvvr (Ruxience) Rituximab-abbs (Truxima) Rituximab-arrx (Riabni)	Adults: Two 1000-mg IV infusions separated by 2 weeks; timing of the third dose is based on patient symptoms (no earlier than 16 weeks)	4	IR	No change	No change	Monitor for infection	Screen for tuberculosis, Hepatitis B
IL-6 Inhibitors							
Tocilizumab (Actemra)	Adults: 4–8 mg/kg IV infusion every 4 weeks SC: if > 100 kg, 162 every week; if < 100 kg, 162 every other week JIA (2 years and older): < 30 kg: 12 mg/kg IV infusion every 2 weeks; > 30 kg: 8 mg/kg every 2 weeks		Elevated LFTs, total cholesterol, triglycerides, and high-density lipoprotein; nasopharyngitis, infection	No data available	No data available	Monitor for infection; LFTs	Screen for tuberculosis, Hepatitis B

(*Continued*)

Table 58–4

FDA-Approved DMARDs for Treatment of RA[1,2,21-26] (*Continued*)

Drug	Dose[a]	Time to Effect (weeks)	ADRs	Dosing in Hepatic Impairment	Dosing in Renal Impairment	Monitoring	Counseling Points
IL-6 Inhibitors (continued)							
Sarilumab (Kevzara)	Adults: 200 mg SC every 2 weeks		ISR, elevated LFTs, neutropenia	Not recommended in patients with hepatic impairment	CrCl < 30 mL/min[b]: no data available	Monitor for infection, LFTs, lipids	Screen for tuberculosis, Hepatitis B
Targeted Synthetic DMARDs (tsDMARDs)							
Janus-Kinase Inhibitors							
Tofacitinib (Xeljanz) Tofacitinib extended-release (Xeljanz-XR)	Adults: 5 mg orally twice daily Adults: 11 mg orally once daily		Infection, headache, HTN, elevated LFTs, D, worsening lipid profile, thrombosis	Mild impairment: no adjustment Moderate: 5 mg once daily Severe: Use not recommended	Mild: no adjustment; Moderate/severe: 5 mg once daily	CBC, Hgb, lipids, LFTs, monitor for infection	Screen for tuberculosis, Hepatitis B
Baricitinib (Olumiant)	Adults: 2 mg once daily		Infection, elevated LFTs, increased LDL cholesterol, thrombosis	Not recommended in patients with severe hepatic impairment	Mild: no adjustment Moderate: 1 mg daily Severe: not recommended	CBC, LFTs, lipids, monitor for infection	Screen for tuberculosis, Hepatitis B
Upadacitinib (Rinvoq)	Adults: 15 mg once daily		Infection, elevated LFTs, thrombosis	Mild/moderate: no adjustment Severe: use not recommended	No adjustment necessary	CBC, LFTs, lipids, monitor for infection	Screen for tuberculosis, Hepatitis B

[a] Geriatric patients should receive the usual adult dose unless renal or hepatic impairment is present. Pediatric doses are provided for drugs that have FDA-approved indications for juvenile idiopathic arthritis (JIA).

[b] To convert to SI units of mL/s, multiply by 0.0167.

CBC, complete blood count; D, diarrhea; HA, headache; Hgb, hemoglobin; HTN, hypertension; IR, infusion reactions; ISR, injection site reactions; LFTs, liver function tests; MYL, myelosuppression (watch for fever, symptoms of infection, easy bruisability, and bleeding); N, nausea; SC, subcutaneous injection; SOB, shortness of breath.

nonserious infections.[27] Concomitant use of two bDMARDs and tsDMARDs in any combination is contraindicated due to increased infection risk.

▸ *Vaccinations*

In theory, initiation of DMARD therapy suppresses the immune system and reduces the body's ability to mount a response to a pathogen or a vaccine. Studies are underway to determine how much the immune system is affected as data are emerging that vaccines may be safer than originally thought during DMARD-induced immunosuppression. Specifically, administration of killed vaccines (pneumococcal, influenza, hepatitis B), recombinant vaccines (human papillomavirus, recombinant zoster vaccine [Shingrix]), and live attenuated vaccines should be considered prior to and reevaluated during treatment with DMARDs. Live vaccines should be avoided in patients taking bDMARDs and tsDMARDs. Herpes zoster status should be determined prior to initiation of bDMARDs and tsDMARDs and the vaccine administered, if appropriate. The CDC Advisory Committee on Immunization Practices (ACIP) recommends Shingrix for prevention of herpes zoster and related complications in immunocompetent adults aged 50 years or more. At the time of this writing, the CDC ACIP does not recommend use of the newer recombinant zoster vaccine (Shingrix) in immunocompromised persons and those on moderate to high doses of immunosuppressive therapy because these patients were excluded from the efficacy studies.[27] Additional vaccine information is available on the Centers for Disease Control and Prevention website (www.cdc.gov). Vaccination rates in RA are low, therefore every effort should be made during the initial workup to determine immunization status and update if necessary.[28-30]

▸ *Fertility, Pregnancy, and Fetal Development*

Women of childbearing potential should be counseled early and often about the impact of antirheumatic drugs on fertility, pregnancy, fetal development, and lactation. Some women may experience a reduction in disease symptoms during pregnancy; however, many agents used to treat RA are known teratogens. In addition, some women may present with signs and symptoms of RA for the first time during the postpartum period. Women desiring motherhood must consult with their physicians to discuss contraception and carefully plan for a pregnancy to reduce risks to the developing fetus and the patient.[19]

Methotrexate use is associated with spontaneous abortion, fetal myelosuppression, limb defects, and CNS abnormalities; therefore, pregnancy must be avoided. Methotrexate should be discontinued 3 months prior to attempting conception.[19] Patients of childbearing potential receiving methotrexate should be counseled on the importance of effective contraception (ie, oral contraceptives, condoms plus spermicidal foam). If pregnancy occurs, the patient should notify their healthcare providers immediately. Leflunomide is teratogenic in animal studies, and discontinuation prior to conception is recommended.[19]

TNF inhibitors are considered safe during pregnancy. Certolizumab may be the preferred TNF inhibitor during pregnancy because the transfer of medication across the placenta is very low. Abatacept and tocilizumab may be continued while the patient is trying to conceive and should be discontinued when pregnancy is confirmed. Use of rituximab in pregnancy will risk the fetus having reduced B cells upon delivery, but use is recommended if the mother has severe or life-threatening disease. Insufficient data exist regarding use of JAK inhibitors during pregnancy.[19]

Patient Encounter Part 2: Medical History, Physical Examination, and Laboratory Tests

PMH: Rheumatoid arthritis (15 years)

FH: Mother died age 88 from cardiovascular disease, also had RA; father died age 89 from pancreatic cancer

Allergies: NKDA

Meds: Methotrexate 20 mg orally once weekly; folic acid 1 mg orally daily; prednisone 10 mg orally every morning; leflunomide 20 mg orally daily

Previous Meds: Hydroxychloroquine (ineffective), sulfasalazine (ineffective)

ROS: (+) Fatigue, (–) N/V/D, HA, SOB, chest pain, cough

PE:

VS: BP 138/76 mm Hg, P 64 beats/min, RR 16 breaths/min, T 38.0°C (100.4°F); Ht 5′4″ (163 cm), Wt 56 kg (124 lb)

Skin: Warm, dry

HEENT: NC/AT, PERRLA, TMs intact

CV: RRR, normal S_1 and S_2, no m/r/g

Chest: CTA

Abd: Soft, NT/ND

Neuro: A&O × 3; CN II to XII intact

Ext: Bilateral tender and swollen PIPs and MCPs

Labs: ESR 64 mm/hour, RF (+), ACPA (high +), AST 85 IU/L (1.42 μkat/L) , ALT 92 IU/L (1.53 μkat/L)

Synovial fluid analysis: Yellow, cloudy, decreased viscosity

Hand x-rays: Soft-tissue swelling, joint space narrowing, evidence of erosions

Disease Activity Score 28 (DAS-28): 5.2

DXA Scan: T score –2.5

How would you categorize this patient's disease activity—low, moderate, or high? Why? How does this affect your treatment plan?

What nonpharmacologic and pharmacologic alternatives are appropriate for this patient?

Treatment plans must also consider the potential effects on breastfeeding babies. Low-dose corticosteroids, certain NSAIDs, hydroxychloroquine, sulfasalazine, and certain biologic DMARDs (eg, certolizumab, etanercept) may be considered

Patient Encounter Part 3: Creating a Care Plan

Based on the information available, create a care plan for this patient's RA. The plan should include the following:

(a) A statement of the drug-related needs and/or problems

(b) A patient-specific detailed care plan (including specific medications and associated doses)

(c) Monitoring parameters to assess safety and efficacy

(d) Key patient education topics

Patient Encounter Part 4: Patient Counseling

While meeting with the patient, she tells you that she is deathly afraid of needles. She is most comfortable with her current medication regimen and is frustrated that she has swelling and tenderness in her hands.

How does this information change your care plan?

during pregnancy. Healthcare providers and patients are encouraged to visit MotherToBaby (https://mothertobaby.org) for educational information regarding medication use in pregnancy and ongoing studies designed to learn more about medication exposure during pregnancy.

Male patients with RA must receive counseling about the effects of certain medications on their fertility. It is difficult to establish causality between use of a medication by a male and the effect on fertility or fetal development; therefore, a conservative approach must be taken. **KEY CONCEPT** Women of childbearing

Patient Care Process

Collect Information:

- Perform a medication history to determine current prescription, nonprescription, and dietary supplements. Inquire about previous medications for RA and reasons why they were discontinued. Ask about allergies (and the associated reaction) and immunizations.
- Determine whether physical examination findings and patient-reported symptoms are consistent with RA. Evaluate the duration of symptoms and impact on daily living.
- Review the medical history. Determine if comorbidities are present.

Assess the Information:

- Determine if any of the patient's medications are causing the signs or symptoms.
- Review laboratory test results to establish baseline renal and hepatic function and blood cell status. Review other findings specific to RA (RF, ACPA, etc).
- Determine disease severity.
- If the patient is already receiving pharmacotherapy for RA, assess efficacy, safety, and patient adherence.
- Review immunization history and determine if vaccinations are necessary prior to initiating new medications.

Develop a Care Plan:

- If newly diagnosed with RA, make sure the patient receives DMARD therapy immediately to minimize disease progression and joint destruction.
- Consider bridge therapy with an NSAID or glucocorticoid to provide symptomatic relief until the DMARD reaches its time to effect (Table 58–4).
- Review current medications to proactively identify potential drug interactions with the addition of one more DMARDs.
- Select DMARD therapy that is likely to be safe and effective (see Figures 58–2 and 58–3).
- Ensure that drug doses are optimal (see Table 58–4).
- Incorporate measures to control the increased risk of present comorbidities.
- *Cardiovascular:* Keep doses of NSAIDs and glucocorticoids low; consider initiating folic acid, low-dose aspirin, hypertensive and/or lipid therapy; encourage tobacco cessation, physical activity, and a healthy diet.[8,9] Screen and aggressively treat elevated blood pressure and lipids.
- *Infection:* Inform the patient to wash hands routinely, limit contact with individuals who are ill, and report signs and symptoms of infection immediately (eg, fever, weight loss, and night sweats).
- *Malignancy:* Have the patient report new signs and symptoms (eg, fever, chills, anorexia, and night sweats) immediately.
- *Osteoporosis:* Encourage the patient to ingest adequate amounts of calcium and vitamin D; consider initiating medications for prevention/treatment of osteoporosis (eg, a bisphosphonate) if the patient is taking glucocorticoids chronically or has evidence of low bone mineral density. Review glucocorticoid-induced osteoporosis guidelines.[17]

Implement the Care Plan:

- Educate the patient on pharmacologic and nonpharmacologic measures, including medication administration.
- Screen for tuberculosis if initiation of a bDMARD or tsDMARD is under consideration.
- Stress the importance of adherence with medications and laboratory monitoring.
- Determine whether the patient has prescription coverage. If not, determine if the patient is eligible for prescription assistance programs.

Follow-up: Monitor and Evaluate:

- Assess the patient's response to initiation of DMARD therapy after allowing adequate time for the medication to achieve its therapeutic effect.
- Determine whether any adverse reactions to medications are present.
- Reevaluate need for bridge therapy and discontinue if possible.
- Monitor laboratory parameters to ensure patient safety and reduce the risk of adverse reactions.
- Longitudinally evaluate the patient's clinical response to therapy and the impact on quality of life and mobility. If disease is controlled, consider tapering therapy to the lowest effective dose.[31]
- Assess patient understanding of RA and their medications. Provide additional education where appropriate.

potential and their partners must be counseled to: (a) use proper birth control while undergoing treatment for RA, and (b) involve healthcare providers in discussions regarding family planning to carefully consider all risks and treatment options.[19]

OUTCOME EVALUATION

- Rheumatologists rely on standardized criteria to assess treatment interventions through measurement of disease activity. The ACR uses criteria for improvement based on percentage improvement in tender and swollen joint count, and the presence of at least three or more of the following measures: (a) pain, (b) patient global assessment, (c) physician global assessment, (d) self-assessed physical disability, and (e) acute-phase reactants.[32] ACR20, ACR50, and ACR70 are common efficacy endpoints in clinical trials. The number corresponds with the percentage improvement. As drug development continues to evolve, the acceptable criteria for 20% improvement may be too low.
- Physical disability from RA can be measured through the Stanford Health Assessment Questionnaire (HAQ).[33,34] This patient self-assessment tool was developed to evaluate patient outcomes in five dimensions of chronic conditions: (a) disability, (b) discomfort, (c) drug adverse effects, (d) dollar costs, and (e) death. Clinicians and clinical studies in rheumatology use the HAQ to assess longitudinal changes that influence the patient's quality of life.[33,34]
- Before starting treatment for RA, assess the subjective and objective evidence of disease. For joint findings, this includes the number of tender and swollen joints, pain, limitations on use, duration of morning stiffness, and presence of joint erosions. Systemic findings may include fatigue and the presence of extraarticular manifestations. Obtain laboratory measurements of CRP and ESR. The impact of the disease on quality of life and functional status is also important.
- At follow-up visits, compare the patient's status to baseline or previous visits using standardized criteria for improvement of disease activity (ie, DAS-28) and the influence on quality of life.
- **KEY CONCEPT** In addition to designing an individualized therapeutic regimen to control the progression of RA, the clinician must evaluate the presence of comorbidities and implement measures to control the increased risk.

Abbreviations Introduced in This Chapter

ACPA	Anticitrullinated protein antibodies
ACR	American College of Rheumatology
CRP	C-reactive protein
DAS	Disease Activity Score
DMARD	Disease-modifying antirheumatic drug
ESR	Erythrocyte sedimentation rate
EULAR	European League Against Rheumatism
HAQ	Health Assessment Questionnaire
HLA	Human leukocyte antigen
IL	Interleukin
JIA	Juvenile idiopathic arthritis
MCP	Metacarpophalangeal joint
MTP	Metatarsophalangeal joint
NSAID	Nonsteroidal anti-inflammatory drug
PIP	Proximal interphalangeal joint
RA	Rheumatoid arthritis
TNF	Tumor necrosis factor

Osteoarthritis

Christopher R. Piszczatoski, Steven M. Smith, and John Gums

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiologic mechanisms involved in the development of osteoarthritis (OA).
2. Identify risk factors associated with OA.
3. Recognize the clinical presentation of OA.
4. Determine the goals of therapy for individual patients with OA.
5. Formulate a rational nonpharmacologic plan for patients with OA.
6. Recommend a pharmacologic plan for treating OA, taking into consideration patient-specific factors.
7. Develop monitoring parameters to assess effectiveness and adverse effects of pharmacotherapy for OA.
8. Modify an unsuccessful treatment strategy for OA.
9. Deliver effective patient counseling, including lifestyle modifications and drug therapy, to facilitate effective and safe management of OA.

INTRODUCTION

KEY CONCEPT Osteoarthritis (OA) is the most common form of arthritis and is strongly related to age. Sometimes called degenerative joint disease, OA primarily affects the weight-bearing joints (eg, hips, knees, spine), but non–weight-bearing joints, especially hands, may also be involved. OA causes tremendous morbidity and financial burden because of its high prevalence and effect on joints critical for daily functioning.[1] OA is the leading cause of chronic mobility disability and the most common reason for total-hip and total-knee replacement.[2]

EPIDEMIOLOGY AND ETIOLOGY

Approximately 32.5 million Americans have signs and symptoms of OA.[3] OA is more common in women and older persons, affecting an estimated 18% of women and 10% of men over age 60 years. The knee is the most commonly affected joint, followed by the hand and hip.[4] Hip OA occurs more frequently in men. However, women tend to have more generalized disease and joint inflammation. The prevalence of OA in Black individuals is similar to Whites, but African Americans often experience more severe and disabling disease.

PATHOPHYSIOLOGY

OA is characterized by damage to diarthrodial joints and joint structures (Figure 59–1). The pathophysiology is multifactorial and typified by progressive destruction of joint cartilage, erratic new bone formation, thickening of subchondral bone and the joint capsule, bony remodeling, development of osteophytes, variable degrees of mild synovitis, and other changes.[5]

The earliest stages of OA are characterized by increasing water content and softening of cartilage in weight-bearing joints. As the disease progresses, proteoglycan content of cartilage declines, and eventually, cartilage becomes hypocellular. Procatabolic and proinflammatory changes precede cartilage degradation and are thought to play important roles in OA development and progression.[6]

Subchondral bone undergoes metabolic changes, including increased bone turnover, that appear to be precursors to tissue destruction. The normally contiguous bony surface becomes fissured. Persistent use of the joint eventually results in loss of cartilage, permitting bone-to-bone contact that ultimately promotes thickening and eburnation of exposed bone. Microfractures may appear in subchondral bone, and osteonecrosis may develop beneath the surface, especially in advanced disease.

New bone is formed haphazardly, creating osteophytes that extend into the joint capsule and ligament attachments and may encroach on joint space. Progressive loss of joint cartilage, subchondral damage, joint space narrowing, and changes in underlying bone and soft tissue may culminate in deformed, painful joints.

Classification

OA is classified as primary (idiopathic) or secondary. *Primary OA* is the predominant form, occurring in the absence of a known precipitating event. Primary OA may be localized, generalized, or erosive. Localized OA is distinguished from generalized disease by the number of sites involved. Erosive disease—typically in hand or foot joints—is characterized by erosive bone destruction and in some cases bony proliferations. Secondary OA results from congenital or developmental disorders or inflammatory, metabolic, or endocrine diseases.

Risk Factors

OA develops when systemic factors and biomechanical vulnerabilities combine. Systemic factors include increased age, female sex, genetic predisposition, and nutritional status. Age is the

strongest predictor of OA, although advanced age alone is insufficient to cause OA.

Joints exposed to biomechanical factors are at increased risk. Occupational and recreational activities involving repetitive motion or injury can provoke OA, although most daily activities do not produce enough joint trauma to cause OA. However, daily activities may lead to OA if a joint is susceptible because of previous injury, joint deformity, muscle weakness, or systemic factors. Heavy physical activity is a stronger predictor of OA than light-to-moderate activities, especially for older individuals, in whom

Clinical Presentation of OA

General

- Patients usually are more than 50 years old.
- Presentation may range from asymptomatic to severe joint pain and stiffness with functional limitations.
- Joint involvement has an asymmetric local distribution without systemic manifestations.
- Unlike some other arthritic conditions (eg, rheumatoid arthritis, gout), inflammation is usually absent or mild and localized.

Symptoms

- KEY CONCEPT The most common symptoms are joint pain, reduced range of motion, and brief joint stiffness after inactivity.
- The cardinal symptoms are use-related joint pain, typically described as deep and aching in character, and stiffness. In advanced cases, pain may occur continuously and at rest.
- Joint stiffness ("gelling") abates with motion and recurs with rest.
- Joint stiffness generally lasts fewer than 30 minutes after extended periods of inactivity, limits the range of joint motion, impairs daily activities, and may be related to weather.
- Weight-bearing joints may be unstable.

Signs

- One or more joints may be involved, usually in an asymmetric pattern.
- The following sites are most often involved in primary OA:
  - Distal interphalangeal finger joints (Heberden nodes)
  - Proximal interphalangeal finger joints (Bouchard nodes)
  - First carpometacarpal joint
  - Knees, hips, and cervicolumbar spine
  - Metatarsophalangeal joint of the great toe
- Joint examination may reveal local tenderness, bony prominence, soft tissue swelling, **crepitus**, muscle atrophy, limited motion with passive/active movement, and effusion.

joint structures are less capable of coping with highly stressful activities.[7] Obesity increases load-bearing stress on hip and knee joints. OA risk increases by 10% for each kilogram above ideal body weight.[8]

CLINICAL PRESENTATION AND DIAGNOSIS

OA is diagnosed clinically from symptoms and physical examination of the joint(s), sometimes supported by radiographic evidence (see Clinical Presentation of OA). Peripheral joint OA can be diagnosed by the presence of persistent usage-related joint pain in one or more joints, with morning stiffness lasting no more than 30 minutes, in patients at least 45 years of age.[9] Some patients develop bony enlargements of the fingers, called **Bouchard nodes** or **Heberden nodes**, in the absence of inflammation. Radiographic changes are often absent in early OA. As OA progresses, joint space narrowing, subchondral bone sclerosis, and osteophytes may develop. Laboratory tests are not helpful for diagnosing OA but may rule out related diseases. The erythrocyte sedimentation rate (ESR) and the hematologic and chemistry panels are usually unremarkable in OA. Synovial fluid aspirated from an affected joint should be sterile, without crystals, and with a white blood cell (WBC) count less than $1.5 \times 10^3/\text{mm}^3$ ($1.5 \times 10^9/\text{L}$). Gross joint deformity and joint effusions may occur in late severe OA.

TREATMENT

Desired Outcomes

KEY CONCEPT Goals of therapy include: (a) educating the patient and caregivers, (b) relieving pain, (c) maintaining or restoring mobility, (d) minimizing functional impairment and associated adverse outcomes (eg, falls), (e) preserving joint integrity, and (f) improving quality of life.

General Approach to Treatment

Treatment is individualized considering medical history, physical examination, radiographic findings, distribution and severity of joint involvement, and response to previous treatment. Comorbid diseases, concomitant medications, and allergies are integrated into a holistic treatment approach.

As shown in Figure 59–2, nonpharmacologic treatment is integral to achieving optimal outcomes and is the first step in OA management. Pharmacologic therapy is an adjunctive measure to relieve pain; available medications do not substantially modify the disease course. Surgical intervention generally is reserved for patients with advanced disease complicated by unremitting pain or severely compromised function.

Patient Encounter Part 1

A 72-year-old obese man presents to his primary care physician with right knee pain that has significantly worsened over the past several years. He describes the pain as deep and aching, with stiffness when he wakes up and that abates after moving around. He has used acetaminophen infrequently in the past, but states that the pain is now so significant and consistent that he is seeking recommendations. He is retired and states that the knee pain has interfered with his weekly golf game. This activity is the only exercise he gets and is his primary form of socializing, so he wants to regain as much function as possible.

What information is suggestive of osteoarthritis (OA)?

What risk factors for OA does this patient have?

What other information will you need to differentiate OA from rheumatoid arthritis?

What potential comorbidities should be considered in this patient?

What other information will be required before formulating a treatment plan?

Nonpharmacologic Therapy

KEY CONCEPT Nonpharmacologic therapy is the cornerstone of treatment: education, exercise, weight loss, and cognitive behavioral intervention are integral components.

Educational programs are designed to improve health behaviors and health status, thereby slowing OA progression. The goal is to increase patient knowledge and self-confidence in adjusting daily activities in the face of evolving symptoms. Effective programs produce positive behavioral changes, decrease pain and disability, and improve functioning and psychological outcomes (eg, depression, self-efficacy, life satisfaction). Patients can be referred to the Arthritis Foundation (www.arthritis.org) for educational materials and information on support groups.

Lifestyle modification should be encouraged for all patients at risk for, or with established OA. Low-impact exercise is advisable for most patients, especially with knee or hip OA. Aerobic exercise and strength-training programs improve functional capacity in older adults. Balance and stretching exercises, such as Tai Chi or yoga, can also be recommended. In general, exercises should target affected and vulnerable joints. Isokinetic and isotonic exercises performed at least three to four times weekly improve physical functioning and decrease disability, pain, and analgesic use. Clinicians should consider the patient's physical capabilities when implementing any exercise program. Referral to a physical or occupational therapist may be helpful, particularly in patients with functional disabilities. Physical therapy is tailored to the patient and may include assessment of muscle strength, joint stability, and mobility; use of heat (especially prior to increased activity); structured exercise regimens; and assistive devices such as canes, crutches, and walkers. Occupational therapists advise on optimal joint protection and function, energy conservation, and use of splints and other assistive devices.

The association between body weight and OA onset and progression make weight loss a pivotal goal in overweight and obese patients. Weight loss significantly reduces pain and improves function in patients with knee OA.[10] Women who reduce body weight by 5 kg (11 lb) can halve their risk of developing OA.[11] Weight loss should be pursued through diet modification and increased physical activity (see Chapter 102, Overweight and Obesity).

Knee braces may delay the progression of knee OA. Cane use and tibiofemoral or patellofemoral knee braces can be recommended for patients with OA causing significant issues with ambulation or joint stability.[11] Kinesiology taping, the application of an adhesive elastic that provides joint stability without hindering range of motion, may also be considered. Hand orthoses are strongly recommended for patients with carpometacarpal (CMC) OA. Modified shoes or wedged insoles are not recommended.[12]

Application of heat or cold to involved joints may improve range of motion, reduces pain, and decreases muscle spasms. Applications of heat include warm baths or warm water soaks. Heating pads should be used cautiously, especially in older

FIGURE 59–2. Treatment of osteoarthritis.

(OA, osteoarthritis; CV, cardiovascular; IA, intra-articular; NSAID, nonsteroidal anti-inflammatory drug.)

[a]Topical NSAIDs can be considered before oral NSAIDs for superficial joints due to their favorable side effect profile.

persons, and patients must be warned of the potential for burns if used inappropriately.

Acupuncture, radiofrequency ablation, and paraffin (an alternative method of heat therapy) may offer some benefit, but robust evidence is lacking. Massage therapy may offer indirect benefits in symptom management. Current evidence does not support use of iontophoresis, pulse vibration therapy, and transcutaneous electrical stimulation (TENS).

Pharmacologic Therapy

Various topical, oral, and intra-articular (IA) therapies exist for managing OA, with nonsteroidal anti-inflammatory drugs (NSAIDs) representing the first line of treatment (Table 59–1).

▸ *Nonsteroidal Anti-Inflammatory Drugs*

Prostaglandins play an important role in the function of several organ systems. These compounds are synthesized via the interaction of two isoforms of the cyclooxygenase enzyme (COX-1 and COX-2) with their substrate, arachidonic acid.

The COX-1 enzyme is expressed constitutively in various body tissues (eg, gastric mucosa, kidney, platelets). Prostaglandins produced by the actions of the COX-1 enzyme in the gastrointestinal (GI) tract preserve GI mucosal integrity by increasing mucous and bicarbonate secretion, maintaining mucosal blood flow, and decreasing gastric acid secretion. Prostaglandins associated with COX-1 also promote normal platelet activity and function. In the kidney, COX-1–mediated prostaglandins dilate the afferent arteriole, thereby maintaining intraglomerular pressure and glomerular filtration rate when renal blood flow is reduced.

In contrast, the COX-2 enzyme is normally undetectable in most tissues, but its expression can be induced rapidly in the presence of inflammation and local tissue injury. This change leads to the synthesis of prostaglandins involved in pain and inflammation. Consequently, blocking the COX-2 enzyme is thought to result in analgesic and anti-inflammatory effects. All NSAIDs inhibit both the COX-1 and COX-2 enzyme isoforms, but nonselective NSAIDs (eg, ibuprofen, naproxen) are not particularly selective for one isoform, whereas COX-2 inhibitors (eg, celecoxib, and to a lesser extent, diclofenac) preferentially inhibit COX-2.

KEY CONCEPT NSAIDs are the first-line therapy, regardless of affected joint location.[12] NSAIDs reduce pain and improve functioning in patients with OA, although individual responses vary widely. The route of administration (ie, oral or topical) should be based on affected joint(s), patient preference, ability to administer, and an assessment of risk for adverse effects of systemic NSAIDs.

Topical NSAID administration minimizes systemic exposure while providing pain relief comparable to oral NSAIDs. Consensus guidelines strongly recommend topical NSAIDs in patients with knee OA. They may also be preferable in hand OA, although evidence regarding efficacy in this setting is less robust, and concerns have been raised regarding inadvertent drug removal during daily activities (eg, handwashing). Deeper joints, especially the hip, should not be treated with topical NSAIDs owing to insufficient drug penetration. Currently, the only commercially available topical NSAID in the United States is diclofenac, which is marketed in a variety of preparations (ie, solution, gel, topical patch) available both over-the-counter (gel formulation only) and by prescription. These products decrease pain and improve joint function, with similar efficacy across dosage forms.[13,14] Systemic absorption of topical diclofenac is significantly less than that of oral diclofenac. Thus, with proper administration, GI, cardiovascular, and renal adverse effects are rare and similar in incidence to placebo.[13,14] The most common adverse effects are application site dermatitis, pruritus, and phototoxicity.

For patients with OA affecting deeper joints (ie, hip, shoulder, spine), or who have not achieved adequate response to topical NSAIDs, an oral NSAID should be considered. **KEY CONCEPT** At equipotent doses, the analgesic and anti-inflammatory activities of all oral NSAIDs, including COX-2–selective inhibitors, are similar. The selection of a specific oral NSAID should be based on patient preference, previous response, tolerability, side-effect profile, dosing frequency, cost, and underlying GI risk. Pain relief occurs rapidly (within hours), but anti-inflammatory response occurs after 2 to 3 weeks of continuous therapy. This latter period is the minimal duration that should be considered an adequate oral NSAID trial. If an insufficient response is achieved with one oral NSAID, another oral NSAID should be tried.

KEY CONCEPT All systemic NSAIDs are associated with adverse GI, renal, hepatic, cardiovascular, central nervous system (CNS), and hypertensive effects, particularly in older individuals. Inhibition of the COX-1 enzyme is thought to be responsible primarily for the adverse effects on the gastric mucosa, kidney, and platelets. Direct irritant effects also may contribute to adverse GI events. Minor GI complaints, including nausea, dyspepsia, anorexia, abdominal pain, flatulence, and diarrhea, are reported by 10% to 60% of patients treated with oral nonselective NSAIDs. Asymptomatic gastric and duodenal mucosal ulceration can be detected in 15% to 45% of patients. Perforation, gastric outlet obstruction, and GI bleeding are the most severe complications and occur in 1.5% to 4% of patients annually.[15]

KEY CONCEPT COX-2 inhibitors are preferred for patients at high risk for GI complications.[16,17] Several risk factors predict a greater likelihood of GI complications in oral NSAID-treated patients (see Chapter 19, Peptic Ulcer Disease). Identifying at-risk patients based on symptoms alone is impractical because the presence of symptoms and actual gastroduodenal damage are poorly correlated. For patients at particularly high GI risk (eg, previous history of NSAID-induced GI bleed), a selective COX-2 inhibitor combined with a proton pump inhibitor reduces risk for GI hemorrhage more than a COX-2 inhibitor alone, which in turn has lower GI bleed risk than a nonselective NSAID combined with a proton pump inhibitor.[18-21] A COX-2 inhibitor alone, or a nonselective NSAID plus proton pump inhibitor, can be used in patients at moderate risk of GI complications.[16] See Chapter 18 (Gastroesophageal Reflux Disease) for more information on proton pump inhibitors.

COX-2 inhibitors have been associated with a greater risk of myocardial infarction than nonselective NSAIDs, which led to removal of rofecoxib and valdecoxib from the market.[22] However, direct comparison of naproxen, ibuprofen, and celecoxib suggests similar cardiovascular risk between these agents.[23,24] Nevertheless, all NSAIDs, except low-dose aspirin, increase cardiovascular risk.[25] To limit this risk, NSAIDs should be used at the lowest effective dose for the shortest duration, consistent with individual patient treatment goals. All oral NSAIDs can increase blood pressure, and patients with hypertension should be monitored within the first 2 to 4 weeks of initiation and periodically thereafter.[26]

All NSAIDs can cause adverse renal effects. Patients who are particularly susceptible include older persons and patients with chronic renal insufficiency, left ventricular dysfunction, and those taking diuretics or drugs that interfere with the renin–angiotensin system. These effects include decreased glomerular filtration, hyperkalemia, and sodium and water retention. Therefore, both nonselective NSAIDs and selective COX-2 inhibitors

Table 59–1

Dosing Parameters of Select Agents Used to Treat OA

Medication	Dosage and Frequency
Oral NSAIDs by Chemical Class	
Carboxylic acid (salicylates)	
Aspirin	325–650 mg every 4–6 hours; max 3600 mg/day
Salsalate	500–1000 mg two to three times daily; max 3000 mg/day
Acetic acid	
Etodolac	300–600 mg twice daily; max 1200 mg/day 400–1000 mg once daily (extended-release)
Diclofenac	50 mg two to three times daily 75 mg twice daily (delayed-release tablets) 100 mg once daily (extended-release tablets) 35 mg three times daily (submicron particle capsules) Max 150 mg/day from any formulation
Indomethacin	25 mg two to three times daily 75 mg one to two times daily (sustained-release) Max 200 mg/day from any formulation
Nabumetone	500–1000 mg one to two times daily; max 2000 mg/day
Propionic acid	
Ibuprofen	400–800 mg three to four times daily; max 3200 mg/day
Naproxen	250–500 mg two times daily 750–1000 mg once daily (controlled-release) 275–550 mg two times daily (naproxen sodium) Max 1650 mg/day from any formulation
Enolic acid	
Meloxicam	7.5–15 mg once daily; max 15 mg/day
Piroxicam[c]	20 mg once daily; max 20 mg/day
Coxibs	
Celecoxib[c]	100 mg twice daily or 200 mg once daily; max 200 mg/day
Para-aminophenol Derivative	
Acetaminophen	325 mg every 4–6 hours or 1000 mg every 6–8 hours; max 4000 mg/day (from all sources)
Serotonin-Norepinephrine Reuptake Inhibitors	
Duloxetine	30–60 mg once daily; max 60 mg/day
Opioids	
Tramadol	50–100 mg every 4–6 hours; max 400 mg/day (300 mg in elderly) CrCl < 30 mL/min (0.50 mL/s): 50–100 mg every 12 hours; max 200 mg/day
Oxycodone	5–15 mg every 4–6 hours (initial dose for opioid naïve); dose depends on degree of opioid tolerance and patient response
Topical Analgesics	
Capsaicin 0.025% or 0.075% cream	Apply to affected joint every 6–8 hours
Diclofenac sodium 1% gel	Upper extremity joints: 2 g four times daily; max 8 g[b] per upper extremity joint per day Lower extremity joints: 4 g four times daily; max 16 g[b] per joint per day
Diclofenac sodium 1.5% solution	40 drops per affected knee, four times per day; max 160 drops per day per knee
Diclofenac sodium 2% solution	40 mg (2 pump actuations) on each painful knee, two times a day; max 80 mg per day per knee
Intra-Articular Glucocorticoid Injection	
Triamcinolone acetonide	2.5–15 mg for single injection; doses can be adjusted to 20–40 mg; administered not more often than every 3 months
Triamcinolone acetonide extended-release	32 mg for a single knee injection
Methylprednisolone acetate	Small joints 4–10 mg; medium joints 10–40 mg; large joints 20–80 mg; administered no more often than every 3 months
Intra-articular Hyaluronic Acid Injection	
Hyaluronic acid	16–30 mg injected into the affected knee every week for a total of 3–5 weeks, depending on the product (see text)
Dietary Supplements	
Glucosamine sulfate	500 mg three times daily or 1500 mg once daily
Chondroitin	400–800 mg up to three times daily with glucosamine

[a] Serum salicylate levels should be monitored for doses greater than 3 g/day.

[b] Total daily dose of diclofenac 1% gel should not exceed 32 g for all affected joints.

[c] Substrate for CYP2C9, consider a 50% reduction in the initial dose in known or suspected poor metabolizers.

CrCl, creatinine clearance.

should be used with caution in patients with hypertension, heart failure, or chronic renal insufficiency. NSAIDs rarely cause tubulointerstitial nephropathy and renal papillary necrosis.

NSAIDs should be avoided if possible during pregnancy due to potential risks to the fetus. However, all NSAIDs should be strictly avoided starting at 30 weeks' gestation to prevent premature closure of the ductus arteriosus in the fetus.

Nonselective NSAIDs and selective COX-2 inhibitors are prone to drug interactions due to high protein binding, detrimental renal effects, and antiplatelet activity. Interactions are encountered frequently with aspirin, warfarin, oral hypoglycemics, antihypertensives, and lithium. When potential interactions are present, vigilant monitoring is warranted for therapeutic efficacy (eg, NSAIDs blunt the antihypertensive efficacy of diuretics) and adverse effects (eg, NSAIDs increase the risk of bleeding in anticoagulated patients).

▶ *Acetaminophen*

Acetaminophen is a centrally acting analgesic that inhibits prostaglandin production in the brain and spinal cord that has historically been recommended as a first-line treatment option for OA. Recent evidence indicates that acetaminophen monotherapy is ineffective or only modestly better than placebo for long-term OA treatment in most individuals.[27] **KEY CONCEPT** Nevertheless, acetaminophen is an inexpensive analgesic appropriate for short-term/episodic use in those who cannot tolerate or have contraindications to NSAID use.[12]

Acetaminophen should be administered initially on an as-needed basis in divided doses up to 4 g daily. Single doses should not exceed 1 g. Some patients may require scheduled dosing to achieve adequate pain relief. Periodic assessment of pain control should be performed to maintain the lowest effective dose. A sufficient trial is defined as up to 4 g daily in divided doses for 4 to 6 weeks.

Despite being among the safest analgesics, acetaminophen can cause significant adverse effects, including hepatic and renal toxicity.[28] Acetaminophen overdose, both intentional and unintentional, is the leading cause of acute liver injury in the United States.[29] Total daily doses greater than 4 g are associated with increased risk of hepatotoxicity. Daily doses of 4 g have been associated with significant liver enzyme elevations, but such elevations do not necessarily portend hepatotoxicity.[30] Concomitant use of alcohol may increase risk of hepatic injury; a maximum acetaminophen dose of 2.5 g daily is recommended for patients who consume more than 2 to 3 alcoholic beverages daily. Acetaminophen does not appear to exacerbate stable, chronic liver disease, but liver function should be monitored regularly in this population.[28] Careful inventory should be taken of all concomitant prescription and over-the-counter (OTC) products to minimize the risk of inadvertent acetaminophen overdose.

▶ *Duloxetine*

Duloxetine, a serotonin and norepinephrine reuptake inhibitor (SNRI), is a centrally acting adjunctive option for patients achieving suboptimal response to oral NSAIDs. Duloxetine can be used as monotherapy or in combination with other agents.[12] Studies of duloxetine have primarily been in knee OA and revealed moderate benefits on pain, function, and quality of life.[31] Such effects may be reasonably extrapolated to hand and hip OA. Benefits typically are observed only after several weeks of therapy with moderate doses (ie, 60 mg/day); larger doses do not provide additional benefit. Duloxetine may be preferred as an adjunct in patients experiencing concurrent neuropathic and musculoskeletal pain. The most common adverse events are nausea, dry mouth, somnolence, constipation, decreased appetite, and hyperhidrosis.[32] Other centrally acting agents with similar mechanisms of action (eg, selective serotonin reuptake inhibitors [SSRI], SNRIs, tricyclic antidepressants [TCA], gabapentin, and pregabalin) have no current role in OA treatment. Concomitant use with other serotinergic agents should be pursued cautiously due to an increased risk of serotonin syndrome. For more duloxetine information, see Chapters 39 (Major Depressive Disorder) and 40 (Bipolar Disorder).

▶ *Tramadol*

Tramadol is an oral, centrally acting synthetic opioid analgesic that also weakly inhibits serotonin and norepinephrine reuptake. Evidence suggests that it imparts a modest benefit in the long-term management of noncancer pain.[33] However, tramadol appears to have minimal effect for OA pain specifically.[34] It is therefore only recommended in patients who have failed or have contraindications to other oral and IA options.[12] Tramadol should be recommended over other opioid agents if an opioid is being considered.

Common adverse events include dizziness, vertigo, nausea, vomiting, constipation, and lethargy. These effects are more pronounced for several days after initiation or a dose increase, and often lead to treatment discontinuation.[34] Seizures have been reported rarely; the risk is dose-related and appears to increase with concomitant use of antidepressants, such as tricyclics or SSRIs. Tramadol should be avoided in patients receiving other serotenergic agents due to the potential for serotonin syndrome.

▶ *Other Opioid Analgesics*

Opioid analgesics other than tramadol are reserved for patients experiencing severe pain for which alternative options are inadequate or contraindicated (eg, renal failure, heart failure, anticoagulation). Opioids may offer symptomatic improvement in patients with OA who are unresponsive to nonpharmacologic therapy and nonopioid analgesics. However, opioids also greatly increase the risk for addiction and other serious adverse effects that limit their use in most patients. Current guidelines strongly recommend against initiating opioids before exhausting other options.[12,17] Evidence has shown only modest improvements in OA pain with oxycodone, oxymorphone, morphine, hydromorphone, codeine, buprenorphine, and transdermal fentanyl, but with significant risk of serious side effects.[35]

Opioids should be initiated with short-acting agents at low doses and titrated to the lowest effective dose for the shortest possible duration to minimize adverse events. When feasible, opioids should be combined with acetaminophen or oral NSAIDs to reduce the opioid requirement. However, adverse effects from opioids are common even with the lowest effective doses.[35] Common or serious adverse effects include nausea, constipation, sedation, and respiratory depression. Use of combination opioid-acetaminophen products should be accompanied by clear instructions to limit additional use of OTC acetaminophen to avoid unintentional overdose.

Clinicians should establish realistic pain and function goals for all patients before starting opioid therapy. The US Centers for Disease Control and Prevention recommends taking a detailed history, providing information regarding treatment expectations, and developing a management plan with goals and safeguards, including how opioid therapy will be discontinued if benefits do not outweigh risks (see Chapter 35, Pain

Management). Additional recommendations to mitigate the risk of opioid therapy misuse include frequent follow-up, urine drug testing initially and at least yearly thereafter to assess use of prescribed medications or other illicit substances, and use of prescription drug monitoring programs to identify filling of opioid prescriptions from other providers. Patient response to opioid therapy should be assessed within 1 to 4 weeks of initiation or dose increase and every 3 months thereafter. Clinicians should use both nonopioid analgesics and nondrug therapies, as appropriate, to lower opioid doses or taper to opioid discontinuation.

▸ *Intra-Articular Therapy*

IA therapy is an alternative to oral and topical agents for joint pain treatment, typically used after failure of first-line oral or topical NSAID therapy. Two therapies, glucocorticoids and hyaluronic acid, are approved for IA injection. IA glucocorticoid injection is remarkably effective for reducing pain in the short term (weeks). Glucocorticoids are strongly recommended over hyaluronic acid in consensus guidelines, especially for knee or hip OA.[12] Hylauronic acid may offer some benefit, however many of the studies supporting its use are of low quality.[36] Both treatments are used to improve symptoms but do not reverse disease progression.

Glucocorticoids Glucocorticoids with reduced solubility, such as methylprednisolone and triamcinolone, are usually preferred. The affected joint can be aspirated and subsequently injected with the chosen agent. The aspirate should be examined for the presence of crystal formation and infection. Pain relief begins within days after the injection but may wane beyond 3 weeks for most agents. Triamcinolone acetonide extended-release may provide pain relief for up to 12 weeks. Glucocorticoid injections should be administered as infrequently as possible to avoid joint damage. Specifically, a single joint should generally not be treated more than every 3 months to reduce the risk of glucocorticoid-induced cartilage and joint damage. Because the recommended dosing interval exceeds the typical duration of benefit for most agents, IA glucocorticoids are usually ineffective as monotherapy for chronic OA treatment.

The crystalline nature of glucocorticoid suspensions can provoke a postinjection flare that mimics the flare of arthritis and inflammation that accompanies infection. Cold compresses and analgesics are recommended to treat symptoms in affected patients. There is concern that use of IA glucocorticoid therapy can lead to loss of hyaline cartilage and acceleration of OA progression.[37,38]

Hyaluronic Acid The mechanism of action of hyaluronic acid is not fully understood. Healthy cartilage and synovial fluid are replete with hyaluronic acid, a viscous substance believed to facilitate lubrication and shock absorbency under varying load-bearing conditions. Patients with OA demonstrate an absolute and functional decline in hyaluronic acid; thus, exogenous administration is referred to as viscosupplementation.

Pain and joint function following IA hyaluronic acid injections have been evaluated frequently in clinical trials, most of which were of low quality. Treatment courses are typically expensive and may not confer benefit over the placebo effect. Several hyaluronic acid formulations are available in the United States for knee OA:

- Durolane: 60 mg (3 mL) for a single injection
- Euflexxa: 20 mg (2 mL) injected every week for a total of 3 weeks
- Gelsyn-3: 16.8 mg (2 mL) injected every week for a total of 3 weeks
- Gel-One: 30 mg (3 mL) for a single injection
- GenVisc 850: 25 mg (2.5 mL) injected every week for a total of five injections
- Hyalgan: 20 mg (2 mL) injected every week for a total of five injections
- Monovisc: 88 mg (4 mL) for a single injection
- Orthovisc: 30 mg (2 mL) injected every week for a total of 3 to 4 weeks
- Supartz FX: 10 mg (1 mL) injected every week for a total of five injections
- Synvisc: 16 mg (2 mL) injected every week for a total of 3 weeks
- Synvisc-One: 48 mg (6 mL) for a single injection
- TriVisc: 25 mg (2.5 mL) injected every week for a total of 3 weeks

Injections are generally well tolerated, although patients may report injection site reactions. A local anesthetic such as lidocaine may be injected simultaneously to provide more rapid onset of pain relief. Patients should be counseled to minimize activity and stress on the joint for several days after each injection. As an injectable agent, there is a small risk of infection. Additionally, injections are more expensive than oral options, which may limit their use.

▸ *Over-the-Counter Agents*

Glucosamine and Chondroitin Glucosamine is believed to function as a "chondroprotective" agent, stimulating the cartilage matrix and protecting against oxidative chemical damage. Consensus guidelines do not support the use of glucosamine due to inconsistent efficacy and large placebo effects in most trials. Despite this, glucosamine is one of the most commonly used dietary supplements. Chondroitin, often administered with glucosamine, is thought to inhibit degradative enzymes and serve as a substrate for proteoglycan production.[12] Chondroitin is not recommended in knee and hip OA, but limited evidence from a single trial suggest it may be suitable for hand OA.[12] If used, these agents should be adjuncts to evidence-based nonpharmacologic and pharmacologic therapies and discontinued after 3 to 6 months if no benefit is achieved.

Patients with shellfish allergies should be warned of the potential for severe anaphylactic reactions with the use of glucosamine products (derived from crab, lobster, or shrimp shells). Because the allergic reaction is caused by shellfish proteins rather than the animal shell, most products pose little risk.[39] However, patients should be aware that products may be contaminated with shellfish proteins given that these agents are loosely regulated in the United States as dietary supplements, product standards are inconsistent, and the constituents are not validated by any regulatory agency. Additionally, glucosamine may alter cellular glucose uptake, thus elevating blood glucose levels in patients with diabetes.[40] Because the clinical significance of this is unclear, blood glucose levels in diabetic patients should be monitored closely after glucosamine initiation or dosage adjustments.

Other Topical Agents Limited data support use of salicylate-containing rubefacients (eg, methyl salicylate, trolamine salicylate) or other counterirritants (eg, menthol, camphor, methyl nicotinate) in OA.[41] See Chapter 61 (Musculoskeletal Injuries) for more information on these products.

Patient Encounter Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH: Obesity (BMI 37 kg/m^2), HTN, T2DM × 15 years, asthma, COPD, hyperlipidemia

PSH: Carpal tunnel surgery 5 years ago

FH: Father had OA of the hip and knee; mother died of breast cancer at 76

SH: Retired businessman; drinks 6 to 12 beers per week; smokes cigars while golfing; denies illicit drug use

Allergies: NKDA; shellfish allergy (hives)

Meds: Lisinopril 40 mg once daily; atorvastatin 40 mg once daily; fluticasone 250 mcg/salmeterol 50 mcg 2 inhalations twice daily; albuterol 1 to 2 puffs as needed for wheezing/shortness of breath; metformin 1000 mg twice daily; empagliflozin 10 mg once daily

ROS: (+) SOB on exertion, right knee pain 7/10 in the mornings, 5/10 while golfing

PE:

VS: BP 130/76 mm Hg, pulse 64 beats/min, RR 11 breaths/min, T 98.6°F (37.0°C).

Skin: Warm, dry, cracked skin on feet bilaterally.

HEENT: NC/AT, PERRLA, TMs intact.

CV: RRR, normal S_1 and S_2, no m/r/g.

Chest: CTA

Abd: Soft, NT/ND.

Neuro: A&O × 3; CN II to XII intact.

Ext: No edema, swelling, or tenderness of the soft tissue surrounding right knee. Noticeable decreased range of motion of the right knee. No other joint involvement.

Labs: ESR 11 mm/hour; basic metabolic panel within normal limits.

Knee x-rays: Right knee shows joint space narrowing, minor osteophyte formation, and subchondral bone sclerosis.

What clinical parameters are consistent with a diagnosis of OA?

What are the treatment goals for this patient?

What nondrug options are available to treat this patient?

What pharmacologic options are available to treat this patient?

What factors are important to consider when selecting medications for this patient?

Capsaicin relieves pain by depleting substance P from spinal sensory neurons, thereby decreasing pain transmission. Capsaicin is not effective for acute pain; it may take up to 2 weeks of daily administration to relieve pain. As with other topical products, capsaicin is best suited for treating superficial joints (eg, hand OA). The lower concentration (0.025%) is better tolerated, but most patients experience a localized burning sensation. The discomfort usually does not result in discontinuation and often abates within the first week with regular use. Contact with eyes or mucous membranes should be avoided and patients should be counseled to wash their hands after application.

Surgery

Surgery generally is reserved for patients who fail medical therapy and have progressive limitations in activities of daily living. In joint replacement surgery (arthroplasty), the damaged joint surfaces are replaced with metal or plastic prostheses. Hip and knee joints are most commonly replaced, but arthroplasty may also be performed on shoulders, elbows, fingers, and ankles. Total knee arthroplasty combined with physical and medical therapy improves knee OA symptoms more than physical and medical therapy alone.[42] Most patients achieve significant pain relief and functional restoration after arthroplasty, and it is a reasonable option in carefully selected patients.

Surgical debridement may be performed arthroscopically. With this procedure, a tiny video camera is inserted into the affected joint through a small incision, and the surgeon removes torn cartilage or other debris from the joint. The long-term benefits of arthroscopic surgery for OA are unclear, and it may be no better than optimized physical and medical therapy.[43]

OUTCOME EVALUATION

- At baseline, quantify pain using a visual analog scale, assess range of motion of affected joints, and identify activities of daily living that are impaired.
- In patients treated with acetaminophen or oral NSAIDs, assess pain control after 2 to 3 weeks. Full anti-inflammatory effects of NSAIDs may take longer to occur.
- Incorporate other measures to track disease progress. Use radiography to assess severity of joint destruction, determine 50-ft (~15-m) walking time and grip strength, and administer the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) and the Stanford Health Assessment Questionnaire, where appropriate, to assess activities of daily living.
- If pain control is adequate, continue the current therapy at the lowest effective dose. If pain is improving but still inadequate, titrate to maximum therapeutic dose or consider adjunctive agents. If the patient has no improvement after 2 weeks, assess medication adherence and consider switching therapy.
- Ask patients if they are experiencing side effects or other problems with their medications and respond with more specific questions.
- Educate patients to not exceed maximum daily doses of medications.

Patient Encounter Part 3: Creating a Care Plan

Based on the available information, create a care plan for this patient's OA. The plan should include:

(a) A statement of the drug-related needs and/or problems

(b) An individualized, detailed therapeutic plan

(c) A plan for follow-up monitoring to document the patient's response and identify adverse reactions

Pharmacist's Patient Care Process

Collect Information:

- Obtain a thorough history of previous device and drug use, including prescription drugs, OTC drugs, and dietary supplements.
- Ask the patient about known allergies to medications and other substances, including type and severity of reaction.
- Determine lifestyle habits, preferences and beliefs, health goals, and socioeconomic factors that affect overall patient care.
- Consider obtaining laboratory tests depending on degree of clinical suspicion for inflammatory etiology (eg, ESR, C-reactive protein [CRP], rheumatoid factor [RF], antinuclear antibodies [ANA]).

Assess the Information:

- Determine whether the patient's symptoms are consistent with OA. Review the medical history to determine whether other rheumatic diseases may be involved.
- Assess symptoms to determine whether pain warrants additional attention. Does the pain affect quality of life or interfere with activities of daily living?
- Assess radiographs for diagnosis and disease severity (joint-space narrowing, subchondral bone sclerosis, osteophyte formation, joint deformity, joint effusion).

Develop a Care Plan:

- At baseline, quantify pain using a visual analog scale, assess range of motion of affected joints, and identify activities of daily living that are impaired.
- Evaluate the effectiveness of current or previous pharmacotherapy, including dose, frequency, and duration to determine whether an adequate trial was given.
- Establish realistic treatment goals with the patient, including acceptable levels of pain and function.
- Formulate a plan for lifestyle modifications and alteration/addition of pharmacotherapy that considers risks, benefits, and patient preference, given the patient's medical history, concomitant medications, and previous response to OA therapies.

Implement the Care Plan:

- Discuss with the patient any modifications to nondrug or pharmacological treatment plans and how to implement the new care plan.
- Address patient concerns related to OA and its treatment, with special focus on the expected benefits and potential adverse effects of medications.
- Emphasize the value of adherence to medication regimens and lifestyle modifications.
- Facilitate adherence by implementing medication regimens and lifestyle plans that are simple and consistent with the patient's lifestyle.

Follow-up: Monitor and Evaluate:

- Schedule follow-up within 1 to 2 weeks to assess the effectiveness of therapy and associated adverse effects; the specific time frame depends on patient factors and the treatment regimen chosen.
- If laboratory tests (eg, renal function for NSAIDs) are appropriate for monitoring drug therapy, provide the patient with an order for the laboratory test(s) and instructions to complete them before the follow-up appointment.
- If the patient has hypertension and is taking an oral NSAID, monitor blood pressure at each follow-up visit within 2 to 4 weeks of initiating therapy and then every 1 to 2 months.
- Document whether the patient has had improvements in pain, quality of life measures, mobility and functioning, ability to perform activities of daily living, and well-being.
- If pain control is adequate, continue the current therapy at the lowest effective dose. If pain is improving but still inadequate, titrate as needed to the maximum therapeutic dose or consider adjunctive agents. If the patient has no improvement after 2 weeks, assess medication adherence and consider switching therapy.
- Ascertain new OTC medication use; for patients prescribed acetaminophen or oral NSAIDs, pay particular attention to OTC sources of these drugs.
- Evaluate for the presence of adverse drug reactions, drug hypersensitivity, and potential drug interactions.

- Consider baseline liver function tests in patients being prescribed acetaminophen who are at high risk for hepatotoxicity.
- Assess acetaminophen exposure from all sources, including OTC products.
- In patients with hypertension, who are taking oral NSAIDs, monitor blood pressure at baseline, every 2 to 4 weeks for 1 to 2 months, and then periodically thereafter.
- For patients prescribed NSAIDs, monitor for weight gain, edema, and skin rash, and inquire about CNS adverse effects such as headaches and drowsiness at baseline and at least every 6 to 12 months.
- Evaluate serum creatinine, complete blood count, and serum transaminases at baseline and at every 6 to 12 months in patients treated with oral NSAIDs or acetaminophen.
- Perform stool guaiac in patients taking oral NSAIDs when clinically indicated.
- Monitor for drug interactions, including with alcohol, at every visit.

Abbreviations Introduced in This Chapter

ANA	Antinuclear antibodies
BMI	Body mass index
CMC	Carpometacarpal
CNS	Central nervous system
COX	Cyclooxygenase
CRP	C-reactive protein
CYP	Cytochrome P450

ESR	Erythrocyte sedimentation rate
GI	Gastrointestinal
IA	Intra-articular
NSAID	Nonsteroidal anti-inflammatory drug
OA	Osteoarthritis
OTC	Over-the-counter
RF	Rheumatoid factor
SNRI	Serotonin-norepinephrine reuptake inhibitor
SSRI	Selective serotonin reuptake inhibitor
TCA	Tricyclic antidepressant

Gout and Hyperuricemia

Maria Miller Thurston and Jenny Lin

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the pathophysiologic mechanisms underlying gout and hyperuricemia.
2. Recognize major risk factors for developing gout in a given person.
3. Assess the signs and symptoms of an acute gout attack.
4. List the treatment goals for a patient with gout.
5. Develop a pharmacotherapeutic plan for a patient with acute gouty arthritis that includes individualized drug selection and monitoring for efficacy and safety.
6. Identify patients for whom prophylactic urate-lowering therapy for gout and hyperuricemia is warranted.
7. Formulate appropriate educational information for a patient on lifestyle modifications to help prevent gouty arthritis attacks.
8. Select an appropriate drug to reduce serum uric acid (SUA) levels in patients with gout, and outline a plan for monitoring efficacy and toxicity.

INTRODUCTION

KEY CONCEPT Gout is an inflammatory condition of the arthritis-type that results from deposition of uric acid crystals in joint spaces or surrounding tissues, leading to an inflammatory reaction that causes intense pain, erythema, and joint swelling. It is associated with hyperuricemia, defined as a serum uric acid (SUA) level of 6.8 mg/dL (404 μmol/L) or greater, but not all patients with hyperuricemia demonstrate symptoms.[1] Four organizations publish guidelines that provide recommendations for the diagnosis and/or management of gout.[2–8] There is much similarity in the recommendations, and this chapter focuses primarily on the American College of Rheumatology (ACR) guideline for the management of gout.[5] However, the American College of Physicians (ACP) guideline includes some distinct and controversial differences.[7,8]

EPIDEMIOLOGY AND ETIOLOGY

The National Health and Nutrition Examination Survey (NHANES) 2019 estimates that gout affected about 9.2 million adults (3.9%) in 2015–2016, with gout occurring two to six times more frequently in men than women.[9,10] The incidence increases due to unhealthy dietary habits, lack of exercise, and obesity.[10] There is also a significant economic cost and humanistic burden associated with gout that increases with worsening disease severity.[11]

Dietary risk factors for developing gout include ingestion of purines, fructose, and alcohol. Patients experiencing frequent attacks and those with poorly controlled advanced disease should be educated to avoid sweetbreads (organ meats such as thymus and pancreas), liver, and kidney meat; high-fructose corn syrup; and alcohol use.[5] Other risk factors include male sex and obesity.[12] Trauma and surgery may also trigger acute gout attacks by increasing SUA.[13] Uric acid excretion is reduced in patients with chronic kidney disease (CKD), putting them at risk for hyperuricemia. Gout involves multiple organ systems and is associated with cardiovascular disease (CVD), type 2 diabetes mellitus (T2DM), CKD, and metabolic syndrome. There is an association between high SUA and endothelial dysfunction, which can promote atherosclerosis.[14] Prospective data indicate that gout is an independent risk factor for coronary heart disease,[15] and the cardiovascular impact of urate-lowering therapy continues to be investigated.[16–18]

KEY CONCEPT Some drugs can cause hyperuricemia and precipitate gout, such as thiazide and loop diuretics, niacin, pyrazinamide, calcineurin inhibitors, and aspirin. In most cases, these drugs block uric acid secretion in the kidney. The effect of aspirin on uric acid is dose-dependent. Aspirin in high analgesic doses (600–2400 mg/day) blocks uric acid reabsorption by the kidneys, increasing uric acid excretion. Aspirin doses below 600 mg/day inhibit uric acid excretion and can elevate SUA levels.[4] However, patients with hyperuricemia or gout and cardiovascular risk factors should continue low-dose aspirin (eg, 81–325 mg/day) for myocardial infarction or stroke prevention, if indicated, because the cardiovascular benefit outweighs the minimal effect on serum urate.[5]

PATHOPHYSIOLOGY

Gout is caused by an abnormality in uric acid metabolism. Uric acid is a waste product of purine breakdown contained in the DNA of degraded body cells and dietary protein. It is water-soluble and excreted primarily by the kidneys, although some is broken down by colonic bacteria and excreted via the gastrointestinal (GI) tract. The SUA level is determined by hepatic production of urate minus urate excretion by the kidneys and GI tract.[13]

Uric acid solubility is dependent on concentration and temperature. At SUA concentrations greater than 6.8 mg/dL (404 µmol/L), monosodium urate (MSU) precipitates, forming crystals. Collections of these crystals (called microtophi) can form in joint spaces in distal extremities as well as soft tissues such as tendons and ligaments. Larger tophi may take 10 years or longer to develop.

Free urate crystals can activate neutrophils and macrophages, which release proinflammatory mediators, including tumor necrosis factor α (TNF-α), interleukin 1 (IL-1), and IL-8. This signals chemotactic movement of neutrophils into the joint space that phagocytize MSU crystals. These neutrophils are then lysed, releasing proteolytic enzymes that trigger the clinical manifestations of an acute gout attack, such as pain and swelling. Inflammatory mechanisms in gout, especially in untreated disease, can lead to cartilage and joint destruction.

The reference range for SUA is 3.6 to 6.8 mg/dL (214–404 µmol/L), and the risk of gout increases as the SUA concentration increases. However, only about 20% of patients with asymptomatic hyperuricemia and SUA greater than 9 mg/dL (535 µmol/L) develop gout within 5 years.[5] Increased SUA concentration involves either the underexcretion (90% of patients) or overproduction of uric acid.[1] The cause is unknown, but there may be genetic influences on uric acid regulation.[10] Observational studies also imply that multifactorial variables, such as sex, age, and ethnicity, affect the underexcretion and overproduction of SUA.[19] In patients with persistently acidic urine and hyperuricemia, uric acid nephrolithiasis can occur. In severe cases, uric acid stones can cause nephropathy and renal failure. KEY CONCEPT Long-term consequences of gout and hyperuricemia include joint destruction, tophi, nephrolithiasis, and nephropathy.

CLINICAL PRESENTATION AND DIAGNOSIS

Refer to the accompanying box for the clinical presentation of acute gout.

Diagnosis

A presumptive diagnosis is often based on presenting symptoms, such as development of severe pain within the past 24 hours, erythema, and swelling in a joint.[1] Gout may be confirmed later with laboratory and other diagnostic tests. Not all patients with signs and symptoms of an acute gout attack have hyperuricemia. The SUA level may be normal or even decreased during an acute attack. An acute gout attack usually occurs in the lower extremities, especially the first metatarsophalangeal joint, which is known as podagra.[1] Acute gout is accompanied by markers of inflammation such as an elevated white blood cell (WBC) count, increased erythrocyte sedimentation rate, tenderness, swelling, and loss of function in the affected area.[10]

Chronic tophaceous gout is diagnosed when the crystals accumulate and form tophi, which may lead to destruction and deformity of the joints. Although difficult to perform, aspiration of affected joint fluid or a tophus is essential for a definitive diagnosis.[7] Needle-shaped negatively birefringent MSU crystals in the aspirate confirm the diagnosis, allowing for the differentiation of tophi from other nodules (Figure 60–1).[10] Joint fluid may also have an elevated WBC count with neutrophils predominating.[2]

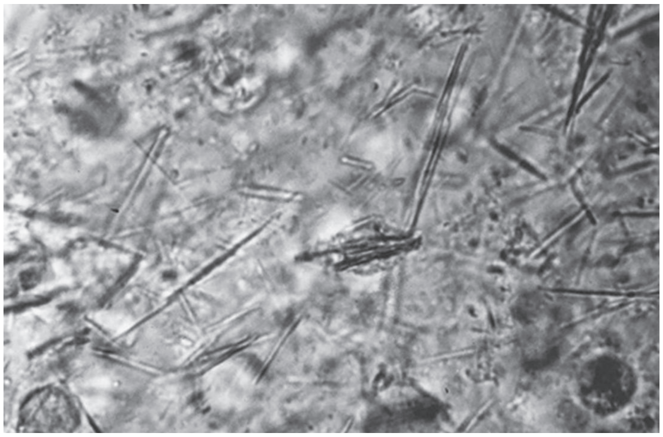

FIGURE 60–1. Synovial fluid containing extracellular and intracellular needle-like, negative birefringent monosodium urate crystals. (Reprinted with permission from: Schumacher HR, Chen LX. Chapter 365. Gout and Other Crystal-Associated Arthropathies. In: Jameson JL, Kasper DL, Longo DL et al., eds, Harrison's Principles of Internal Medicine, 20th ed. New York: McGraw-Hill; c2018 [cited 2020 May 20]. Available from: https://accesspharmacy.com.

Radiographs of affected joints may have characteristic cystic changes, punched-out lytic lesions with overhanging bony edges, and soft-tissue calcified masses. These signs may also appear in other arthropathies and are generally not apparent with the first acute gout attack.[20] Therefore, radiographs are often reserved for patients with long-standing disease.

A 24-hour urine collection can determine whether the patient is an overproducer or an underexcretor of uric acid. Individuals who excrete more than 800 mg (4.8 mmol) of uric acid are overproducers. Patients with hyperuricemia who excrete less than 600 mg/day (3.6 mmol/day) are classified as underexcretors. However, this approach is not often used because the urine collection is inconvenient for patients and clinicians, and it does not identify patients who may be both overproducers and underexcretors.

Clinical Presentation of Acute Gout

General

- Acute inflammatory monoarthritis.
- Patients are usually in acute distress.

Symptoms

- There is severe pain and swelling in the affected joint(s).
- Symptoms reach maximal intensity within 6 to 12 hours.
- The attack is usually monoarticular; the most common site is the metatarsophalangeal joint.
- In older patients, gouty attacks may be atypical with insidious and polyarticular onset, often involving hand or wrist joints.

Signs

- Affected joint(s) are warm, erythematous, and swollen.
- Mild fever may be present.
- Tophi (usually on hands, wrists, elbows, or knees) may be present in chronic, severe disease.

Patient Encounter Part 1

A 53-year-old African American woman presents to the rheumatology clinic with complaints of excruciating pain in her left elbow that has progressed quickly since onset yesterday evening. She is a poor historian but reports no recent injuries. She states that these symptoms have occurred three times within the past year. Furthermore, she reports using herbal supplements since pain medications seem to make her break out. On examination, she can barely move her left elbow due to pain, and it is red, swollen, tender, and warm to the touch. She also has radiographic evidence of multiple small, firm nodules under the skin on her left hand. She currently works as a caregiver, and she is concerned that she will not be able to work with this recurring pain.

What information is suggestive of acute gouty arthritis?

What additional information is necessary to differentiate gout from other joint abnormalities?

What additional information do you need before creating a treatment plan for this patient?

What are aspects to consider when providing care for a patient who has socioeconomic difficulties?

What is a potential when considering concomitant therapy risk for a patient who readily self-treats with herbals?

TREATMENT OF GOUT

KEY CONCEPT Treatment of gout involves: (a) acute relief of a gouty arthritis attack with topical application of ice and drug therapy commonly including NSAIDs, colchicine, glucocorticoids, or a combination thereof, and (b) in some patients, long-term prophylactic treatment with urate-lowering therapy (ULT) to prevent subsequent attacks.

Desired Outcomes

Treatment goals for gout are to: (a) achieve rapid and effective pain relief during an acute flare, (b) maintain joint function, (c) prevent disease complications, (d) avoid treatment-related adverse effects, (e) provide cost-effective therapy, and (f) improve quality of life.[3] Infrequent gouty arthritis is a self-limited disease, and treatment usually focuses on symptomatic relief.

TREATMENT OF ACUTE GOUT FLARE

Nonpharmacologic Therapy

Nondrug modalities play an adjunctive role and usually are not effective when used alone. Immobilization of the affected extremity speeds resolution of the attack. Applying ice packs to the joint is most effective in decreasing pain and swelling.[5]

Pharmacologic Therapy

KEY CONCEPT Nonsteroidal anti-inflammatory drugs (NSAIDs), colchicine, and glucocorticoids are considered first-line monotherapy for acute flares, with the option of combination therapy for severe flares unresponsive to monotherapy.[5,13] Selection depends on the number of joints affected, presence/absence of infection, clinician/patient preference, prior response, and patient factors such as comorbidities and renal function (Figure 60–2). Each drug class has a unique safety and efficacy profile in gout that should be considered carefully before choosing a specific agent (Table 60–1). Generally, the earlier in the course of the arthritic attack these agents are employed (ie, within 24 hours), the better the outcome.[5] Therefore, the ACR guideline encourages an early approach with a "medication-in-pocket" strategy for patients to identify the early signs of an acute gout flare and treat with medication on-hand, since crystal formation is reversible and lowering the SUA quickly can limit solubility.[6,13] Corticotropin (adrenocorticotropic hormone, ACTH) and IL-1 inhibitors are alternatives in select cases.[5] Over a quarter of patients with an acute gout flare are prescribed opioids in emergency departments; however, opioid analgesics have little to no role in acute gout, which results from overwhelming inflammation.[21]

▶ *Nonsteroidal Anti-Inflammatory Drugs*

NSAIDs, which reduce the pain and inflammation associated with an acute attack, have largely supplanted colchicine as the treatment of choice (see Chapter 59, Osteoarthritis, for more detailed information on NSAIDs). These agents are most effective when given within the first 24 hours of the onset of pain. Most studies have shown similar results among agents, and no one NSAID is preferred over another. Doses should be prescribed at the higher end of the therapeutic range, for the shortest duration of time, typically until 24 hours after symptoms subside.[5,13] Lower doses can prolong duration of therapy and lead to further pain and discomfort.[13] Clinicians may consider tapering the dose if a patient has multiple comorbidities, including hepatic or renal failure.

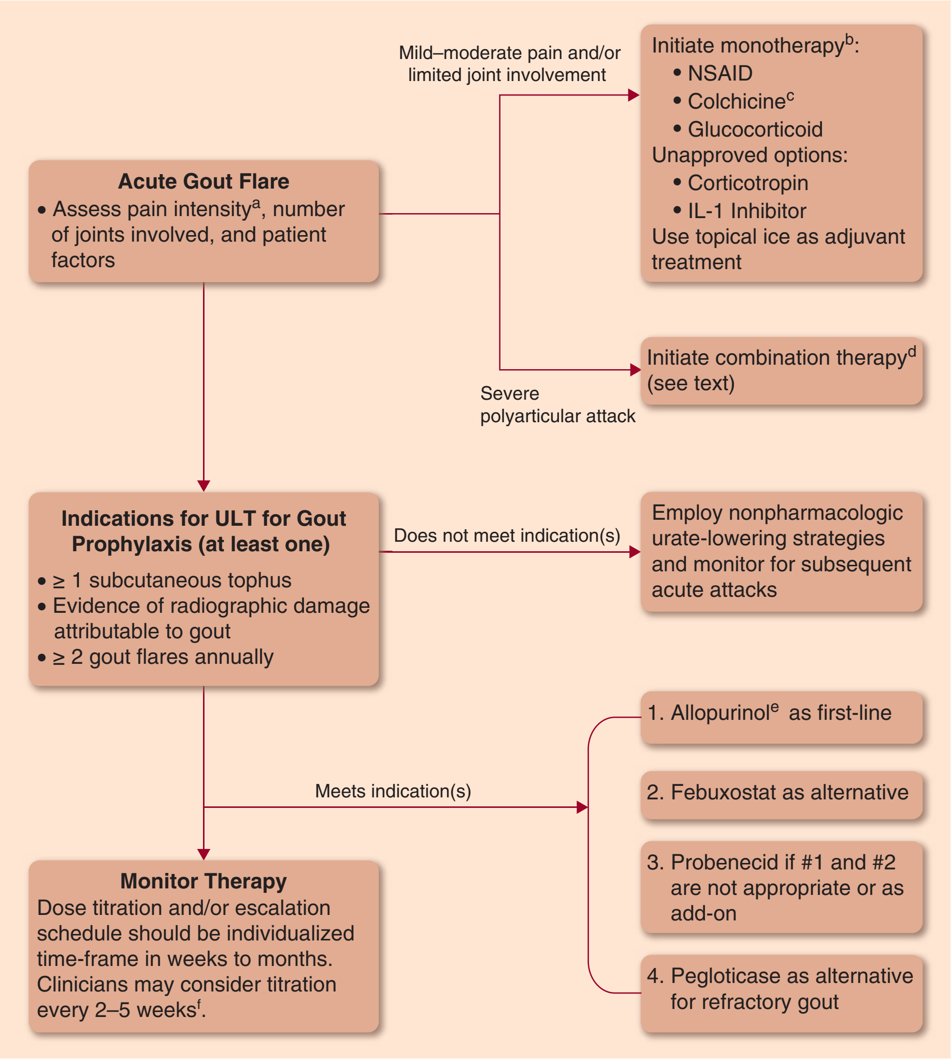
Only naproxen, indomethacin, and sulindac are Food and Drug Administration (FDA) approved for treatment of acute gout. Although indomethacin has been used traditionally, its relative cyclooxygenase-1 (COX-1) selectivity increases its gastropathy risk. Studies comparing indomethacin to other NSAIDs consistently show similar efficacy with greater incidence of side effects with indomethacin; thus, other generic NSAIDs may be preferred. The patient's overall clinical status, including comorbidities and medications, should be evaluated prior to NSAID initiation because adverse effects include gastropathy (primarily peptic ulcers), renal dysfunction, and fluid retention.[5] In general, NSAIDs should be avoided in patients at risk for peptic ulcers; those taking anticoagulants; and those with renal insufficiency, uncontrolled hypertension, or heart failure. Gastroprotective agents such as proton pump inhibitors may protect against ulcer development in patients receiving NSAIDs for acute gout.

Cyclooxygenase-2 (COX-2)–selective inhibitors produce results comparable to traditional NSAIDs, with celecoxib being the only available product in the US market currently.[22] However, the need for large COX-2 inhibitor doses during an acute gouty attack (ie, celecoxib 800 mg daily), cardiovascular safety concerns, and high cost make the risk–benefit ratio unclear for this disorder.

▶ *Colchicine*

Colchicine has a long history of successful use for initial gout flares and was the treatment of choice for many years.[13] It is used less commonly today because of its low therapeutic index and increased cost compared to other acute treatments, despite generic availability. Colchicine is thought to exert its anti-inflammatory effects by interfering with the function of mitotic spindles in neutrophils by binding of tubulin dimers; this inhibits its phagocytic activity.[23] Colchicine is not considered to be an analgesic.

About two-thirds of patients with acute gout respond favorably if colchicine is given within the first 24 hours of symptom onset.[24]



Acute Gout Flare
• Assess pain intensity[a], number of joints involved, and patient factors
Mild–moderate pain and/or limited joint involvement
Initiate monotherapy[b]:
• NSAID
• Colchicine[c]
• Glucocorticoid
Unapproved options:
• Corticotropin
• IL-1 Inhibitor
Use topical ice as adjuvant treatment
Severe polyarticular attack
Initiate combination therapy[d] (see text)
Indications for ULT for Gout Prophylaxis (at least one)
• ≥ 1 subcutaneous tophus
• Evidence of radiographic damage attributable to gout
• ≥ 2 gout flares annually
Does not meet indication(s)
Employ nonpharmacologic urate-lowering strategies and monitor for subsequent acute attacks
Meets indication(s)
1. Allopurinol[e] as first-line
2. Febuxostat as alternative
3. Probenecid if #1 and #2 are not appropriate or as add-on
4. Pegloticase as alternative for refractory gout
Monitor Therapy
Dose titration and/or escalation schedule should be individualized time-frame in weeks to months. Clinicians may consider titration every 2–5 weeks[f].

FIGURE 60–2. Treatment algorithm for hyperuricemia in gout. (NSAID, nonsteroidal anti-inflammatory drug; SUA, serum uric acid.)

[a] Self-reported pain score using a visual analog scale of 6 or less may be considered mild/moderate pain and 7 or more may be considered severe pain.

[b] May consider switch to alternate monotherapy, add-on combination therapy, or off-label therapy for inadequate response (eg, < 20% improvement in pain score within 24 hours or < 50% at 24 hours or longer).

[c] Colchicine may be most beneficial if started within 36 hours of symptom onset.

[d] Intra-articular glucocorticoids may be used in combination when only one or two large joints are affected.

[e] Initiate concomitant anti-inflammatory prophylaxis and continue for indicated duration.

[f] May add on uricosuric therapy if unable to achieve target SUA on maximally dosed xanthine oxidase inhibitor therapy; switch to pegloticase for refractory cases.

Presently, colchicine is only indicated if given within 36 hours of attack onset.[5] GI effects (eg, nausea, vomiting, diarrhea, and abdominal pain) are most common and should warrant a dose reduction or interruption.[10] This is because GI effects are considered a forerunner of more serious systemic toxicity, including myopathy and bone marrow suppression (usually neutropenia). However, systemic colchicine toxicity can occur without prior GI effects, especially with renal insufficiency. In the presence of severe renal impairment (creatinine clearance [CrCl] less than 30 mL/min [0.5 mL/s]), dosing should be repeated no more than once every 2 weeks. Dose reductions are required when coadministered with p-glycoprotein or strong CYP3A4 inhibitors (eg, clarithromycin, verapamil, ritonavir, cyclosporine, ranolazine).[23] Colchicine should be used with caution in patients with liver disease or taking statins. Because of these problems, colchicine may be reserved for patients who are at risk for NSAID-induced gastropathy or who have failed NSAID therapy.

The FDA-approved dosage regimen is 1.2 mg (two 0.6-mg tablets) at the onset of an acute flare, followed by 0.6 mg 1 hour later.[23] Dose adjustment is required for renal insufficiency. Colchicine should not be used for an acute attack if the patient is currently prescribed colchicine for prophylaxis and was previously treated with colchicine for an acute attack within the last 14 days. Intravenous colchicine (no longer commercially available) should never be used in gout management.

Table 60–1

Pharmacotherapy Regimens for Acute Gout Treatment

Drug	Usual Dosage Range
NSAIDs	
Etodolac	200–400 mg po every 6 to 8 hours as needed; max 1200 mg/day
Fenoprofen	200 mg po every 4 to 6 hours as needed
Ibuprofen	400–800 mg po three to four times daily
Indomethacin[a]	50 mg po three times daily initially until pain is tolerable, then quickly taper to discontinue
Ketoprofen	25–50 mg po every 4 to 6 hours as needed; max 300 mg/day
Naproxen[a]	750 mg po initially, then 250 mg po every 8 hours
Sulindac[a]	200 mg po two times daily for 7 days
Celecoxib	800 mg po followed by 400 mg po on day 1, then 400 mg po twice daily for 1 week
Colchicine[b]	1.2 mg po at the onset of attack, then 0.6 mg po 1 hour later; **or** 0.6 mg three times daily on first day of attack
Glucocorticoids	
Local glucocorticoids	
Triamcinolone acetonide	5–15 mg (large joint), 2.5–5 mg (small joint) for one dose by intra-articular injection
Methylprednisolone	40 mg (large joint), 30 mg (medium joint), 10 mg (small joint) for one dose by intra-articular injection
Systemic glucocorticoids	
Prednisone	0.5 mg/kg/day po for 5–10 days
Triamcinolone acetonide	40–80 mg by IM injection for one dose[c]
Methylprednisolone	40–60 mg by IM injection as single dose; may repeat once or twice in 48 hour intervals
Corticotropin[d]	25–40 units SC as initial dose; may repeat if clinically indicated
Interleukin-1 Inhibitors[d]	
Anakinra	100 mg SC once daily for 3 days
Canakinumab	150 mg SC for 1 dose

[a] This drug has FDA approval for the treatment of acute gout.

[b] Dose reduction recommended for renal impairment.

[c] Administration of IM triamcinolone should be followed by oral prednisone or prednisolone.

[d] Not FDA approved for this indication.

Drug regimens derived from various sources.

IM, intramuscular; NSAIDs, nonsteroidal anti-inflammatory drugs; po, by mouth; SC, subcutaneous.

▶ *Glucocorticoid*

It is important to determine the number of joints affected when considering a glucocorticoid for first-line therapy. Glucocorticoids are a useful option in patients with contraindications to NSAIDs or colchicine (primarily renal impairment) or polyarticular attacks, especially in older patients. Furthermore, glucocorticoids and NSAIDs have been shown to be equally effective in acute gout treatment.[25,26] Glucocorticoids can be administered orally, intravenously, intramuscularly, and intra-articularly.[5] Clinicians generally use oral prednisone or prednisolone at a dose of at least 0.5 mg/kg daily for 5 to 10 days, followed by abrupt discontinuation, or full-dose therapy for 2 to 5 days with a 7- to 10-day taper to discontinue. Oral methylprednisolone (ie, the 6-day dose pack consisting of a 21-tablet taper of 4 mg tablets, starting with 6 tablets on day 1 [divided into three separate doses] and ending with one tablet on day 6) and naproxen have been shown to be equivalent in treating acute gout attacks.[27]

When only one or two large joints are affected, an intra-articular glucocorticoid injection can provide rapid relief with a relatively low incidence of side effects, and it may be used in combination with either an NSAID, colchicine, or glucocorticoid. Joint fluid obtained by arthrocentesis should be examined for evidence of joint space infection and crystal identification. If uric acid crystals are present and there is no infection, intra-articular injection can proceed. An alternative regimen consisting of a single intramuscular injection of a long-acting glucocorticoid such as triamcinolone acetonide for patients who cannot tolerate oral intake is acceptable. Due to insufficient evidence, guidelines do not support subsequent use of anti-inflammatory agents when patients do not respond to the initial administration of parenteral glucocorticoids.[5] For severe flares that require hospitalization, an intravenous glucocorticoid can be used, such as methylprednisolone 40 mg administered intravenously twice daily with a stepwise reduction when the patient improves.[13]

Adverse effects from glucocorticoids include fluid retention, hyperglycemia, CNS stimulation, weight gain, GI upset, and increased risk of infection. Patients with diabetes should have blood glucose levels monitored carefully during the glucocorticoid therapy course, and caution should be exercised when treating patients with a history of peptic ulcer disease.

▶ *Corticotropin (Adrenocorticotropic Hormone)*

Exogenous administration of intramuscular adrenocorticotropic hormone (ACTH) stimulates production of cortisol and corticosterone by the adrenal cortex. Clinical studies have shown efficacy similar to other agents for acute gout; however, its use is limited by its cost.[13] Although not a first-line option (or FDA approved for this use), the ACR supports its use for patients unable to take medications orally.[5] The product is available in the United States only through specialty pharmacy distribution.

▶ *Interleukin-1 Inhibitors*

Several small clinical trials have demonstrated efficacy of IL-1 inhibitors in inhibiting inflammation associated with acute gout attacks. While their role is unclear and the available products (anakinra and canakinumab) are not FDA approved for this purpose, the ACR guidelines conditionally recommend IL-1 inhibitors for patients who cannot tolerate or have contraindications to the other anti-inflammatory therapies. Interleukin-1 inhibitors provide rapid relief in severe acute attacks or in patients with refractory gout.[5,13] Canakinumab and anakinra are both administered subcutaneously, with the most commonly reported side effect being injection site reaction.[13]

▶ *Combination Therapy*

In severe polyarticular attacks, particularly attacks involving multiple large joints, colchicine may be used in combination with an NSAID or oral glucocorticoid. Intra-articular glucocorticoid injections may be used in combination with any other first-line agent (NSAID, colchicine, oral glucocorticoid).[5]

URATE-LOWERING THERAPY FOR GOUT PROPHYLAXIS

Gout is an episodic disease, and the number of attacks varies widely among patients. Thus, the benefit of long-term acute attack prophylaxis must be weighed against the cost and potential toxicity of therapy that may not be necessary in all patients. Urate-lowering therapy (ULT) is not recommended when patients experience their first gout flare. **KEY CONCEPT** Additionally, ULT is not recommended for patients with asymptomatic hyperuricemia.[5] It is conditionally recommended for patients who have experienced more than one gout flare but have fewer than two attacks a year.[5] However, the benefits of long-term use (more than 12 months) in patients with single or infrequent gout attacks have not been evaluated. Therefore, the duration of ULT therapy is unclear.[8]

Nonpharmacologic Therapy

Historically, lifestyle modifications alone have been insufficient for lowering SUA levels, and low purine diets are not well tolerated. Patients should be educated on general nutrition principles and advised to engage in regular exercise to lose weight if obese, strictly limit or discontinue ethanol consumption, maintain hydration, and manage other comorbidities (eg, hypertension, diabetes). Evidence suggests that men who follow the Dietary Approaches to Stop Hypertension (DASH) diet have a reduced risk for gout compared to those who eat a Western diet.[28] Furthermore, recent studies in both men and women demonstrated that the DASH diet had a greater SUA reduction in those with SUA ≥ 6 mg/dL (357 μmol/L) within the first 30 days.[29] While the ACR guideline encourages patients to consume low/nonfat dairy products and vegetables, it also cites a lack of specific evidence (similar to the ACP guidelines) that judge the available evidence insufficient to recommend specific dietary changes.[5,8] Complementary therapies are considered to be inappropriate for gout due to insufficient evidence of benefit, such as cherry juice/extract, flaxseed, and celery root.[5,30] Drugs that may cause or aggravate hyperuricemia should be discontinued if clinically appropriate, such as hydrochlorothiazide. Cardioprotective medications such as low-dose aspirin and statins should be continued in patients who require primary or secondary prevention.[5] Clinical experience indicates that few patients adhere to lifestyle modifications long-term, and pharmacologic therapy usually is needed to treat hyperuricemia adequately.

Pharmacologic Therapy

KEY CONCEPT Patients with frequent gout flares (2 or more per year), radiographic evidence attributable to gout, or at least one subcutaneous tophus are candidates for *prophylactic* therapy with allopurinol, febuxostat, probenecid, and/or pegloticase to lower SUA levels (see Figure 60–2).[5] However, ULT may be considered in patients who have experienced more than one flare in their lifetime but have infrequent flares (fewer than 2 per year) and if they also have one of the following: moderate to severe CKD (Stage ≥ 3), SUA levels greater than 9 mg/dL (535 μmol/L), or urolithiasis.[5] Prophylactic therapy commonly involves either decreasing uric acid production or increasing excretion (Table 60–2). For patients with asymptomatic hyperuricemia, initiation of ULT is not recommended.[5] The goal of therapy is to decrease SUA levels significantly, leaving less uric acid available for conversion to MSU crystals.[3] **KEY CONCEPT** ULT may be started during an acute attack if anti-inflammatory treatment has been initiated. Similarly, ULT should be continued during acute flares.

Table 60–2

Pharmacotherapy Regimens for Urate Lowering

Drug	Usual Dosage Range
Xanthine Oxidase Inhibitors	
Allopurinol[a]	100 mg po initially, then titrate to achieve SUA level < 6 mg/dL (357 μmol/L); maximum 800 mg po daily
Febuxostat	40 mg po once daily initially, then increase to 80 mg po once daily if SUA does not decline to 6 mg/dL (357 μmol/L) or lower after 2 weeks of treatment
Uricosurics	
Probenecid	250 mg po two times daily for 1 week, then 500 mg po twice daily; may increase by 500 mg every 4 weeks to achieve SUA level < 6 mg/dL (357 μmol/L); maximum 2 g po daily
Other	
Pegloticase	8 mg given as an IV infusion over at least 2 hours once every 2 weeks, optimal duration unknown

[a]Initial dose reduction recommended for renal impairment.

Drug regimens derived from various sources.

po, by mouth; SUA, serum uric acid.

Because allopurinol (which reduces uric acid production) is effective in both overproducers and underexcretors and is generally well tolerated, many clinicians treat patients empirically with it. Both allopurinol and febuxostat are xanthine oxidase inhibitors (XOIs) and are first-line and second-line ULT agents, respectively.[5] Probenecid, a **uricosuric** agent, is an alternative option. Combination therapy with an XOI and probenecid may be used if single-agent XOI therapy is insufficient. Pegloticase, a recombinant urate oxidase, is reserved for refractory cases.[5]

▸ *Allopurinol*

Allopurinol is considered first-line therapy for most patients in the United States due to its affordability and efficacy. In addition, it is not associated with renal function decline in patients with CKD.[31] The drug and its primary active metabolite, oxypurinol, reduce SUA concentrations by inhibiting the enzyme xanthine oxidase, thereby blocking the two-phase oxidation of hypoxanthine and xanthine to uric acid.

Allopurinol is well absorbed, with a short half-life of 2 to 3 hours. The half-life of oxypurinol approaches 24 hours, allowing allopurinol to be dosed once daily. Oxypurinol is primarily renally cleared and can accumulate in patients with reduced kidney function. Although there is no evidence that allopurinol is renal protective, it continues to be recommended for patients with moderate to severe CKD.[5,32]

Allopurinol may be started during an acute gout attack only if anti-inflammatory treatment is also initiated, because sudden shifts in SUA levels from mobilization of tissue urate stores may precipitate or exacerbate gouty arthritis. Thus, most clinicians provide anti-inflammatory prophylaxis during initiation of ULT with colchicine (0.6 mg once or twice daily or 0.3 mg daily if severe renal impairment) or a low-dose NSAID (eg, naproxen 250 mg twice daily) with acid-suppressing therapy (eg, omeprazole 20 mg once daily). If a patient is being treated with colchicine for an acute attack, the prophylactic colchicine dose may be administered 12 hours after the last treatment dose. This approach, with colchicine having a stronger evidence grade, is supported by the ACR guideline. The guideline recommends that all acute gout patients receive prophylaxis when ULT is started with continuation of therapy for 3 to 6 months after no clinical evidence of gout activity and the target SUA has been achieved.[5] Patients receiving colchicine for prophylaxis should be screened for drug–drug interactions (via the cytochrome p-450 system) that may increase the risk of colchicine adverse effects. Low-dose prednisone or prednisolone (< 10 mg/day) is an alternative for patients unable to take colchicine or NSAIDs. The IL-1 inhibitors have also been investigated off-label as potential alternatives.

The initial dose of allopurinol is based on the patient's renal function. If renal function is normal, an initial dose no greater than 100 mg daily is recommended. The initial dose should be reduced to 50 mg daily in patients with CKD.[5] However, the dose can be adjusted upward every 2 to 5 weeks as needed and tolerated to the SUA target, even in patients with renal insufficiency provided that they are monitored and educated appropriately.[5,33]

SUA levels must be monitored in an individualized time-frame in weeks to months during titration. Clinicians generally check SUA every 2 to 5 weeks during initiation then every 6 months after the target SUA is achieved. ACR recommends targeting an SUA level < 6 mg/dL (357 μmol/L).[5] It is not recommended to have an SUA level < 3 mg/dL (178 μmol/L) long term.[6] The allopurinol dose should be titrated upward (to a maximum of 800 mg/day) or downward as these levels dictate.[5] However, the ACP guideline does not support the ACR's proactive "treat-to-target" approach due to a lack of adequate supporting evidence; rather, the ACP recommends "treating-to-avoid-symptoms."[8] Nevertheless, most clinicians likely follow the ACR recommendations and strategies at this time. The typical allopurinol dose prescribed is 300 mg/day in patients with normal renal function, but this dose often fails to achieve the target SUA level.[5]

Allopurinol is typically well tolerated; nausea and diarrhea occur uncommonly. A generalized, maculopapular rash occurs in about 2% of patients. Although usually mild, this can progress to severe skin reactions such as Stevens-Johnson syndrome. The most serious side effect is allopurinol hypersensitivity syndrome (AHS), which occurs in about 1 in 1000 patients and may involve severe desquamating skin lesions, high fever (usually greater than 39.0°C [102.2°F]), hepatic dysfunction, leukocytosis with predominant eosinophilia, and renal failure.[34] The risk appears to be highest in the first few months of therapy, and although rare, this severe reaction has a 20% to 25% mortality rate.[5,35,36] Prior to initiating allopurinol, pharmacogenomic screening via human leukocyte antigen (HLA)-B*5801 testing is recommended for patients at an elevated risk for AHS (eg, patients of Southeast Asian descent [Han Chinese, Korean, and Thai], and African Americans).[5] Additional risk factors for AHS include renal impairment and concurrent thiazide use.[34] If results are positive, the patient should be provided with an alternative to allopurinol. Patients with a history of AHS should never again receive allopurinol (including desensitization) or oxypurinol (available outside the United States). Patients with a mild skin rash who require allopurinol can be desensitized to it using published protocols or be switched to febuxostat.[37] Febuxostat is more expensive than allopurinol, so testing for HLA-B*5801 can be more cost-effective than substituting febuxostat for allopurinol.[34]

There are several important drug–drug interactions with allopurinol. The effects of both theophylline and warfarin may be potentiated by allopurinol. Azathioprine and 6-mercaptopurine are purines whose metabolism is inhibited by concomitant allopurinol therapy; the dose of these drugs must be reduced by 75% with allopurinol cotherapy. Patients taking allopurinol who receive ampicillin are at increased risk of skin rashes.

▶ *Febuxostat*

Febuxostat is a nonpurine XOI structurally distinct from allopurinol that is FDA approved for chronic hyperuricemia associated with gout. The initial dose is 40 mg orally once daily. The dose may be increased to 80 mg orally once daily if the SUA does not decrease to 6 mg/dL (357 μmol/L) or less after 2 weeks of treatment. No dosage adjustment is necessary in patients with mild or moderate renal impairment (CrCl 30–89 mL/min [0.5–1.48 mL/s]); however, febuxostat is not recommended in severe renal insufficiency (CrCl < 30 mL/min [0.5 mL/s]).[38] Because of its potency and rapid reduction of SUA levels, anti-inflammatory prophylaxis with low-dose colchicine or an NSAID is also recommended during initiation and titration of therapy and for at least 6 months as previously discussed for allopurinol.

Adverse effects of febuxostat include nausea, arthralgias, rash, transient elevation of hepatic transaminases, and cardiovascular events. Periodic liver function tests are recommended (eg, at baseline, 2 and 4 months after starting therapy, and then periodically thereafter). Due to differences in chemical structure, febuxostat would not be expected to cross-react in patients with a history of AHS.

In patients with history of CVD, febuxostat was found to be noninferior to allopurinol in preventing cardiovascular events. However, febuxostat was associated with a higher rate of cardiovascular mortality than allopurinol.[39,40] Therefore, after considering risks vs benefits febuxostat may be an appropriate alternative for patients who do not tolerate allopurinol and those who cannot achieve SUA levels of 6 mg/dL (357 μmol/L) or less despite maximal allopurinol therapy.[1] Allopurinol remains first-line therapy due to greater dosing flexibility and a longer period of clinical experience with its use.

▶ *Probenecid*

Probenecid is a uricosuric agent that blocks the tubular reabsorption of uric acid and increases its excretion.[10] Because of its mechanism of action, probenecid is not recommended for urate overproducers and is contraindicated in patients with a history of urolithiasis or urate nephropathy. Probenecid loses its effectiveness as renal function declines and should be avoided in those with CKD (Stage ≥ 3) and when the CrCl is 50 mL/min (0.83 mL/s) or less.[41] Probenecid is an alternate first-line agent if XOI therapy is either not tolerated or contraindicated. It may also be added to XOI therapy that has been titrated to the maximum dose without attainment of the target SUA level.[5]

Although generally well tolerated, probenecid can cause GI side effects (nausea), as well as fever, rash, and rarely, hepatic toxicity.[41] Patients should maintain adequate hydration and urine output to decrease the risk of uric acid stone formation. Some experts advocate alkalinizing the urine to decrease this risk, but no specific recommendations are provided by the ACR.

▶ *Escalating Urate-Lowering Therapy*

Switching to another XOI or adding a uricosuric agent is recommended if the SUA level remains above 6 mg/dL (357 μmol/L), in patients who continue to have more than 2 gout flares annually, or in those with persistent subcutaneous tophi.[5] Other medications with mild uricosuric effects may be appropriate adjunctive therapy in some patients. Losartan increases both uric acid excretion and urine pH and is conditionally recommended in hypertensive patients with gout. For select dyslipidemic patients with gout, statins remain the preferred agents for lipid-lowering therapy. Switching to another lipid-lowering agent such as fenofibrate is

Patient Encounter Part 2

PMH: Stage 2 CKD, hypertension, dyslipidemia, seasonal allergies, prediabetes mellitus (type 2).

FH: Father has history of myocardial infarctions. Mother has heart disease. No siblings.

SH: Employed as caregiver. Reports drinking 2 cans of beer on weekends. Denies use of tobacco products. Diet consists of packaged and microwaveable food.

Allergies: No known drug allergies.

Meds: Hydrochlorothiazide 25 mg once daily, fenofibrate 67 mg once daily, aspirin 325 mg TID PRN pain, loratadine 10 mg once daily, turmeric supplement 2 capsules once daily.

ROS: Aside from pain in her wrist, she reports occasional shortness of breath. No fatigue, N/V/D, chest pain, or cough.

PE:

VS: 150/87, P 85, RR 17, T 37.3°C (99.1°F), Ht 63 inches (160 cm), Wt 79.3 kg.

Skin: Warm, dry with excessive warmth surrounding left elbow.

HEENT: NC/AT, PERRLA, TMs intact.

CV: RRR, normal S1 and S2, no m/r/g.

Chest: CTA.

Abd: Slightly overweight, but soft, NT/ND. Normal bowel sounds in all quadrants.

Ext: Left elbow is warm to the touch and extremely painful (9/10 on the pain scale). Signs of tophi on left hand. No swelling of other joints.

Neuro: A&O × 3, CN II to XII intact.

Labs: Serum creatinine 1.3 mg/dL (115 µmol/L), SUA 15.6 mg/dL (928 µmol/L), WBC $14 \times 10^3/\mu L$ ($14 \times 10^9/L$), AST 20 IU/L (0.33 µkat/L), ALT 51 U/L (0.85 µkat/L), LDL 137 mg/dL (3.54 mmol/L), HDL 46 mg/dL (1.19 mmol/L), TG 167 mg/dL (1.89 mmol/L).

Other: Joint aspirate from wrist tap: > 50 WBC/HPF, containing negatively birefringent monosodium urate crystals. Wrist and hand radiographs negative for break or trauma, but indicate cystic changes and calcified masses.

What risk factors promote gout and hyperuricemia in this patient?

Given this additional information, what is your assessment of the patient's condition?

Identify your gout treatment goals for this patient.

What nonpharmacologic and pharmacologic alternatives are available for this patient's acute gout flare?

What testing is recommended for the patient prior to initiating urate-lowering therapy for gout prophylaxis?

What is the recommended first-line agent for urate-lowering therapy for gout prophylaxis in this patient?

not recommended despite its urate-lowering effects because risks, such as side effects, outweigh the potential benefits.[5] Either losartan or fenofibrate may be combined with an XOI in patients who fail to achieve the target SUA level on maximized therapy.[5]

▶ *Lesinurad*

Lesinurad is a uric acid transporter 1 (URAT1) inhibitor that increases renal excretion of SUA and is approved for coadministration with a XOI (allopurinol or febuxostat) in patients who fail to meet their SUA target on a XOI alone.[42] Lesinurad was withdrawn from the market in 2019 due to business reasons and not because of any safety, efficacy, or quality issues.[43]

▶ *Pegloticase*

Gout does not occur in most nonprimate mammals because these species produce the enzyme uricase, which catalyzes oxidation of uric acid into the more soluble compound allantoin, which is readily excreted. Humans lack this enzyme, which allows uric acid to accumulate, leading to gout in some individuals.

Patient Encounter Part 3

The patient states that she was recently furloughed and her husband was laid off, so finances have been tight. She has medical insurance but worries about a potentially high copayment for the medications needed for gout.

Based on all of the information provided, create a care plan for this patient's gout. The plan should include: (a) a statement of the drug-related needs and/or problems, (b) a patient-specific detailed therapeutic plan, and (c) monitoring parameters to assess efficacy and safety.

Pegloticase is a recombinant form of uricase (also known as urate oxidase) conjugated to multiple strands of polyethylene glycol (PEG).[13] It is FDA approved for treatment of chronic gout refractory to other therapies. The approved dose of 8 mg by IV infusion over at least 2 hours every 2 weeks rapidly (within 6 hours) decreased SUA in subjects in published trials.[44] However, pegloticase should be limited to patients with severe gout with tophi or nephropathy who cannot tolerate oral ULT or who have not responded to other agents. Before initiation, ULT should be discontinued. Use of pegloticase is limited because of significant adverse effects, including gout flares, infusion reactions, anaphylaxis (in up to 5% of patients), need for pretreatment with antihistamines and glucocorticoids, the inconvenience of IV therapy, and its high cost.[13] Pegloticase is contraindicated in patients with G6PD deficiency due to the risk of hemolysis and methemoglobinemia; therefore, patients should be screened prior to initiation of therapy. Resistance to pegloticase have been reported in patients who develop anti-PEG antibodies, which increases the risk of adverse events.[13]

OUTCOME EVALUATION

Acute Gout Flare

- Monitor the patient for pain relief and decreased swelling of the affected joint(s). Both parameters improve significantly within 48 hours of starting therapy.
- Assess the patient's complaints and objective information for adverse effects:

  - NSAIDs: Be alert for new-onset epigastric pain, dark or tarry stools, blood in vomitus, dizziness or lightheadedness, development of edema, decreased urine output, or shortness of breath.
  - Colchicine: Monitor for nausea or vomiting, diarrhea, easy bruising, cold or flu-like symptoms, lightheadedness, muscle weakness, or pain. Advise the patient to inform you of any new medications started or stopped while taking colchicine.
  - Glucocorticoids: Assess for mental status changes, fluid retention, increased blood glucose, muscle weakness, or development of new infections.
- Intra-articular glucocorticoid injections: Monitor for increased swelling or pain at the injection site.

Urate-Lowering Therapy for Gout Prophylaxis

- Monitor the SUA level in an individualized time-frame in weeks to months (eg, every 2–5 weeks) during ULT initiation and titration. Adjust the dose of ULT to achieve a target SUA level of less than 6 mg/dL (357 μmol/L) or less for those with severe disease. Then continue measurements periodically thereafter and evaluate need for additional therapy.
- Concomitantly initiate anti-inflammatory prophylaxis and continue for 3 to 6 months after achieving target SUA level with no gout signs/symptoms.
- Assess for new gouty arthritis attacks or development of tophi.
- Evaluate patients for adverse medication effects:
  - Allopurinol: Assess for development of rash, nausea, or new fever. These symptoms usually appear within the first 3 months of therapy but can occur anytime.
  - Febuxostat: Monitor for presence of nausea, arthralgias, rash, transient elevation of hepatic transaminases, and cardiovascular events.

Patient Care Process

Collect Information:

- Perform allergy assessment and medication history for prescription, nonprescription, and dietary supplement use.
- Review medical history for contributing lifestyle factors (ie, alcohol use) and comorbidities including CKD that may exacerbate hyperuricemia or help guide therapy.
- Review physical assessment findings and patient symptoms to determine time of attack onset, joint(s) affected, pain level, and observe signs (joint warmth, swelling, redness).
- Identify patient preferences, beliefs, health goals, and socioeconomic factors that affect medication access and other aspects of care.

Assess the Information:

- Identify risk factors and comorbidities associated with gout.
- Determine whether patient is taking products such as diuretic therapy that may contribute to hyperuricemia.
- Determine if a medication is needed to lower SUA to the target level.
- Determine whether patient is experiencing signs/symptoms of an acute gout flare or long-term complications of hyperuricemia.
- If patient is currently receiving pharmacotherapy, assess efficacy (ie, frequency/severity of attacks), safety/adverse reactions, adherence, and potential drug interactions.
- Evaluate SUA level to confirm presence of hyperuricemia and document the level.
- If a gout diagnosis has not been confirmed previously, assess feasibility of aspirating the affected joint to identify uric acid crystals.

Develop a Care Plan: (Figure 60–2)

- Select a regimen for treatment of the acute attack, considering the patient's past response (if any) and comorbidities.
- Ensure patient has met criteria for ULT if already prescribed.
- Select appropriate lifestyle modifications and therapy based on comorbidities and potential safety/efficacy.
- Determine need for continuous ULT (Table 60–2). Use patient factors such as comorbidities to select an agent.
- Choose adjunctive therapy with low-dose colchicine or NSAID during initiation or titration of ULT to prevent rebound flare.
- Initiate ULT during acute attack only in conjunction with effective anti-inflammatory therapy.

Implement the Care Plan:

- Initiate therapy to treat acute gout attack within 24 hours (Table 60–1).
- Educate patient on hyperuricemia/gout, drug therapy, importance of adherence, and lifestyle modifications that may improve symptoms (eg, weight loss, alcohol avoidance).
- Address patient concerns about hyperuricemia/gout and its management.
- Determine if patient has prescription insurance and whether recommended agents (eg, colchicine) are included on formulary.
- Assess the need to continue medications that affect the SUA level.

Follow-up: Monitor and Evaluate:

- Monitor periodically in an individualized time-frame to assess effectiveness (eg, every 2–5 weeks), safety, and titrate ULT or add alternate agent to achieve target SUA; monitor SUA concentration during ULT titration and periodically thereafter.
- Review physical examination, lab tests, and results of other diagnostic tests to assess changes in clinical status.
- Once gout symptoms are controlled, monitor patient and SUA periodically (consider every 6 months); reinforce adherence with regimen to prevent future gout attacks and long-term complications (ie, development of tophi or nephrolithiasis).

- Probenecid: Assess for fever, nausea, or skin rash. Reevaluate therapy if a significant decrease in urine output occurs.
- Pegloticase: Monitor SUA levels before each 2-week IV infusion. Also evaluate patients on pegloticase for development of gouty flares and infusion reactions, which may include anaphylaxis. The manufacturer recommends giving an antihistamine and perhaps low-dose methylprednisolone before the infusion to minimize reactions.

Abbreviations Introduced in This Chapter

ACP	American College of Physicians
ACR	American College of Rheumatology
ACTH	Adrenocorticotropic hormone
AHS	Allopurinol hypersensitivity syndrome
COX	Cyclooxygenase
CKD	Chronic kidney disease
DASH	Dietary Approaches to Stop Hypertension
FDA	Food and Drug Administration
GI	Gastrointestinal
G6PD	Glucose-6-phosphate dehydrogenase
HLA	Human leukocyte antigen
IL-1	Interleukin-1
MSU	Monosodium urate
NSAID	Nonsteroidal anti-inflammatory drug
SUA	Serum uric acid
TLS	Tumor lysis syndrome
URAT1	Uric Acid Transporter 1
ULT	Urate-lowering therapy
WBC	White blood cell
XOI	Xanthine oxidase inhibitor

Musculoskeletal Injuries

Jill S. Borchert and Lisa M. Palmisano

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiologic principles of tissue injury and inflammation.
2. Identify the desired therapeutic outcomes for a patient with musculoskeletal injury or pain.
3. Identify the factors that guide selection of an analgesic or counterirritant for a particular patient.
4. Recommend appropriate nonpharmacologic and pharmacologic therapy for a patient with musculoskeletal injury or low back pain.
5. Design a patient education plan, including nonpharmacologic therapy and preventative strategies.
6. Develop a monitoring plan to assess treatment of a patient with a musculoskeletal injury.

INTRODUCTION

The musculoskeletal system consists of muscles, bones, joints, and associated structures (eg, ligaments, tendons, cartilage, bursas). Injuries related to the musculoskeletal system are classified by etiology. Acute soft-tissue injuries include strains and sprains of muscles and ligaments.[1] Repeated movements in sports, exercise, work, or activities of daily living can lead to repetitive strain injury, where cumulative damage occurs to the muscles, ligaments, or tendons.[2,3] Although tendonitis and bursitis can arise from acute injury, more commonly these conditions occur because of chronic microtrauma and stress.[4,5] This chapter addresses injuries to the skeletal muscle and joint components with a focus on self-care treatment and limited discussion of non–self-care options. Other forms of chronic musculoskeletal pain, such as pain from rheumatoid arthritis (see Chapter 58) or osteoarthritis (see Chapter 59), are discussed elsewhere in this textbook.

EPIDEMIOLOGY AND ETIOLOGY

Musculoskeletal injuries are commonly self-treated, so true estimates of the incidence of both acute and chronic injury are difficult to obtain. In the United States, a 3-year average from 2012 to 2014 demonstrated 145 million physician office visits per year and 423 million prescriptions attributed to musculoskeletal injury.[6] These injuries may arise from activities in the workplace or from sports, and the most common etiology may differ throughout the lifespan.

Workplace musculoskeletal injuries may be caused by trauma, acute overexertion, or repetition and overuse.[6] *Overuse injury* describes musculoskeletal injuries arising from repetitive motion.[2,3] Other common terms include repetitive strain injury or cumulative trauma disorders. The most common sites of workplace injury include the upper extremities (eg, hand, shoulder, and wrist), back, and lower extremities (eg, ankle, knee). Workplace injuries are a leading cause of lost workdays, resulting in a substantial economic burden from lost productivity and lost wages.

Sprains and strains comprise the majority of sports-related injuries.[6] In adults, the ankle is the most common site of injury, whereas in children the forearm, wrist, and hand are the most common injury sites.[7] Tendon injuries are common in the foot and ankle, whereas bursitis tends to occur in the hip, shoulder, elbow and knee.[4,5]

In older adults, musculoskeletal injuries may not be related to work but to daily life. Half of all musculoskeletal injuries occur in the home with falls being the most common cause for those aged 65 and older.[6] In children and adolescents, fractures are more common than muscle and tendon injuries. Half of pediatric sports-related injuries are attributed to overuse rather than acute injury.[8]

PATHOPHYSIOLOGY

Skeletal muscle consists of varying types of fibers and are attached to bones by connective tissues called tendons. Ligaments are connective tissues that connect bone to bone. Tendons and ligaments are composed of collagenous fibers with varying degrees of flexibility, facilitating skeletal movements at joints.

Muscle Strains and Sprains

A sprain is an overstretching of supporting ligaments that results in a partial or complete tear of the ligament.[1] Although a strain also arises from an overstretching of the muscle–tendon unit, it is marked by damage to the muscle fibers or tendon without tearing of the ligament. The key difference is that a sprain involves damage to ligaments, whereas a strain involves damage primarily to muscle.

Overloading the muscle and connective tissue results in complete or partial tears of the soft tissue.[9] Microtears are typically associated with overuse while complete tears (macrotears) may occur after acute trauma and be accompanied by changes in function. This is more likely to occur in mechanical overload such as when the muscle is activated in an *eccentric contraction*, defined as a contraction in which the muscle is being lengthened.[5] Examples of this type of contraction include putting down a large, heavy object or lowering oneself from a chin-up bar. These tears lead to rupture of blood vessels at the site of the injury, resulting in hemorrhage, which causes further tissue damage and extends the injury.[9] Next, leukocytes and other mediators arrive at the site of the injured tissue. During this inflammatory stage, macrophages remove necrotic fibers. Activated neutrophils then release growth factors that activate myocytes for regeneration. Finally, capillaries grow into the area, and muscle fibers regenerate during the repair and remodeling phases of healing.

Bursitis and Tendinopathy

Bursitis is an inflammation of the bursa often caused by overuse of the joint. The bursa, a fluid-filled sac near the joint where the tendons and muscles pass over the bone, serves to reduce friction within the joint space with motion.[4,10] Inflammation at the bursa causes stiffness and pain. Bursitis can be chronic when overuse leads to cumulative microtrauma, or it can arise from acute causes such as injury or infection.

Tendonitis (or *tendinitis*) refers to inflammation precipitated by small tears in the tendon.[5] Tendonitis often results from acute injury; however, repetitive overuse of a tendon can cause cellular changes in the tissues. Many patients diagnosed with chronic tendonitis may not have inflammation but instead have **tendinosis**, a condition marked by degenerative changes in the collagenous tendon tissue. As a result of the cellular changes, the tendon progressively loses elasticity and its ability to handle stress or weight.

Low Back Pain

Low back pain is pain of musculoskeletal origin that extends from the lowest rib to the gluteus and may result in referred somatic pain into the thigh to just above the knee.[11] Conditions such as spinal deformities (eg, **scoliosis** and **spondylolysis**, neurological dysfunctions, extraspinal conditions (eg, genitourinary or vascular), tumors, infections, metabolic disease, fracture, or pregnancy may result in low back pain. The discussion in this chapter will include low back pain from soft tissue injury (ie, without any aforementioned causative condition) where pain is somatic and non-neuropathic.

Inflammation and Peripheral Pain Sensation

Inflammation is a common pathway in soft-tissue injury. Inflammatory processes lead to two outcomes: swelling and pain. They are considered to be a necessary part of the remodeling process because inflammatory cells remove damaged tissue.[9,12] However, inflammation also contributes to continued pain and swelling that limits range of motion.

The initial injury exposes membrane phospholipids to phospholipase A_2, leading to the formation of arachidonic acid.[12] Next, arachidonic acid is transformed by cyclooxygenase (COX) to thromboxanes and prostaglandins (PGs), including prostaglandin E_2 (PGE_2). PGE_2 is the most potent inflammatory mediator; it increases vascular permeability, leading to redness, warmth, and swelling of the affected area. The increased permeability also increases proteolysis, or the breakdown of proteins in the tissue.

Neutrophils, lymphocytes, and monocytes are attracted to the area, and monocytes are converted to macrophages, which then stimulate additional PG production.[12] Phagocytic cells release cytokines, including interleukins, interferon, and tumor necrosis factor, which play a role in inflammation.

In addition to increasing vascular permeability, PGs also induce pain by sensitizing pain receptors to other substances such as bradykinin. Bradykinin, PGs, leukotrienes, and other inflammatory mediators lower the pain threshold through peripheral pain sensitization.[12] These substances make nerve endings more excitable, and the nerve fibers are more reactive to serotonin, heat, and mechanical stimuli. The increased sensitization in the damaged tissue causes tenderness, soreness, **hyperalgesia**, and production of additional PGs. In a cyclic fashion, the PGs then sensitize the nerves to bradykinin action.

Without interruption, the neurochemicals ultimately lead to a firing of the unmyelinated or thinly myelinated afferent neurons. This sends messages along the pain pathway in the periphery and communicates the pain message to the central nervous system (CNS). Interruption of this cycle may occur via the effects of anti-inflammatory agents such as nonsteroidal anti-inflammatory drugs (NSAIDs).

Nerve receptors, or **nociceptors**, release substance P and other peptides when they are activated.[13] Substance P mediates the production and release of inflammatory mediators and acts as a potent vasodilator. This receptor activation also increases the sensitivity of nociceptors to painful stimuli. Capsaicin relieves pain by stimulating the release of substance P from sensory nerve fibers, ultimately depleting stores of substance P.[14]

CLINICAL PRESENTATION AND DIAGNOSIS

See next page for information on the clinical presentation and diagnosis of musculoskeletal injuries.

TREATMENT

Desired Outcomes

KEY CONCEPT The primary goals of treating musculoskeletal injuries are to: (a) relieve pain, (b) maintain functionality, and (c) prevent or minimize overuse injury. This is accomplished by decreasing the severity and duration of pain, shortening the recovery period, preventing the acute injury from becoming an overuse injury, and minimizing the potential for adverse events from nonpharmacologic and pharmacologic therapies. If these goals are achieved, functional limitations are decreased. Further goals include a return to usual activity, prevention of future injury, and allowing for full emotional recovery. Ideally, a patient should be able to continue to perform activities of daily living and maintain normal functions. Children should be able to maintain usual play activities and sports schedules.

General Approach to Treatment

Treatment of musculoskeletal injury involves three phases: (a) nonpharmacologic therapy of an acute injury (eg, using the rest, ice, compression, and elevation [RICE] principle); (b) pain relief using oral or topical agents; and (c) lifestyle and behavioral modifications for rehabilitation and to prevent recurrent injury, overuse injury, or disability (**Figure 61–1**).

The approach to treatment for low back pain with nonpharmacologic and pharmacologic therapies is stratified by duration of pain. In acute low back pain, nonpharmacologic therapy (eg, superficial heat) is preferred, whereas for chronic low back pain pharmacologic therapy may be warranted after failure of nonpharmacologic measures.[11,17]

Acute pain typically improves within 1 to 5 days of therapy. Further evaluation may be warranted if the acute injury symptoms persist longer than 7 to 10 days with treatment.[9,18,19] Some warning signs of more serious conditions that may warrant immediate emergency care include joint deformity, dislocation, immobility, or instability.[1] Some red flags specifically for low back pain include fracture, infection, urinary or bowel incontinence, or foot drop (inability to dorsiflex or lift the front part of the foot).[16]

Clinical Presentation and Diagnosis of Musculoskeletal Injuries[1,3-5,10,15,16]

General

- Clinical presentation varies based on etiology of the disorder.
- Repetitive strain or overuse injuries may have a gradual onset.
- Disorders due to acute injury may be associated with other signs of injury, such as abrasion.

Signs and Symptoms of Acute Soft-Tissue Injury (Strains, Sprains)

- Discomfort ranging from tenderness to pain may occur at rest or with motion.
- Swelling and inflammation of the affected area.
- Bruising.
- Loss of motion.
- Mechanical instability.

Signs and Symptoms of Repetitive Strain or Overuse Injury

- Pain and stiffness that occur either at rest or with motion.
- Localized tenderness on palpation.
- Mild swelling of the affected area.
- Decreased range of motion.
- Muscle atrophy.

Low Back Pain

- Low back pain is often chronic, but some cases may present acutely.
- Pain is often nonspecific and may be accompanied by stiffness upon waking.
- Lifting, twisting, or bending may worsen pain.
- In some cases, pain may radiate to the hip or thigh.

Other Diagnostic Tests and Assessments

- *Radiograph (x-ray)*: Evaluates bony structures to rule out fracture, malalignment, or joint erosion as the primary cause of pain.
- *MRI*: Soft-tissue imaging to evaluate for tendon or ligament tears.
- *Ultrasound*: Superficial soft-tissue imaging evaluates for tears in tendons or ligaments. Ultrasound can be used to detect fluid in the bursa or to rule out other causes of pain. Ultrasound does not penetrate bone, so it is of limited usefulness for assessing tendons or ligaments deep within joints.
- *Electromyogram*: Evaluates electrical activity in muscles and may be used when low back pain is accompanied by leg pain or sciatica to rule out other causes of the pain.
- *Pain scale*: Patient self-rates on a pain scale. For example, a numeric pain scale with zero (no pain) to 10 (worst possible pain) or a visual analog scale. It is used to assess pain both at rest and with movement and determined at baseline and to assess response to therapy.

FIGURE 61–1. Treatment plan for musculoskeletal injury. (See Table 61–2 for treatment of low back pain.)

In children and adolescents, treatment practices are similar to the approach in adults with a focus on nonpharmacologic therapy and oral analgesics. Children younger than 2 years, older adults, and pregnant women also may need special care.[14,18,20]

Nonpharmacologic Therapy: RICE

KEY CONCEPT The cornerstone of nonpharmacologic therapy for acute injury in the first 24 to 72 hours is known by the acronym RICE: rest, ice, compression, and elevation.[9,10,19,21] These four

Patient Encounter 1, Part 1

A 38-year-old man presents with right knee pain. He was playing volleyball with his friends 3 days ago and twisted his knee when he fell. The pain occurs at rest and is worsened with pressure or weight on the knee and with rotation or movement. There is moderate swelling and bruising of the right knee. Abrasions across his knee and leg are noted.

What information is suggestive of a musculoskeletal injury?

What is your assessment of the patient's knee pain?

What additional information do you need to formulate a treatment plan?

Table 61–1

RICE Therapy[9,10,19,21-24]

Therapy	General Guidelines	Therapeutic Benefit
*R*est	Rest the affected area	Analgesia
	Use supports such as slings and crutches as necessary	Anti-inflammatory
	Use during the acute inflammatory phase, 1–5 days after injury	Prevent further injury
*I*ce	Cool the affected area by submersion in cool water (13°C [55°F]) or by application of crushed ice in a plastic bag covered with a thin cloth	Analgesia
	Cool the affected area for 10–20 minutes; for the first 72 hours	Anti-inflammatory
*C*ompression	Compress the affected area with an elastic bandage or support	Anti-inflammatory
	Begin wrapping the bandage at the point most distal to the injury (eg, at the toes for an ankle injury); bind firmly but not tightly	
	If the area distal to the injury (eg, fingers, toes) throbs or turns cold or blue, the bandage is too tight and should be loosened	Adjunctive analgesia
*E*levation	Elevate the area (especially the extremities) above heart level	Anti-inflammatory

methods initially minimize bleeding from broken blood vessels followed by anti-inflammatory and analgesic actions to allow for appropriate healing at the site of injury. See Table 61–1.

Rest eases pressure on the affected area, promotes pain control during the acute inflammatory phase (the first 1–5 days after injury), and prevents additional injury to the affected area.[9,19,24] During acute injury, the ability of muscles and tendons to stretch is limited. Movement in the injured tissue can cause further retraction of the ruptured muscle and increase the size of the gap in the muscle to be healed. For simple injuries, immobilization may be appropriate for 3 to 5 days depending on injury type and severity.[24] Low impact, isometric, and passive stretching or exercise modalities may be started 3 to 4 days after injury while minimizing pain.[9,24] Mobilization too early after injury predisposes a patient to further injury, but prolonged inactivity can lengthen recovery time and delay healing. Longer immobilization may be warranted for more severe injuries (eg, extensive muscle tears or fractures) and may require additional support devices (eg, crutches). In acute injury, braces, splints, and proper taping by a trained professional can immobilize joints and protect them, thereby reducing pain and swelling.[7,10]

The benefits of cryotherapy (modalities that lower tissue temperatures) following acute musculoskeletal injury are well documented.[9,20,22,24] Cold causes vasoconstriction, assisting in prevention of a large hematoma, edema, and providing analgesia by slowing nerve impulses. Immediately after injury, ice also helps to reduce metabolic rate and oxygen demand, thereby reducing tissue damage from hypoxia. Examples of cryotherapy methods include but are not limited to: (1) crushed ice (preferred over large ice pieces to provide more even cooling), (2) cold/ice packs, (3) ice massage, or (4) cold whirlpools. Depending on the method of cryotherapy, application may range from 10 to 20 minutes but should not exceed 20 minutes. For instance, if using crushed ice, patients should wrap the injured surface with a thin moist towel and then apply the crushed ice to the injured site for no longer than 10 minutes and then remove.[22] Applying ice directly to the affected area or for longer than recommended can cause tissue damage; any ice application should be stopped if the area becomes white or blue. When using an ice pack, a cold moist towel should be placed on the injury site, then the ice pack is applied for no more than 20 minutes. For small areas, direct ice massage for 7 to 10 minutes can cool the area and add relief. Alternatively, soaking the area for 7 to 15 minutes in a cool bath (13°C [55°F]) provides effective cooling, but this method must be used cautiously while monitoring for frostbite. Cryotherapy should be repeated for at least the first 72 hours after injury. If swelling is present, cryotherapy can be continued throughout the recovery process, but the duration may be shortened as pain and swelling are reduced.[9,19] There is little evidence for the effectiveness of cryotherapy in relieving low back pain, regardless of presentation.[11,17]

After the acute inflammatory phase when swelling or edema resolves, many patients find that heat decreases pain and eases muscle stiffness.[9,20,22] KEY CONCEPT Heat should not be applied during the acute injury phase (when edema is present) because it promotes swelling and inflammation. A heating pad, heat wrap, or warm bath can be used as long as no edema is present and no swelling develops after heat is applied. Application time should not exceed 20 minutes to minimize tissue injury. Patients should avoid sleeping with, sitting on, or lying on heating pads because this can result in burns. Low-level heat, such as that supplied by therapeutic heat wraps (eg, ThermaCare), may provide a safer means of heat application.

In the presence of low back pain, superficial heat application provides effective pain relief and reduces disability after 4 to 5 days of application.[11,17] For chronic low back pain, there is insufficient evidence to support the effectiveness of superficial heat for reduction of pain or disability (Table 61–2).

Table 61–2

Treatment for Low Back Pain[11,17]

Low Back Pain Type by Duration	Nonpharmacologic Therapy[a]	Pharmacologic Therapy
Acute (< 4 weeks) or Subacute (4–12 weeks)	Superficial heat application, spinal manipulation, massage, acupuncture, exercise	NSAIDs or muscle relaxants
Chronic (> 12 weeks)	Exercise, multidisciplinary rehabilitation, acupuncture, massage, psychological stress reduction, spinal manipulation	NSAIDs, duloxetine[b], opioids[b]

[a] Evidence supporting use ranges from low to moderate.

[b] Refer to Chapter 35 (Pain Management) for further drug review.

Compression and elevation are important steps in the initial treatment of an acute injury. Compression, achieved by wrapping the area with an elastic bandage, massage, or intermittent pneumatic pressure devices, also reduces the size of the developing hematoma and swelling.[9,23,24] Preventing hematoma formation is important because a large hematoma can limit mobility and range of motion. Alternating compression with cryotherapy provides more swelling reduction than use of either method alone.[23] Elevating the injured area is most critical within the first 24 to 48 hours, but elevation should continue as long as swelling is present. Elevation, ideally above the heart level, decreases blood flow and reduces fluid accumulation at the injured site.[9,21,23,24]

Pharmacologic Therapy

KEY CONCEPT There are two main approaches to pharmacologic intervention for pain relief: oral (systemic) and topical agents. In many cases, musculoskeletal injuries are self-treated with over-the-counter (OTC) oral or topical agents, but there are prescription medications available depending on injury type and severity. The choice between systemic or topical options is often guided by patient preference. The extent of musculoskeletal pain also guides treatment choice. **KEY CONCEPT** Localized pain may be treated effectively with local topical therapy, whereas generalized pain is best treated with systemic agents. Factors such as alcohol use, liver function, renal function, allergies, age, and comorbid conditions should be considered when choosing among therapeutic options.

▶ *Oral Analgesics*

Nonopioid analgesics, such as acetaminophen and NSAIDs (including aspirin), are used commonly for musculoskeletal injuries. These agents all provide analgesia, but aspirin and NSAIDs work peripherally by inhibiting the enzyme COX to decrease production of PGE_2, the principal mediator of acute inflammation.[13,19] Although the mechanism of action of acetaminophen is less clear, it appears that acetaminophen acts as a weak inhibitor of PG production via COX-2 inhibition and exerts only a mild anti-inflammatory effect.[14]

Acetaminophen **KEY CONCEPT** Acetaminophen is the drug of choice for mild-to-moderate regional musculoskeletal pain without inflammation.[13,14] However, acetaminophen does not provide adequate analgesia for patients with low back pain.[11,17] Comparative trials between acetaminophen and oral NSAIDs demonstrate equivalent analgesia in some situations, but NSAIDs may be preferred in others. If adequate analgesia is not achieved with acetaminophen, switching to an NSAID is a reasonable alternative. Acetaminophen offers the advantage of less gastrointestinal (GI) toxicity than NSAIDs. Although tolerability of acetaminophen is high at therapeutic doses, hepatotoxicity has been reported after overdose and at therapeutic doses, especially in combination with other factors such as liver disease or excessive alcohol consumption (greater than 15 drinks per week for men and eight drinks or more a week for women).[14,25] Due to concern over liver injury, OTC products are labeled with a maximum recommended dose of 3 g/day.[14] In addition, oral prescription combination products are limited by the US Food and Drug Administration (FDA) to 325 mg acetaminophen per dosage unit.[26] Acetaminophen can be administered using specific dosing regimens in infants, children, adolescents, and older adults.

NSAIDs Oral NSAIDs are used commonly for musculoskeletal pain because of their availability without a prescription and anti-inflammatory effects.[10,13,14] **KEY CONCEPT** NSAIDs are a preferred choice over acetaminophen in musculoskeletal injuries in which inflammation is the primary problem. As a result, NSAIDs are particularly beneficial for chronic overuse injury, in which inflammation is central to the pain and loss of motion.[19] Although NSAIDs may be helpful in relieving pain and inflammation in tendonitis, when inflammation is not present acetaminophen may relieve pain adequately. For patients with low back pain, NSAIDs are first-line pharmacotherapy given evidence demonstrating efficacy.[11,17] There has been some debate that early NSAID use in severe injuries, such as fractures or extensive muscle tears, may impede healing by reducing collagen formation, causing further chronic instability.[19,27] However, use of NSAIDs for less severe injury has shown beneficial effects in the recovery and healing process.[19]

The analgesic effects of NSAIDs are attributed to inhibition of the COX-2 enzyme, whereas the negative GI effects are due to inhibition of COX-1.[14] Patients taking oral anticoagulants, those with a history of peptic ulcer disease, or others at high risk for GI complications may be considered candidates for a selective COX-2 inhibitor (eg, celecoxib) or a combination of a nonselective NSAID with a gastroprotective agent such as a proton pump inhibitor (see Chapter 59). Combination of any NSAID, including COX-2 inhibitors, with alcohol can increase GI adverse effects.[14]

Both nonselective NSAIDs and COX-2 inhibitors are associated with nephrotoxicity.[14,19] NSAIDs should be avoided or used cautiously in the presence of renal dysfunction. See Chapter 59 (Osteoarthritis) for discussion of the relative risks of nonselective NSAIDs and COX-2 inhibitors, treatment options based on an individual patient's cardiovascular and GI risk profile, and maximum dosing recommendations. Refer to the drug package labeling for children and adolescents to ensure correct dosing and safe use. For example, ibuprofen is approved for use in infants 6 months and older, whereas naproxen is approved for individuals age 12 years and older.

Additionally, salicylates, like aspirin, are classified as NSAIDs. These drugs provide analgesic, anti-inflammatory, and antipyretic effects through similar mechanism of NSAIDs. **KEY CONCEPT** Aspirin is not more effective than acetaminophen, and it is not recommended for initial treatment of acute musculoskeletal pain because its adverse effects may be more common and severe.[14] Gastric irritation is more common with aspirin, and bleeding risk is increased because aspirin irreversibly inhibits platelet aggregation. Patients with aspirin-induced asthma should avoid aspirin and other salicylates. Due to the risk of Reye syndrome, aspirin should be avoided in persons younger than age 19.

Some salicylates are specifically marketed for musculoskeletal back pain, such as magnesium salicylate. However, use of salicylates is not supported given the limited evidence showing benefit in treating acute pain.[28] Magnesium salicylate should be used with caution in patients with renal impairment due to risk of hypermagnesemia and should be avoided in patients 19 years old and younger due to risk of Reye syndrome.[29]

▶ *Topical (External) Analgesics*

Topically (or externally) applied drugs exert a local analgesic, anesthetic, or antipruritic effect by either suppressing cutaneous sensory receptors or by stimulating these receptors in a counterirritant fashion, which may lessen acute localized muscle injury symptoms.[14] These medications are applied directly to the affected area to create high local concentrations of the drug and exert action locally in the nerves or tissues. Negligible systemic concentrations are achieved with intact skin, minimizing systemic adverse effects.[14] Occluding or wrapping the area after topical application increases the potential for systemic adverse effects.

Formulations include gel, cream, lotion, patch, liquid, liniment, or aerosol spray. Topical delivery should not be confused with transdermal delivery, in which drug absorption into the bloodstream produces a systemic effect. Musculoskeletal injuries often are treated with topical (not transdermal) medications.

After application, the topical medication penetrates the skin to the soft tissue and peripheral nerves.[14] Topical analgesics suppress the sensitization of pain receptors at the site, thereby reducing pain and burning. Examples include topical NSAIDs and local anesthetics. In contrast, *counterirritant* products are external analgesics that stimulate cutaneous sensory receptors, producing a burning, warming, or cooling sensation that masks the underlying pain. In effect, the irritation or inflammation caused by the counterirritant distracts from the underlying pain.

External analgesics are useful adjuvants to nonpharmacologic therapy and systemic analgesic therapy to provide additional relief. These agents are also an option in patients who cannot tolerate systemic analgesics. However, because these products are not in pill form and many are available without a prescription, they may be overused or misused. Clinicians should advise patients to read and follow directions on the labels of OTC products.

Topical NSAIDs In acute soft-tissue injury such as strains and sprains, efficacy of topical NSAIDs is superior to that of placebo and similar to that of oral NSAIDs.[30] Tissue concentrations of topical NSAIDs are high enough to produce anti-inflammatory effects, but systemic concentrations after application remain low.

Diclofenac is the only topical NSAID commercially available in the United States.[14] Topical diclofenac solution (Pennsaid) and gel (Voltaren) are only indicated for treatment of osteoarthritis, with gel (Voltaren Arthritis) now available OTC (see Chapter 59).[31-33] The diclofenac patch (Flector Patch) is indicated specifically for topical treatment of acute pain from minor sprains and strains in adults.[34] One patch is applied to the most painful area twice daily to intact skin only.[14,34] Patients should be instructed to wash hands before and after application, discard the patch after use, avoid wearing the patch while bathing or showering, and to tape the patch in place if it begins to peel off.

Theoretically, the risk of serious GI adverse events should be less than with oral NSAIDs, but long-term studies evaluating these events are lacking. Like oral NSAIDs, topical NSAIDs should be used with caution in patients with a history of GI bleeding or ulcer.[14] Use of topical NSAIDs with oral NSAIDs is not recommended given the potential for increased systemic adverse effects. See Chapter 59 (Osteoarthritis) for further review of NSAID-related adverse effects. A Cochrane review demonstrated that topical NSAIDs were beneficial to manage acute musculoskeletal pain, but further comparative studies to other topicals (eg, counterirritants) are needed.[30] Local cutaneous adverse reactions (eg, erythema, rash, pruritus, and irritation) are reported and may be due in part to the vehicle used.[14,31,32,34]

Local Anesthetics Nonprescription topical anesthetics such as lidocaine and benzocaine are available in many types of products. Local anesthetics decrease discharges in superficial somatic nerves and cause numbness on the skin surface but do not penetrate deeper structures such as muscle where the pain often lies.[35] Although these topical anesthetics are not effective in direct treatment of musculoskeletal pain, they are helpful when abrasion accompanies the injury. Frequently, anesthetics are formulated in combination with an antibiotic for OTC use; the anesthetic provides soothing relief to the abrasion site while the antibiotic promotes healing of abrasions and prevents soft-tissue infection.

Prescription topical anesthetic agents are not approved for the treatment of acute musculoskeletal pain.[14] Agents include topical lidocaine patch (Lidoderm) and heated lidocaine/tetracaine patch (Synera). The patches deliver lidocaine to local tissues to reduce neuronal impulse, induce an anesthetic effect, and reduce inflammation. The heated lidocaine/tetracaine patch provides a similar mechanism of action but is formulated with an added oxygen-activated heating component to enhance local anesthetic delivery. These agents may be considered for off-label treatment of musculoskeletal and low back pain when other first-line or approved therapies have not provided adequate pain relief.

Counterirritants These products are indicated for temporary relief of minor aches and pains related to muscles and joints.[18] These symptoms may be associated with arthritis, strains, or sprains. Many are available as combination products with ingredients from different counterirritant groups. Active ingredients in marketed products sometimes change; clinicians should be aware of the current ingredients before recommending a product. These products are applied multiple times a day (ranging from 3 to 4 applications daily) for up to 7 days; if pain relief is not achieved by that time, the patient should follow up with the provider to further evaluate the acute musculoskeletal pain.

Nonprescription counterirritants are categorized by the FDA into four groups (groups A through D) based on their primary actions (Table 61–3).[18] They produce a feeling of redness, cooling, warmth, or irritation that diverts sensation from the pain. Because these irritant effects are central to the beneficial actions, counterirritants should not be combined with topical analgesics or topical anesthetics. **KEY CONCEPT** Patient education on proper use of counterirritants is essential to therapeutic success (Table 61–4).[18]

Rubefacients (group A) are counterirritants that produce redness on application. Evidence from clinical trials and a systematic review showed rubefacients to be ineffective for relieving acute pain from strains, sprains, and sports injuries, and for chronic musculoskeletal pain.[28] However, topical rubefacients containing salicylates (eg, methyl salicylate) may be used if a patient does not tolerate or has contraindications to other therapy or prefers an alternative route of administration for acute pain. Topical formulation of salicylates can lead to systemic effects similar to aspirin or NSAID therapy.[14,36] When recommending topical salicylate products, the same factors for use of NSAIDs and aspirin should be considered.[36] Additionally, methyl salicylate, including oil of wintergreen, is a common source of pediatric poisonings.[36,37]

The group B counterirritants menthol and camphor exert a sensation of cooling through direct action on sensory nerve endings, followed by a sensation of warmth.[36,38] The agents cause a burning sensation by stimulating cutaneous nociceptors.[36] For topical analgesic use, menthol is available in creams, lotions, ointment, and patches. The patches can be trimmed to fit the affected area. Despite limits on the concentration of available products, camphor can be toxic to children even in small amounts, posing a seizure risk.[39]

The group C counterirritants methyl nicotinate and histamine dihydrochloride produce vasodilation.[18] Methyl nicotinate produces PG-mediated vasodilation.[40] NSAIDs and aspirin block the production of PGs and decrease methyl nicotinate–induced vasodilation. Application over a large area has been reported to cause systemic symptoms and syncope, possibly due to vasodilation and a decrease in blood pressure.[41] Patients should be educated to apply only scant amounts to the affected area.

The primary counterirritant in group D is capsaicin, a natural substance found in red chili peppers.[14,36] Capsaicin stimulates the release of substance P from local sensory nerve fibers, depleting substance P stores over time, and ultimately reduces transmission

Table 61–3

Nonprescription Counterirritant External Analgesics[18]

Group and Effect	Agents and Concentration	Example Products (If Applicable)	Comments
Group A Rubefacients: Produce redness	Allyl isothiocyanate 0.5%–5%		Mustard derivative; pungent odor; avoid inhalation
	Ammonia water 1%–2.5%		More concentrated solutions are highly caustic; avoid inhalation
	Methyl salicylate 10%–60%	BenGay Ultra Strength,[a] Flexall Plus,[a] Icy Hot Stick[a]	Caution in aspirin sensitivity May produce systemic concentrations May increase INR with warfarin Use in adults and children > 12 years old
Group B Produce cooling	Camphor 3%–11% Menthol 1.25%–16%	JointFlex BenGay Patch, Icy Hot Patch, Mineral Ice[c]	Medicinal odor Sensation of heat follows cooling Mild anesthetic effects at low concentrations Use in adults and children > 12 years old[d]
Group C Produce vasodilation	Methyl nicotinate 0.25%–1%	Arth Arrest[b]	May produce systemic vasodilation Use in adults and children > 2 years old
Group D Irritate without redness	Capsaicin 0.025%–0.25% Capsicum oleoresin 0.025%–0.25%	Capzasin-HP, Zostrix	Must use regularly Burning effect subsides with regular use Use in adults only (ages > 18 years old)

[a] Combination products that also contain menthol and/or camphor.

[b] Combination product that also contains capsaicin.

[c] May be used in adults and children age 2 years old and older.

[d] Based on product labeling; Federal Register recommends to avoid in children less than 2 years old.

INR, international normalized ratio.

of pain impulses to the CNS. As with other counterirritants, capsaicin and its derivatives (capsicum and capsicum oleoresin) exert a warming or burning sensation.[14,36] With repeated application, desensitization occurs, and the burning sensation subsides within the first 1 to 2 weeks. Pain relief is usually noted within 2 to 6 weeks.[14,36] After discontinuation, resensitization occurs gradually over 6 weeks.[36]

Because of the lag time between initiation and effect, capsaicin is not used for treatment of acute pain from injury. Topical capsaicin is used for chronic pain from musculoskeletal (ie, overuse injury) and neuropathic disorders. Capsaicin preparations have been studied for treatment of pain from diabetic neuropathy, osteoarthritis, postherpetic neuralgia, and other disorders.[14,36] It is often used as an adjuvant to systemic analgesics in these chronic pain conditions.

Table 61–4

Patient Education for Counterirritants[18]

Apply up to three to four times daily to affected area.
Only for external use on the skin; do not ingest.
Do not apply to broken or damaged skin or cover large areas.
Wash hands immediately after application.
Avoid contact with the eyes and mouth.
Do not use with heating pads or other methods of heat application, because burning or blistering can occur.
Do not wrap or bandage the area tightly after application.
Discontinue product if excessive skin irritation or rash occurs.
Consult a physician if:

- Symptoms worsen.
- Symptoms persist for more than 7 days[a] for acute pain.
- Symptoms resolve but then recur.

[a] Capsaicin is used for chronic pain, and efficacy is evaluated after 2 weeks.

Although systemic adverse effects to capsaicin are rare, local adverse effects are expected and common.[14,36] Patient education regarding consistent use of capsaicin products is essential to achieving desired outcomes. The product should be applied in a thin layer and rubbed into the skin thoroughly until little remains on the surface. KEY CONCEPT Patients using capsaicin should be advised to apply it regularly and consistently three to four times daily and that full effect may take 2 weeks or longer. Patients should be assured that the burning effects will diminish with repeated application. Adherence to therapy is essential because the burning sensation persists if applications are less frequent than recommended. Patients should avoid hot showers or baths immediately before or after application because the burning sensation is enhanced with heat. Wearing nitrile gloves during application and washing hands immediately after application can decrease the potential for unintended contact with eyes or mucous membranes. Dried product residue has been reported to cause respiratory effects on inhalation (eg, coughing), and caution should be used in patients with asthma or other respiratory illnesses.[14]

▶ *Oral Muscle Relaxants*

Oral muscle relaxants are a useful adjunct to therapy when pain is worsened by muscle spasm.[14] Antispasmodic agents are preferred over antispastic agents for musculoskeletal pain because antispasmodics exert their effect directly on skeletal muscle fibers, polysynaptic reflexes, and/or descending facilitatory systems; whereas antispastic agents mostly target upper motor neuron conditions. Examples of antispasmodic agents include carisoprodol, cyclobenzaprine, metaxalone, and methocarbamol. Muscle relaxants decrease spasm and stiffness associated with either acute or chronic musculoskeletal injuries. For low back pain, a systematic review demonstrated that muscle relaxants provide significant acute or subacute pain relief but are not effective in treating chronic low back pain.[17,42] These agents should be used with caution because they all may cause sedation, especially in combination with alcohol or opioid analgesics. Many produce anticholinergic effects, such as xerostomia and blurred vision, and have potential for abuse. Sudden discontinuation should be avoided because it may lead to withdrawal symptoms. Muscle relaxants should be used with caution in older adults (age 65 years and older), with use reserved for those with no other reasonable alternatives. Clinicians should monitor such adults more closely given the potential adverse effects. Patient-specific factors should be reviewed before recommending muscle relaxants.

▶ *Opioid Analgesics*

Opioid analgesics may be considered in acute pain management if nonopioid analgesics are already optimized and the patient is still experiencing moderate to severe pain.[13,19] Opioids may be used in combination with nonopioids such as acetaminophen or NSAIDs, but the dose should not exceed the recommended daily dose of the respective nonopioid agent(s). Opioids are not recommended as initial therapy for acute or subacute low back pain, given the low level of evidence of effectiveness in reducing pain. Patients presenting with chronic low back pain who are having inadequate response to NSAIDs or duloxetine may benefit from opioid medications.[17] Given the concern for abuse potential and adverse events with opioids, a full patient medical history is recommended before prescribing. See Chapter 35 (Pain Management) for more information on use of duloxetine and opioids.

Patient Encounter 1, Part 2: Medical History, Physical Examination, and Diagnostic Tests

PMH/PSH: Heartburn (food induced).

SH: Smokes 2 to 3 cigarettes per week socially; drinks 6 to 7 beers 4 times a week with friends.

Meds: Famotidine 10 mg one to two tablets once to twice daily as needed; acetaminophen 500 mg two tablets every 6 to 8 hours for knee pain since injury.

Allergies: Sulfa drugs (rash).

Intolerances: None.

Preferences: No preference to topical or oral medications at this time.

Diagnostic Tests: Radiographs of right knee show no evidence of fracture or underlying medical conditions.

Pain (numerical rating scale): 5 out of 10.

What are your treatment goals and desired outcomes?

What nonpharmacologic and pharmacologic treatment options are available? Are there treatment options that should be avoided? If so, which options and why?

▶ *Complementary and Alternative Medicine for Pain Relief*

Various complementary and alternative modalities are available for patients seeking additional or alternative treatments for pain relief or recovery from musculoskeletal injury. Integrative practices include manipulation therapy, acupuncture, massage therapy, yoga, electrical stimulating currents, low-power laser, hyperbaric oxygen therapy, platelet-rich plasma injections, and ultrasound therapy.[9,10,14,21,24]

Massage therapy, spinal manipulation, and acupuncture have shown potential benefit in relieving acute or subacute low back pain.[11,17] Acupuncture and cognitive behavioral therapy have demonstrated moderate benefit in reducing chronic low back pain.

Dietary supplements that have been shown to potentially reduce pain and/or inflammation include devil's claw, willow bark extract, aspen or goldenrod, cannabinoids, and turmeric.[14] Given the mechanisms of action and metabolism of these supplements, it is highly recommended to review potential adverse events, drug interactions, and a patient's current medical history before recommending any of these supplements.[43] Overall evidence of benefit may be limited or conflicting, and patients should be educated on the benefits and risks of these therapies before initiation as additional treatment.

Lifestyle and Behavioral Modifications

After treatment of an acute injury, repetitive strain injury, or low back pain with nonpharmacologic and pharmacologic therapy, the final phase of therapy is rehabilitation and prevention of future injury. For most injuries, prolonged immobilization can lengthen the recovery time by causing wasting of the healthy muscle fibers and increased scarring.[9,19,22,24] Rehabilitation starts with decreasing inflammation, then increasing range of motion and flexibility via stretching exercises. The patient should warm the muscle first with light activity or moderate heat. Warmth produces relaxation and increases elasticity. Next, the patient may start general strengthening exercises. The focus of the rehabilitation may not be the injured muscle itself but nearby muscles to assist with stability. End goals of rehabilitation are specific to each patient and may range from return to activities of daily living to a rigorous sports schedule. Similar to the acute injury phase, braces, splints, and proper taping by a trained professional can protect the joint and promote alignment.[7,10]

Patient Encounter 1, Part 3: Creating a Care Plan

Based on the information presented, create a care plan to treat this patient's knee injury. Your plan should include the following:

(a) The goals of therapy and desired outcomes

(b) A patient-specific therapeutic plan, including nonpharmacologic therapy

(c) A plan to monitor the outcome of therapy to determine whether goals of therapy have been met and adverse effects avoided

Patient Encounter 2

A 32-year-old woman presents with left wrist pain. Upon questioning, you find she is a triathlon athlete for the past 5 years. She reports gradual onset of wrist pain over the last few months while cycling. When she wakes in the morning, she has minimal pain after resting overnight, but the pain begins to intensify during the middle of her morning cycling and lasts throughout the day. She denies any swelling. She reports decreased range of motion compared to her right wrist. She is 29 weeks pregnant and only takes a daily prenatal multivitamin.

Given this information, what is your assessment of the patient's wrist pain? What is the likely etiology of the pain?

What nonpharmacologic and pharmacologic treatment options should be considered?

Based on the information presented, create a care plan for this patient's wrist injury. Your plan should include the following:

(a) The goals of therapy and desired outcomes

(b) A patient-specific therapeutic plan, including nonpharmacologic therapy

(c) A monitoring plan to determine whether goals of therapy have been met and adverse effects avoided

After rehabilitation, the patient should be educated about behavior changes to prevent reinjury.[19] The strength and flexibility exercises learned in the rehabilitation phase should be continued. For overuse injury, correction of biomechanical abnormalities with proper footwear and changes in technique may correct misalignments and imbalances.[2]

In the workplace, repetitive motion can be decreased through proper ergonomic design, improved posture, and redesigning job tasks.[3] In pain of the back or lower extremity, weight loss in overweight or obese patients can help to prevent reinjury or repetitive strain injuries.[16]

OUTCOME EVALUATION

- Use a pain scale to monitor treatment interventions to ensure that pain relief is achieved. Ask the patient to rate pain on a scale of 0 (no pain) to 10 (worst possible pain) both at rest and with movement. Compare the results with baseline pain assessment to monitor the response to therapy. In pediatric patients, use a visual pain scale with facial expressions depicting various degrees of pain.
- Assess range of motion at baseline and after treatment by comparing movement with the unaffected limb and functionality before the injury. Assess functionality by asking patients if they are able to perform activities of daily living or participate in exercise as desired.
- If pain from acute injury does not decrease greatly within 7 to 10 days, further diagnostic evaluation is warranted.

Patient Care Process

Collect Information:

- Establish the timing of injury (if applicable), duration, type and degree of pain, and exacerbating factors. Ask about interference with usual activities or range of motion.
- Ask the patient about exacerbating or alleviating factors. Inquire if the patient has tried any successful or unsuccessful nonpharmacologic or pharmacologic treatments for the current complaint or for this condition in the past.
- Obtain a complete medication history, including prescription and nonprescription drugs and dietary supplement use. Gather patient history, including social history and alcohol use. Inquire about drug allergies and chronic health problems such as asthma. Collect physical assessment and laboratory data when available.
- Inquire about patient preference for systemic (oral) or local (topical) therapy including acceptability of topical medication with frequent application and/or a medicinal odor. Identify the patient's goals, beliefs, lifestyle habits, and socioeconomic factors relevant to development of care plan.

Assess the Information:

- Assess the efficacy, safety, and patient adherence of any nonprescription or prescription medications currently being used for the condition and consider alignment with patient preferences for therapy.
- Based on review of symptoms and timing, assess whether empirical care or diagnostic evaluation is appropriate and whether pharmacologic therapy is warranted.

Develop a Care Plan:

- Develop goals of therapy in collaboration with the patient.
- Determine if referral to another healthcare provider on the team is warranted based on the symptoms provided.
- Recommend nonpharmacologic and pharmacologic therapy appropriate for the specific patient (Tables 61–1, 61–2, and 61–3; Figure 61–1).

Implement the Care Plan:

- Educate the patient on nonpharmacologic therapy for the presenting pain type when appropriate (Tables 61–1 and 61–2).
- Educate on proper use of oral or topical agents selected (Tables 61–3 and 61–4). If a counterirritant is recommended, counsel patients on the irritant effect of the product and recommend washing hands immediately after use and to avoid heating pads. For patients using a capsaicin product, emphasize adherence.
- Coordinate any referrals, when applicable.

Follow-up: Monitor and Evaluate:

- If pain is from an acute injury, assess effectiveness within 7 to 10 days. For chronic pain treated with capsaicin, begin to assess pain control in 2 weeks.
- Evaluate for adherence, adverse effects (systemic or local), and drug interactions.

Patient Encounter 3

An 82-year-old man presents with acute lower back pain complaining of a "pulled muscle." He states that he was at his daughter's house yesterday and tripped on one of his grandson's toys, twisting his back. He reports decreased range of motion, tightness, and tenderness, but denies any nerve pain.

PMH/PSH: Atrial fibrillation, coronary artery disease, hypertension, dyslipidemia.

SH: Nonsmoker, 1 glass of wine on holidays.

Meds: Apixaban 2.5 mg twice daily, lisinopril 10 mg one tablet orally daily, metoprolol XL 50 mg daily, atorvastatin 40 mg one tablet orally daily, aspirin 81 mg one tablet orally daily, multivitamin one tablet orally daily.

Allergies: NKDA

Intolerances: None.

Preferences: No preference to oral or topical medications.

Vital signs: BP 140/92 today, HR 77.

Diagnostic Tests: None.

Pain (numerical rating scale): 3 out of 10. Pain worsens to 4 out of 10 with bending or lifting.

Given this information, what is your assessment of the patient's acute lower back pain? What is the likely etiology of the pain?

What nonpharmacologic and pharmacologic treatment options should be considered?

Based on the information presented, create a care plan for this patient's lower back injury. Your plan should include:

(a) Goals of therapy and desired outcomes

(b) Patient-specific therapeutic plan, including nonpharmacologic therapy

(c) A plan to monitor the outcome of therapy to determine whether goals of therapy have been met and adverse effects avoided

- In patients with chronic low back pain, periodically assess the patient for new signs and symptoms that may warrant further workup.
- Assess adherence to recommended treatments for therapeutic benefit. For all products except capsaicin, assess for acute pain relief within 7 days. For topical capsaicin, assess chronic pain control in 2 weeks.
- Assess medication adverse effects on a regular basis. When NSAIDs and aspirin are used, ask about GI tolerability, bruising, and bleeding. Inquire about local adverse effects, such as burning, when topical counterirritants are used for treatment. When oral muscle relaxants are used, inquire about anticholinergic effects such as xerostomia and blurred vision. Refer to Chapter 35 (Pain Management) for opioid side effects.
- Evaluate adherence to preventative rehabilitation measures such as proper footwear, warm-up before activity, strength training, and proper lifting technique.

Abbreviations Introduced in This Chapter

CNS	Central nervous system
COX	Cyclooxygenase
FDA	Food and Drug Administration
GI	Gastrointestinal
NSAIDs	Nonsteroidal anti-inflammatory drugs
OTC	Over-the-counter
PG	Prostaglandin
RICE	Rest, ice, compression, and elevation

Glaucoma

Daniel O. Clegg, Jr.

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Identify risk factors for the development of primary open-angle glaucoma (POAG) and acute angle-closure glaucoma.
2. Recommend a frequency for glaucoma screening based on patient-specific risk factors.
3. Compare and contrast the pathophysiologic mechanisms responsible for open-angle glaucoma and acute angle-closure glaucoma.
4. Outline the clinical presentation of chronic open-angle glaucoma and acute angle-closure glaucoma.
5. List the goals of managing patients with POAG suspect, POAG, and acute angle-closure glaucoma.
6. Choose the most appropriate therapy based on patient-specific data for open-angle glaucoma, glaucoma suspect, and acute angle-closure glaucoma.
7. Develop a monitoring plan for patients on specific pharmacologic regimens.
8. Counsel patients about glaucoma, drug therapy options, ophthalmic administration techniques, and the importance of adherence to the prescribed regimen.

INTRODUCTION

Glaucoma refers to a spectrum of ophthalmic disorders characterized by neuropathy of the optic nerve and loss of retinal ganglion cells, which typically leads to permanent deterioration of the visual field (peripheral vision) initially and potentially total vision loss (including central vision). It is often, but not always, eye pressure related.[1-3] Table 62–1 describes the general classification of glaucoma. *Glaucoma suspects* are patients with a higher than average risk of developing glaucoma because of the presence of certain clinical findings, including elevated intraocular pressure (IOP) or optic nerve features consistent for glaucoma, risk factors, family history, or racial background. Glaucoma suspects are further classified as open-angle glaucoma suspects or angle-closure glaucoma suspects.

Primary open-angle glaucoma (POAG) and primary angle-closure glaucoma (PACG) represent the most common types of glaucoma and therefore are the focus of this chapter. PACG can present clinically as acute angle-closure crisis (AACC). AACC is the sudden obstruction of the trabecular meshwork, which leads to a rapid increase in IOP resulting in pressure-induced optic neuropathy if untreated.[1-4] **KEY CONCEPT** In contrast, patients with POAG typically have a slow, insidious loss of vision, which is often asymptomatic until the latter stage of the disease process. This is contrasted by the course of AACC, which can lead to rapid and painful vision loss that develops over hours to days.

EPIDEMIOLOGY AND ETIOLOGY

It is estimated that nearly 76 million people had glaucoma in 2020, making it the second leading cause of blindness after cataracts. By 2040 this number may increase to greater than 110 million people worldwide.[5] In North America it is estimated that almost 4 million people are affected by POAG, and by 2040 this number will increase to nearly 5 million.[5] The prevalence varies with race and ethnicity, and it is three to five times more prevalent in African Americans than White Americans.[6] The prevalence of POAG increases with age and is rarely seen in patients younger than 40 years.[6,7] The prevalence of POAG suspects is difficult to estimate at this time, but it is expected that 3.5% to 4.5% of White and Hispanic patients older than 40 years have ocular hypertension.[2]

Approximately 20 million people were estimated to have angle-closure glaucoma in 2013, and this is projected to increase to 32 million people by 2040.[5] The prevalence of angle-closure glaucoma is lower than POAG and varies significantly by race and ethnicity. The prevalence is lower in patients of European ancestry (0.4%) but higher in patients of Asian ancestry (1.2%).[5] PACG is also more prevalent with increasing age and among females.[4]

PATHOPHYSIOLOGY

The pathophysiology of glaucomatous neurodegeneration has not been completely elucidated but appears to be caused by both IOP-dependent and IOP-independent factors. Elevated IOP is clearly associated with damage and eventual death of optic nerves; however, optic neuropathy can occur in patients without elevated IOP, which indicates the presence of independent factors that contribute to ganglion cell death.[8,9] The key to understanding the pathophysiology and treatment of glaucoma relies on an understanding of aqueous humor dynamics, IOP, and optic nerve anatomy and physiology.

Aqueous Humor and Intraocular Pressure

IOP maintains the curvature of the cornea which is important for the refractive properties of the eye.[10] The distribution of IOP in

Table 62–1

Glaucoma Classifications[3,4]

Classification	Description
Primary glaucoma	Glaucoma that cannot be attributed to a preexisting ocular or systemic disease.
Secondary glaucoma	Glaucoma that can be attributed to preexisting ocular or systemic disease. Examples include pigment dispersion syndrome, neovascular glaucoma, and pseudoexfoliative syndrome.
Open-angle glaucoma	Glaucoma characterized by normal anterior-chamber angles and glaucomatous changes of the optic disc. Can be further classified as primary or secondary.
Angle-closure glaucoma	Glaucoma characterized by the obstruction of the anterior-chamber angle resulting in either intermittent or progressive elevated IOP with subsequent damage to the optic nerve. Can be further classified as primary or secondary.

the general population is 10 to 21 mm Hg (1.3–2.8 kPa) and is slightly skewed toward higher values. However, caution should be used in assigning this as the "normal range" for IOP because some patients may have optic neuropathy in the "normal range" while for other patients optic neuropathy may be absent at higher IOPs. Elevated IOP is generally considered greater than 21 mm Hg (2.8 kPa).[11]

Aqueous humor is an optically neutral fluid that provides oxygen and nutrition to the avascular lens and cornea. IOP is dependent on the balance between aqueous humor production and outflow from the anterior segment (Figure 62–1A). The anterior segment of the eye is separated by the iris into the posterior and anterior chambers. The ciliary body is a ring-like structure that surrounds and supports the lens. It also produces aqueous humor through the diffusion and ultrafiltration of plasma. The nonpigmented epithelium of the ciliary body secretes the aqueous humor into the posterior chamber. Aqueous humor production can be modified pharmacologically through the α- and β-adrenoceptors, carbonic anhydrase, and sodium and potassium adenosine triphosphatase of the nonpigmented ciliary epithelium.[12,13]

After secretion, the aqueous humor flows from the posterior chamber through the pupil into the anterior chamber. From the anterior chamber, approximately 80% of aqueous humor then exits through the trabecular meshwork while the remaining 20% exits through the uveoscleral pathway.[12,13]

The trabecular meshwork is a lattice of connective tissue that surrounds peripheral edge of the anterior chamber located in the inside intersection of the edge of the cornea and the iris insertion. The size of the trabecular meshwork can be altered by the contraction or the relaxation of the ciliary muscle. Stimulation of muscarinic receptors on the ciliary muscle causes contraction, which in turn causes the pores of the trabecular meshwork to open, increasing aqueous humor outflow into Schlemm canal and the episcleral venous system.[12] The contraction can also be decreased by inhibiting rho kinases that are involved in the regulation of the contractile tone of the trabecular meshwork tissue.[13]

In the uveoscleral pathway, aqueous humor exits the anterior chamber through the iris root and through spaces in the ciliary muscles, which then drain into the suprachoroidal space. Uveoscleral outflow can be pharmacologically modulated by adrenoceptors, prostanoid receptors, and prostamide receptors.[10,14]

Optic Nerve

In the posterior segment of the eye, retinal ganglion cells are responsible for transmitting visual signaling from the retina to the brain. The axons of the retinal ganglion cells converge at the retinal nerve fiber layer to form the optic nerve. The optic nerve head (also called the optic disc) is the portion of the optic nerve that is visible on funduscopic examination. The optic nerve head is typically vertically oval and pink to pale yellow with a depression in the center of the optic nerve, called a physiologic cup, which is formed as the axons converge and exit the eye as a bundle through the lamina cribrosa (Figure 62–2). The optic nerve synapses at the lateral geniculate nucleus in the brain.[8,9,15,16]

Pathophysiology of Open-Angle Glaucoma

In patients with POAG, the cause of elevated IOP is not obvious, as obstruction in aqueous humor outflow is not clinically discernible (Figure 62–1B). Possible causes of this increased IOP may be related to an increase in outflow resistance in the trabecular meshwork.[8,9,13,15]

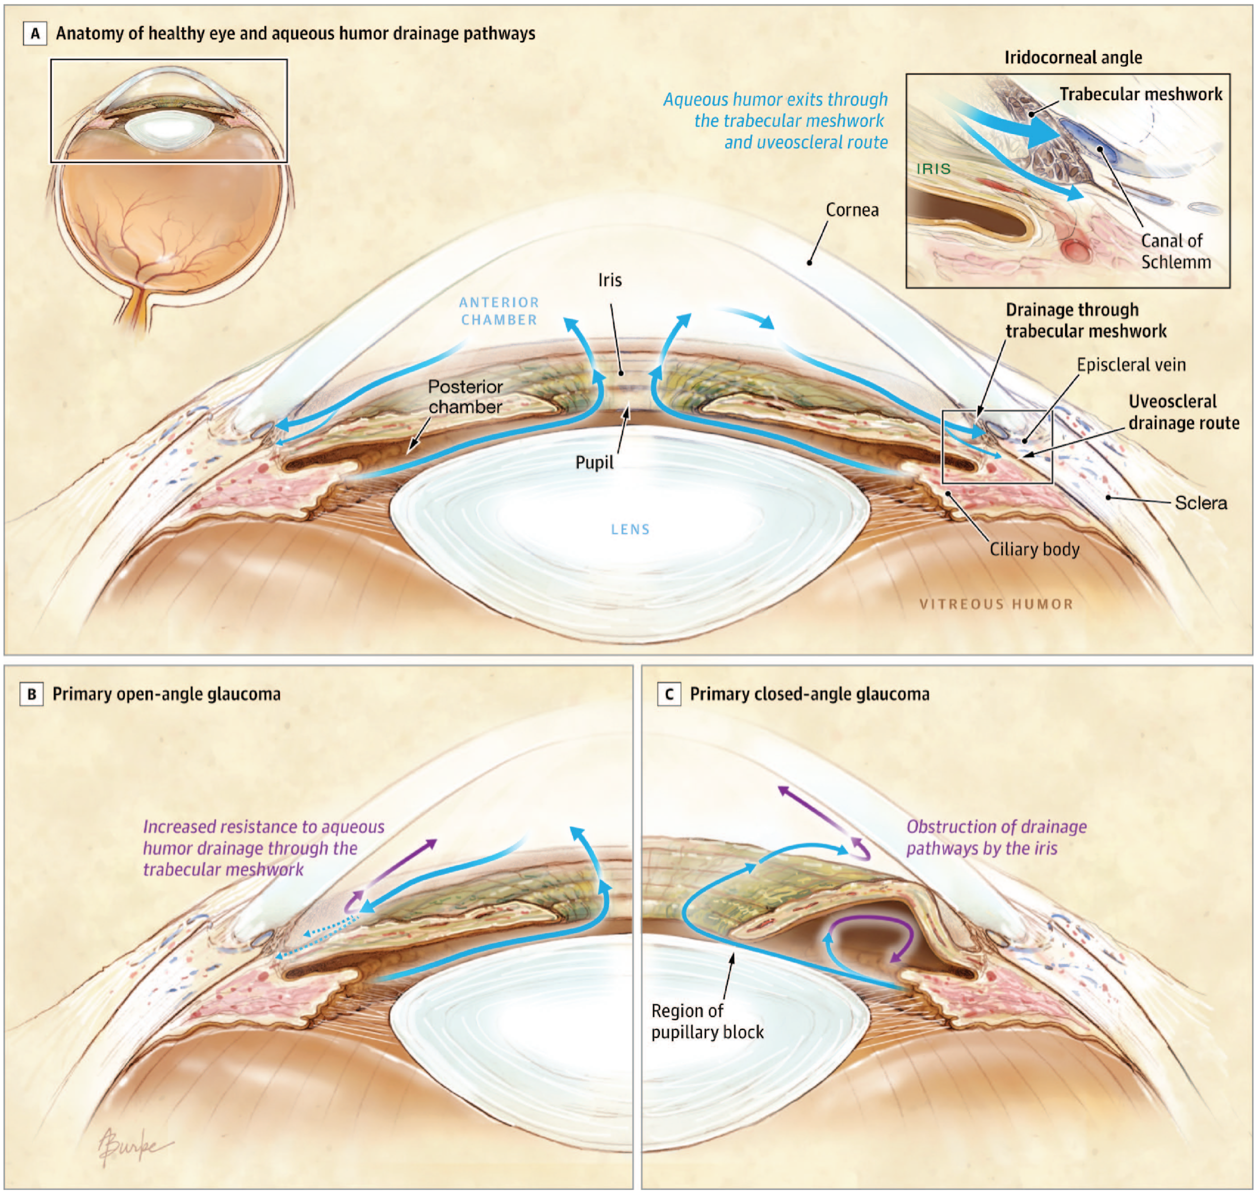
Glaucomatous optic neuropathy may also occur independent of increased IOP. Pressure independent causes of optic neuropathy include abnormal ocular perfusion, oxidative stress, and inflammation.[8,9,11,15]

Regardless of the underlying cause, elevated IOP initiates several detrimental changes to glial cells, the lamina cribrosa, and retinal ganglion cells. The increase in IOP can lead to alterations in retinal blood flow and axonal transport of neurotrophic factors, resulting in cellular stress of the retinal ganglion cells. This stress activates the glial cells in a manner that leads to inappropriate remodeling of the extracellular matrix. Elevated IOP deforms the lamina cribrosa, which places mechanical strain on the retinal ganglion cells. Chronic elevation of IOP ultimately causes the retinal ganglion cells to undergo apoptosis.[8,9,15,17,18]

Current glaucoma therapies fail to target IOP-independent glaucoma pathophysiologic factors. However, IOP reduction may still be beneficial, as the rate of visual field progression is decreased in many patients who exhibit IOP reduction via medical or surgical modalities.[3,8]

Pathophysiology of Angle-Closure Glaucoma

PACG involves a mechanical obstruction of aqueous humor outflow through the trabecular meshwork by the peripheral iris (Figure 62–1C). Two major mechanisms of trabecular meshwork obstruction by the peripheral iris include pupillary block and an abnormality of the iris called iris plateau. Pupillary block is the more common mechanism of obstruction and results from a complete or functional apposition of the central iris to the anterior lens and is associated with mid-dilation of the pupil. The trapped aqueous humor in the posterior chamber increases pressure behind the iris, causing the peripheral iris to bow forward and obstruct the trabecular meshwork. Plateau iris refers to an anterior displacement of the peripheral iris caused by anteriorly positioned ciliary processes. In this configuration, the peripheral iris bunches as the eye dilates. Both of these mechanisms result in the occlusion of aqueous humor outflow, causing IOP elevation at extreme levels that can lead to vision loss in hours to days.[4,8,19] The degree of iridotrabecular contact (angle closure) can be assessed by visualizing the anatomy of the iridocorneal angle by an examination technique called gonioscopy.



A Anatomy of healthy eye and aqueous humor drainage pathways

CLINICAL PRESENTATION AND DIAGNOSIS

Risk Factor Evaluation

For POAG, only 4% to 8% of patients may progress to legal blindness. Vision loss does not occur until there has been significant loss of the retinal ganglion cells. It may take 13 to 16 years for a patient to go blind from glaucoma. A patient's quality of life may not be affected until significant visual field loss is present, and the patient can no longer perform the activities of daily living.[20] **KEY CONCEPT** Practitioners play an important role in eye care by assessing patients for risk factors and referring to an eye care specialist for appropriate screening and evaluation. Risk factor evaluation is essential in determining the frequency of comprehensive eye examinations for patients (Table 62–2).[21] Glaucoma risk factors are also useful in deciding when to start therapy and determining the sequence of pharmacotherapeutic or surgical treatment modalities.[2-4] Table 62–3 lists the major risk factors associated with POAG and PACG.

Patient Encounter, Part 1

CM, a 70-year-old Caucasian woman with a history of congestive heart failure and hypertension, presents to your clinic for her yearly checkup. She states that she is concerned about losing her eyesight because her sister has started losing her vision from glaucoma. She denies changes in her vision.

Meds: Losartan 100 mg orally once daily, metoprolol succinate 50 mg orally once daily, furosemide 20 mg orally once daily

Based on the patient's medical and family history, what risk factors does this patient have for glaucoma?

How often would you recommend that this patient receive a comprehensive eye evaluation?

What objective assessments should be gathered in order to fully evaluate her risk factors for glaucoma?

How often would you recommend that this patient receive a comprehensive eye evaluation?

Table 62–2

Recommended Frequency of Comprehensive Adult Medical Eye Evaluation[21]

Age (Years)	With Risk Factors for Glaucoma	No Known Risk Factors for Ocular Disease
65 or above	1–2 years	1–2 years
55–64	1–2 years	1–3 years
40–54	1–3 years	2–4 years
Under 40	1–2 years	5–10 years

The development of PACG is associated with several anatomical risk factors that lead to shallow anterior chambers. PACG patients may have a thick, anteriorly displaced lens that results from continued growth of the lens and/or cataractous changes. The anterior chamber depth is typically shallower in many individuals with PACG, which predisposes these eyes to anatomically narrower iridocorneal inlets that are a setup for developing critically narrow angles more susceptible to closure (from an enlarging cataractous lens or other insults).[4,19]

Patients with PACG are characterized by at least 180 degrees of iridotrabecular contact, elevated IOP, and ophthalmic examination characteristic of glaucomatous changes. Recurrent attacks or a prolonged acute attack can lead to the development of peripheral anterior synechia, which partially obstructs the flow of aqueous humor through the trabecular meshwork.[4,19]

TREATMENT

Primary Open-Angle Glaucoma

▶ *Desired Outcomes and Goals*

KEY CONCEPT The goals of therapy are to prevent further loss of visual function; minimize adverse effects of therapy and impact on the patient's vision, general health, and quality of life; maintain IOP at or below a pressure at which further optic nerve damage is unlikely to occur; and educate and involve the patient in the management of their disease. KEY CONCEPT Current therapy is directed at altering the flow and production of aqueous humor, which is the major determinant of IOP.

▶ *General Approach*

KEY CONCEPT Because POAG is a chronic, often asymptomatic condition, the decision of when and how to treat patients is difficult, as the treatment modalities are often expensive and have potential adverse effects or complications. Currently lowering

Clinical Presentation and Diagnosis of POAG

General

- Adult onset (usually > 40 years of age)
- Insidious onset with diagnosis often occurring during routine eye examination
- Unilateral or bilateral presentation with asymmetric disease progression

Symptoms

- Severe disease progression may cause peripheral vision loss ("tunnel vision") or paracentral, nasal, and arcuate scotoma (blind spots)

Signs

Ophthalmoscopic examination may reveal:

- Optic nerve head (optic disc) cupping
- Large cup-to-disc ratio
- Diffuse thinning, focal narrowing, or notching of the optic nerve head rim
- Splinter hemorrhages
- Optic nerve head/nerve fiber layer changes occur before visual field changes can be detected

Diagnostic Tests

- Gonioscopy—Anterior-chamber angles are open
- Applanation tonometry—Elevated IOP (> 21 mm Hg [2.8 kPa]). However, POAG can present with signs of optic neuropathy without elevated IOP
- Pachymetry—Corneal thickness less than 540 μm is a risk factor
- Automated static threshold perimetry—visual field defects may present without evidence of vision loss
- Other diagnostic tests—scanning laser polarimetry, confocal scanning laser ophthalmoscopy, and optical coherence tomography

Table 62–3

Risk Factors for Glaucoma[3,4]

POAG	PACG
Elevated IOP	Advancing age
African or Hispanic descent	Asian or Eskimo ethnicity
Family history of glaucoma	Female sex
Older age	**Hyperopia**
Thinner CCT	Shallow anterior chamber
Type 2 diabetes	Family history of angle-closure glaucoma
Low ocular perfusion pressures	
Myopia	

CCT, central corneal thickness; IOP, intraocular pressure; POAG, primary open-angle glaucoma; PACG, primary angle-closure glaucoma.

Table 62–4

Select Nonpharmacologic Treatment Options for POAG[3,4,14]

Treatment Option	Description
Laser Trabeculoplasty	Laser energy aimed at trabecular meshwork Improves aqueous humor outflow
Trabeculectomy	Surgical removal of a portion of the trabecular meshwork Improves aqueous humor outflow Mitomycin C and fluorouracil are used to decrease scarring
Cyclodestructive surgery	Transscleral laser reduces rate of aqueous humor production Reserved for patients who have failed other options
Aqueous shunts	Drainage device that redirects the outflow of aqueous humor through a small tube into an outlet chamber placed underneath the conjunctiva

IOP is the best method to reduce the risk of visual field loss.[1,22] The clinician should evaluate the potential effectiveness, toxicity, and the likelihood of patient adherence for each therapeutic modality. The ideal therapeutic regimen should have maximal effectiveness and patient tolerance to achieve the desired therapeutic response. The American Academy of Ophthalmology (AAO) publishes Preferred Practice Patterns for POAG and POAG Suspect.[2,3]

Before the selection of a therapeutic modality, the target IOP should be determined for each patient. The target IOP ideally represents an IOP range that will slow the progression of optic neuropathy and not simply obtain an IOP in the range of 10 to 21 mm Hg (1.3–2.8 kPa). Currently, the initial target IOP is an estimate, but it should be modified based on the progression of the disease at each follow-up visit (treatment is individualized). **KEY CONCEPT** The AAO recommends an initial target IOP to be set at least 25% lower than the patient's baseline IOP. The target IOP can be set lower (30%–50% of baseline IOP) for patients who already have severe disease, risk factors for disease progression, or have normal-tension glaucoma (NTG).[3,23] Risk factors for progression include high IOP, older age, hemorrhage of the optic disc, large cup-to-disc ratio, thinner central corneal thickness (CCT), and established glaucomatous progression (velocity of disease progression is nonlinear).

Initial IOP control can be achieved by medical, laser, surgical, or combination of these therapies. The AAO guidelines[3] do not provide a specific recommendation on which therapeutic modality should be selected first, but patients in the early stages of glaucoma should receive treatment. In general, medical and laser trabeculoplasty are preferred as early treatment options over surgical as surgical interventions are not without potential intraoperative or postoperative complications.[22] The ophthalmologist will individualize therapy based on the risk and benefits for a specific patient. Table 62–4 describes nonpharmacologic treatment modalities for POAG.[3]

Medical treatment is the most commonly selected therapeutic modality. A well-tolerated ocular antihypertensive, at the lowest concentration, should be selected as the initial mediation (Table 62–5). The prostaglandin analogs are preferred first-line

Clinical Presentation and Diagnosis of Acute Angle-Closure Crisis

General

- Medical emergency due to high risk of vision loss
- Unilateral presentation, but fellow eye is at risk

Symptoms

- Ocular pain
- Red eye
- Blurry vision
- Halos around lights
- Systemic symptoms may develop
  - Nausea/vomiting
  - Abdominal pain
  - Headache
  - Diaphoresis

Signs

- Cloudy cornea caused by corneal edema
- Conjunctival hyperemia
- Pupil semidilated and nonreactive to light
- Firm closed-eye palpation

Diagnostic Tests

- Gonioscopy: Closed anterior chamber angles and possible peripheral anterior **synechiae**
- Applanation tonometry: Elevated IOP (> 21 mm Hg [2.8 kPa], but when symptoms are present, IOP may be > 30 mm Hg [4.0 kPa]).
- **Slit-lamp biomicroscopy**: Shallow anterior-chamber depth. Signs of previous attacks include peripheral anterior synechiae, iris atrophy, and pupillary dysfunction.

Table 62–5

Topical Drugs Used in the Treatment of Open-Angle Glaucoma

Drug	Pharmacologic Properties	Common Brand Names/Generic	Dose Form	Strength (%)	Usual Dose[a]	Mechanism of Action
β-Adrenergic Blocking Agents						
Betaxolol	Relative β_1 selective	Generic	Solution	0.5	One drop twice a day	All reduce aqueous production of ciliary body
		Betoptic-S	Suspension	0.25	One drop twice a day	
Carteolol	Nonselective, intrinsic sympathomimetic activity	Generic	Solution	1	One drop twice a day	
Levobunolol	Nonselective	Betagan/Generic	Solution	0.25, 0.5	One drop twice a day	
Metipranolol	Nonselective	OptiPranolol	Solution	0.3	One drop twice a day	
Timolol	Nonselective	Timoptic, Betimol, Istalol/Generic	Solution	0.25, 0.5	One drop every day—one to two times a day	
		Timoptic-XE/Generic	Gelling solution	0.25, 0.5	One drop every day[a]	
Adrenergic Agonists						
α_2-Adrenergic Agonists						
Apraclonidine	Specific α_2-agonists	Iopidine	Solution	0.5, 1	One drop two to three times a day	Both reduce aqueous humor production; brimonidine known to also increase uveoscleral outflow; only brimonidine has primary indication
Brimonidine		Alphagan P 0.1/ Generic 0.2, 0.15	Solution	0.2, 0.15, 0.1	One drop two to three times a day	
Cholinergic Agonists Direct Acting						
Carbachol	Direct and indirect acting	Carboptic, Isopto Carbachol	Solution	1.5, 3	One drop two to three times a day[a]	All increase aqueous humor outflow through trabecular meshwork
Pilocarpine	Direct acting	Isopto Carpine, Pilocar/Generic	Solution	1, 2, 4	One drop two to three times a day[a] One drop four times a day	
Cholinesterase Inhibitors						
Echothiophate	Indirect acting cholinesterase inhibitor	Phospholine Iodide	Solution	0.125	Once or twice a day	
Carbonic Anhydrase Inhibitors Topical						
Brinzolamide	Carbonic anhydrase type II inhibition	Azopt	Suspension	1	Two to three times a day	All reduce aqueous humor production of ciliary body

Topical Drugs Used in the Treatment of Open-Angle Glaucoma (*Continued*)

Drug	Pharmacologic Properties	Common Brand Names/Generic	Dose Form	Strength (%)	Usual Dose[a]	Mechanism of Action
Systemic						
Acetazolamide		Generic	Tablet	125 mg, 250 mg	125–250 mg two to four times a day	
		Injection	500 mg/vial	250-500 mg		
		Diamox Sequels	Capsule	500 mg	500 mg twice a day	
Methazolamide		Generic	Tablet	25 mg, 50 mg	25–50 mg two to three times a day	
Prostaglandin Analogs						
Latanoprost	Prostanoid agonist	Xalatan/Generic	Solution	0.005	One drop every night	Increases aqueous uveoscleral outflow and to a lesser extent trabecular outflow
Latanoprostene Bunod	Prostanoid agonist	Vyzulta	Solution	0.024	One drop every night	
Bimatoprost	Prostamide agonist	Lumigan 0.01/ Generic 0.03	Solution	0.01, 0.03	One drop every night	
Travoprost	Prostanoid agonist	Travatan Z / GenericTravoprost	Solution	0.004	One drop every night	
Tafluprost	Prostanoid agonist	Zioptan	Preservative free solution	0.0015	One drop every night	
Rho Kinase Inhibitors						
Netarsudil	Rho Kinase Inhibitor	Rhopressa	Solution	0.02	One drop every night	
Combinations						
Timolol–dorzolamide		Cosopt Generic	Solution	Timolol 0.5/ Dorzolamide 2	One drop twice daily	
Timolol–brimonidine		Combigan	Solution	Timolol 0.5/ Brimonidine 0.2	One drop twice daily	
Brinzolamide–brimonidine		Simbrinza	Suspension	Brinzolamide 1/ Brimonidine 0.2	One drop three times daily	
Netarsudil-latanoprost		Rocklatan	Solution	Netarsudil 0.02/ Latanoprost 0.005	One drop every night	

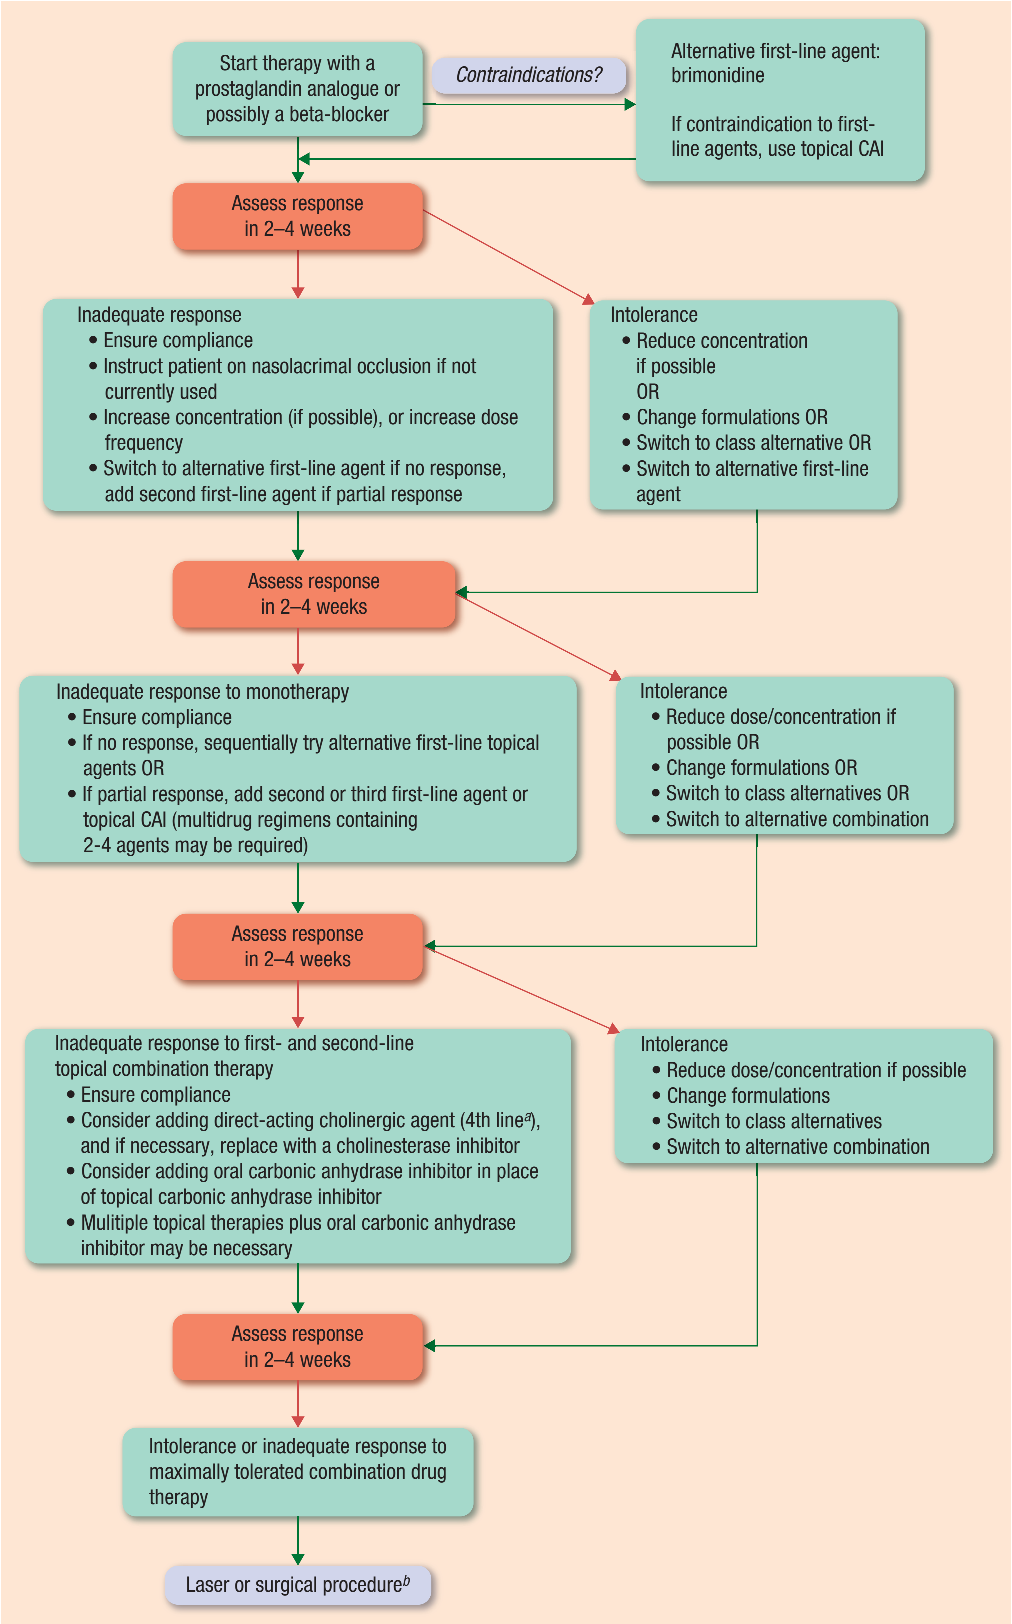
[a] Use of nasolacrimal occlusion will increase the number of patients successfully treated with longer dosage intervals.

agents since they are the most effective at lowering IOP of both peak and trough measurements by at least 25% of baseline IOP.[24-28] Additionally, these agents lack systemic side effects and are dosed once daily. If monotherapy alone lowers IOP but does not reach target pressure, or there is evidence of progression, then combination therapy or switching to another agent is appropriate. The addition of a second agent from another class generally has an additive effect on IOP reduction. Prostaglandin analogs, timolol, carbonic anhydrase inhibitors, brimonidine, or rho kinase (ROCK) inhibitors are reasonable choices for addition as a second agent.[3,8,11] Combination eyedrops reduce the number of drops that need to be administered. Increasing the concentration or dose frequency can also be tried when possible. An eyedrop's therapeutic agent or inactive excipients, such as preservatives, can cause adverse effects. Benzalkonium chloride is a common eyedrop preservative that has been associated with superficial punctate keratitis, corneal erosion, and conjunctival allergy. Intolerances to preservatives can be resolved by changing to a preservative-free eyedrop.[29] Figure 62–3 presents an algorithm to select and optimize POAG treatment.

A monocular trial can be used to assess the safety and effectiveness of a topical medication before initiation in both eyes; however, monocular drug trials do not always predict the IOP response of the second eye. Ideally, medication effectiveness should be assessed independently using baseline IOP measurements.

▶ *Treatment Considerations for POAG Suspects*

POAG suspects should be considered for topical medication therapy if they are at high risk for developing POAG or have a high IOP in which glaucomatous nerve damage is likely. POAG suspects with evidence of glaucomatous damage or visual field defect have developed POAG and should be treated accordingly.[2] The Ocular Hypertension Treatment Study (OHTS) demonstrated that a 20% decrease in IOP can reduce the progression from ocular hypertension to POAG over a 5-year period. The incidence of progression to POAG in the treatment (4.4%) and control



Start therapy with a prostaglandin analogue or possibly a beta-blocker
Contraindications?
Alternative first-line agent: brimonidine
If contraindication to first-line agents, use topical CAI
Assess response in 2–4 weeks
Inadequate response
• Ensure compliance
• Instruct patient on nasolacrimal occlusion if not currently used
• Increase concentration (if possible), or increase dose frequency
• Switch to alternative first-line agent if no response, add second first-line agent if partial response
Intolerance
• Reduce concentration if possible OR
• Change formulations OR
• Switch to class alternative OR
• Switch to alternative first-line agent
Assess response in 2–4 weeks
Inadequate response to monotherapy
• Ensure compliance
• If no response, sequentially try alternative first-line topical agents OR
• If partial response, add second or third first-line agent or topical CAI (multidrug regimens containing 2-4 agents may be required)
Intolerance
• Reduce dose/concentration if possible OR
• Change formulations OR
• Switch to class alternatives OR
• Switch to alternative combination
Assess response in 2–4 weeks
Inadequate response to first- and second-line topical combination therapy
• Ensure compliance
• Consider adding direct-acting cholinergic agent (4th line^a), and if necessary, replace with a cholinesterase inhibitor
• Consider adding oral carbonic anhydrase inhibitor in place of topical carbonic anhydrase inhibitor
• Mulitiple topical therapies plus oral carbonic anhydrase inhibitor may be necessary
Intolerance
• Reduce dose/concentration if possible
• Change formulations
• Switch to class alternatives
• Switch to alternative combination
Assess response in 2–4 weeks
Intolerance or inadequate response to maximally tolerated combination drug therapy
Laser or surgical procedure^b

FIGURE 62–3. Algorithm for the pharmacotherapy of open-angle glaucoma. [a]Fourth-line agents are not commonly used any longer or are commercially unavailable. [b]Most clinicians believe the laser procedure should be performed earlier (eg, after three-drug maximum, poorly adherent patient). (CAI, carbonic anhydrase inhibitor.)

(9.5%) groups was small, which underscores the importance of selecting patients at high risk of progressing to POAG.[30] When medical therapy is indicated, a well-tolerated agent should be selected and optimized following the POAG treatment algorithm (see Figure 62–3). The benefit of therapy should be reassessed in patients who may require third- or fourth-line agents to control IOP. Surgical or laser interventions are not indicated in the treatment of glaucoma suspects.[2]

Primary Angle-Closure Glaucoma

▶ *Desired Outcomes and Goals*

Therapeutic modalities for PACG are targeted at decreasing IOP. The goals of therapy are to preserve visual function by controlling the elevation in IOP, prevent damage to the optic nerve, and manage or prevent an acute attack of angle closure.[4]

▶ *General Approach*

KEY CONCEPT Acute angle-closure crisis is a medical emergency and requires urgent laser or surgical intervention. The treatment of choice for PACG is peripheral laser iridotomy. Laser iridotomy uses laser energy to cut a hole into the iris to alleviate the aqueous humor buildup behind the iris, resulting in reversal of appositional angle closure. Patients currently experiencing an acute angle-closure crisis should receive medical therapy to lower IOP, reduce pain, and reverse corneal edema before the iridotomy. IOP should first be lowered with topical β-blockers, topical α-agonist, prostaglandin $F_{2\alpha}$ analog, systemic carbonic anhydrase inhibitors, or hyperosmotic agents. Once the IOP has been controlled, pilocarpine can be used to break the pupillary block. A topical IOP-lowering agent should be continued to control IOP until laser iridotomy can be performed. Corneal indentation with a cotton-tipped applicator or gonioscopic lens may break pupillary block. If laser iridotomy cannot be performed, then surgical incisional iridectomy is used. Incisional iridectomy is the surgical removal of a small portion of the peripheral iris to allow flow of aqueous humor trapped in the posterior chamber to migrate to the anterior chamber (bypassing the normal flow pattern through the pupil). Topical corticosteroid may be employed to decrease inflammation postoperatively. The fellow eye is at high risk to develop an acute attack and should receive prophylactic iridotomy within a reasonable interval of time. Lens extraction surgery may be another treatment modality as it increases the anterior chamber depth. PACG patients may require chronic medical therapy if the patient has PACG superimposed on preexisting POAG or if synechia formation causes reduced outflow with a continued increase in IOP.[4,8,19]

Pharmacologic Therapy

▶ *Prostaglandin Analogs*

Prostaglandin analogs in typical ophthalmology practice are considered first-line agents along with β-blockers because of their superior efficacy and safety profiles. Many clinicians may choose to use prostaglandin analogs as first line, especially in patients who have an initial requirement to lower IOP by greater than 25%.[27,28,31,32] All four of the available agents currently have an FDA indication for both POAG and ocular hypertension. Latanoprost and travoprost have dosing aids that help patients administer each medication. Travoprost and tafluprost are available as benzalkonium chloride–free solutions.

Latanoprost, travoprost, and tafluprost are analogs of prostaglandin $F_{2\alpha}$ and are agonists of the prostanoid FP receptor, which appears to lower IOP by increasing aqueous humor outflow through the uveoscleral pathway. Bimatoprost is a prostamide analog and appears to lower IOP by activating prostamide receptors in the uveoscleral pathway and possibly through increasing outflow through the trabecular meshwork. The exact mechanism of how uveoscleral outflow is increased is still unclear, but stimulation of prostanoid FP receptors and prostamide receptors in the ciliary body cause remodeling of the extracellular matrix, making it more permeable to aqueous humor, thus increasing aqueous humor outflow through the ciliary muscles. Bimatoprost was recently approved as a 10-mcg anterior chamber implant. This may be an option for patients nonadherent to eyedrops; however, it may be an expensive alternative.[31,33-35]

Latanoprostene bunod 0.024% is a new agent, and when instilled, it is converted to latanoprost and nitric oxide (NO). Latanoprost has action on the uveoscleral pathway, and NO relaxes the trabecular meshwork and Schlemm canal to enhance trabecular outflow.[36] Once-daily latanoprostene bunod demonstrated greater intraocular pressure reduction when compared with twice-daily timolol 0.5% and once-daily latanoprost 0.005%.[37]

Prostaglandin analogs are administered once daily at bedtime and should not be increased to twice daily, as this may decrease effectiveness. Prostaglandin analogs can provide a consistent reduction in IOP over a 24-hour period.[32] For patients nonresponsive to latanoprost, they may respond to bimatoprost, presumably because of the difference in the site of action of each drug.[38,39]

Prostaglandin analogs are well tolerated and rarely cause systemic side effects (headache has been reported). Local effects include conjunctival hyperemia, stinging upon instillation, deepening of the upper eyelid sulcus, **hypertrichosis**, and increase in pigmentation of the iris or the eyelashes. Increases in iris pigmentation occur most commonly in patients with multicolored irides on long-term prostaglandin analog therapy. The mechanism of this effect is by its action on melanocytes of the iris, in which the irides become darker because of increased production of melanin in the iris.[29] Increased iris pigmentation appears to be only a cosmetic effect but may affect your product selection, especially when choosing monocular therapy. Conjunctival hyperemia or engorgement of conjunctival blood vessels is a common adverse effect caused by a vasodilatory effect on scleral blood vessels. It is most prominent early in therapy and usually subsides over time.[29,31]

Prostaglandin analogs should be used with caution in certain patients, since they may worsen anterior uveitis and herpetic keratitis. Cystoid macular edema has been reported during treatment with prostaglandin analogs; therefore, use caution in patients with intraocular inflammation, **aphakia**, **pseudophakia** with a history of intraoperative complications (eg, torn posterior lens capsule), or with risk factors for macular edema.[29]

Counsel patients prescribed prostaglandin analogs on potential adverse effects and appropriate administration. Instruct patients receiving latanoprost or tafluprost to refrigerate unopened medication. Once open, latanoprost may be stored at room temperature for 6 weeks. Tafluprost single-use containers may be stored at room temperature for up to 30 days.

▶ *β-Adrenergic Antagonists*

Topical β-adrenergic antagonists (β-blockers) are considered a second-line agent after the prostaglandin analogs for the treatment of POAG unless contraindications are present.[3,8] Topical β-blockers decrease IOP by reducing the formation of aqueous humor made by the ciliary body, which results in a 20% to 35% reduction in IOP.[27,28,31,32] Timolol, levobunolol, and carteolol are nonselective for β_1- and β_2-adrenergic receptors, whereas betaxolol has β_1-selective properties.[31,32] Betaxolol reduces IOP to a lesser extent than the nonselective β-blockers, but part of its efficacy may be related to a neuroprotective mechanism independent of IOP reduction.[40]

Topical β-blockers are typically administered twice daily. A gel-forming solution of timolol is indicated once-daily dosing. Tachyphylaxis may occur in 20% to 50% of patients on monotherapy with a β-blocker, resulting in the need for a different agent or combination therapy. Patients on concurrent systemic β-blockers may experience less IOP reduction than patients on only topical β-blockers.[31,32]

β-Blockers can cause significant systemic adverse effects through nasolacrimal drainage and subsequent systemic absorption in the mucus membranes of the nasal-pharyngeal cavity. This route bypasses first-pass hepatic metabolism resulting in pharmacologically significant serum drug concentrations.[41] Bronchospasm is the most common pulmonary effect of topical β-blockers. Pulmonary edema, status asthmaticus, and respiratory arrest have been reported with β-blockers as well. Cardiovascular effects include bradycardia, hypotension, and congestive heart failure exacerbation. As with systemic β-blockers, topical β-blockers have also been reported to cause depression and hyperlipidemia and mask symptoms of hypoglycemia. The β_1-selective properties of betaxolol may cause less exacerbation of pulmonary disease. Despite the intrinsic sympathomimetic activity demonstrated by carteolol, this does not translate to a clinically significant decrease in pulmonary or cardiovascular adverse effects. Topical β-blockers are generally contraindicated in patients with asthma, chronic obstructive pulmonary disease (COPD), sinus bradycardia, second- or third-degree heart block, cardiac failure, and hypersensitivity to the product.[29,32,41]

Stinging upon instillation is the most common adverse effect. Other local adverse effects include conjunctivitis, keratitis, dry eyes, and uveitis.[29,31]

Counsel patients prescribed topical β-blockers on the nasolacrimal occlusion technique to decrease systemic absorption.

α_2-Adrenergic Agonists Brimonidine and apraclonidine are α_2-adrenergic agonists that decrease IOP by reducing aqueous humor production. Brimonidine has a higher selectivity to the α_2-receptor than apraclonidine and has a dual mechanism of action by increasing uveoscleral outflow.[31,32] Apraclonidine is indicated for the prevention and treatment of postsurgical IOP elevations but is rarely used. Brimonidine lowers IOP by 14% to 25%. Peak IOP-lowering effect is similar to that of timolol, but the trough IOP-lowering effect is less than that of timolol.[26,27] Brimonidine may exhibit a neuroprotective effect and has been shown to delay visual field progression compared with timolol, but there is insufficient evidence it prevents retinal ganglion cell death.[42]

Brimonidine is typically used as an adjunctive agent in combination with other agents and is usually administered every 8 hours. A 12-hour dosing schedule may be employed when used in combination therapy. Brimonidine-purite 0.1% and 0.15% solution (Alphagan-P) has similar efficacy compared with the brimonidine 0.2% solution, because the purite solution's higher pH allows for more drug to penetrate the cornea.[31,32] Localized side effects include blepharoconjunctivitis, conjunctivitis, and ocular allergy. Systemic side effects include headache, dry mouth, and fatigue.[29,31,32]

The frequency of dosing and local adverse effects may lead to nonadherence in some patients. Counsel patients using brimonidine on the nasolacrimal occlusion technique to reduce systemic adverse effects and to improve efficacy.[31,32]

▶ *Rho Kinase Inhibitors*

Netarsudil and ripasudil are novel, potent ROCK inhibitors dosed once daily in the evening. ROCK inhibition decreases intraocular pressure by limiting adhesions within the trabecular meshwork and contraction of the ciliary muscle, facilitating aqueous humor outflow by increasing the meshwork pore size. Other minor pathways of pressure reduction include decreasing episcleral venous pressure and production of aqueous humor. The most common ocular adverse effect is conjunctival hyperemia. Systemic adverse effects are uncommon.[43] Combination of netarsudil and latanoprost is available as a once-daily product.

▶ *Carbonic Anhydrase Inhibitors*

Carbonic anhydrase inhibitors decrease aqueous humor production by inhibition of the carbonic anhydrase isoenzyme II located in the ciliary body. In the eye, carbonic anhydrase catalyzes the conversion of H_2O and CO_2 to HCO_3^- and H^+, a significant step in aqueous humor production. Carbonic anhydrase inhibitors are available in systemic and topical preparations.[31,32]

Topical Carbonic Anhydrase Inhibitors Dorzolamide and brinzolamide are the topical carbonic anhydrase inhibitors in production. Both are administered every 8 hours and are used as adjunctive therapy or as monotherapy for patients who cannot tolerate first-line therapies. Nasolacrimal occlusion may allow for a 12-hour dosing interval. They lower peak and trough IOP by 17% to 20%.[27,28,31,32]

Local side effects include burning, stinging, itching, foreign body sensation, dry eyes, and conjunctivitis. Brinzolamide may have fewer side effects since the drug is in a neutral pH solution. Dorzolamide has been reported to cause irreversible corneal decompensation. Dysgeusia has been reported with each agent. Both topical carbonic anhydrase inhibitors are sulfonamides and should be used with caution in patients with history of sulfonamide hypersensitivity.[29,31,32,44]

Systemic Carbonic Anhydrase Inhibitors There are two systemic carbonic anhydrase inhibitors: acetazolamide and methazolamide. These agents effectively lower IOP by 20% to 30% but are reserved as third-line to fourth-line agents because of their significant adverse effects. They are typically used as bridge therapy from maximal medical therapy to laser or surgical intervention or to control IOP in the perioperative period following a laser or surgical ocular procedure. The systemic carbonic anhydrase inhibitors can also be used to lower IOP in acute angle-closure glaucoma. Acetazolamide has an IV formulation that can be used in patients who are experiencing nausea due to the angle-closure attack.[4,31,32]

The systemic carbonic anhydrase inhibitors are associated with significant adverse effects that include paresthesias of the hands and feet, nausea, vomiting, and weight loss. Patients can develop systemic acidosis, hypokalemia, hyponatremia, and nephrolithiasis due to the inhibition of renal carbonic anhydrase. Sulfonamide allergy, renal failure, hepatic insufficiency, COPD, and decreased serum potassium and sodium levels are all contraindications of systemic carbonic anhydrase inhibitor therapy. Blood dyscrasias from bone marrow suppression have been reported and include agranulocytosis, aplastic anemia, neutropenia, and thrombocytopenia.[31,32]

▶ *Cholinergic Agents*

Cholinergic agents (also called parasympathomimetics or miotics) at one time were the first class of agents to treat glaucoma. The class can be divided into direct-acting cholinergic agents and indirect-acting cholinergic agents.

Patient Encounter, Part 2

CM was referred to an ophthalmologist for a comprehensive eye evaluation. The ophthalmology report reveals the patient has an IOP (as assessed by applanation tonometry) of 17 mm Hg (2.3 kPa) in the right eye and 19 mm Hg (2.5 kPa) in the left eye. Gonioscopic examination reveals open anterior angles in both eyes. Ophthalmoscopy reveals cupping of the optic discs in both eyes. Visual field examination reveals a nerve fiber bundle defect consistent with glaucoma in the left eye.

What is your assessment of this patient's glaucoma type?

What pharmacologic and nonpharmacologic treatment modalities are available for this patient?

Direct-Acting Cholinergic Agents Pilocarpine directly stimulates the muscarinic (M_3) receptors of the ciliary body, which causes contraction of the ciliary muscle. This results in the widening of spaces in the trabecular meshwork, which causes an increase in aqueous humor outflow and reduces IOP by 20% to 30%.

Pilocarpine requires administration four times daily, since the duration of IOP-lowering effect is approximately 6 hours. Pilocarpine is available in 1%, 2%, and 4% concentrations. Higher concentrations may be needed for patients with dark irides to obtain adequate IOP reduction.[31] Pilocarpine is considered a fourth-line agent for POAG. In the treatment of PACG, it is important to delay use until IOP has been controlled, because pilocarpine could worsen angle closure by causing anterior displacement of the lens. Once IOP is controlled, pilocarpine can be used to break pupillary block by instilling one drop applied twice in an hour.

The adverse effects of pilocarpine are caused by the induction of miosis. The contraction of the ciliary muscle causes the lens to displace forward, which can cause accommodation spasm and myopia, which can lead to brow ache. Pupillary constriction can also affect night vision. Pilocarpine should be avoided in patients with severe myopia as it increases the risk of developing retinal detachment. Systemic effects may occur at higher concentrations including nausea, vomiting and diarrhea, and bradycardia.[29]

Indirect-Acting Cholinergic Agents Echothiophate iodide inhibits acetylcholinesterase, which increases the acetylcholine available to stimulate the muscarinic (M_3) receptors of the ciliary body. This product is given twice daily and has similar efficacy to pilocarpine in the degree of IOP reduction. The side effect profile is similar to that of pilocarpine; however, it can deplete systemic cholinesterases and pseudocholinesterases and may cause the formation of cataracts. This agent should be discontinued at least 1 week prior to surgical procedures requiring general anesthesia. Succinylcholine and some local anesthetics are metabolized by pseudocholinesterases; therefore, depletion of this enzyme by echothiophate may lead to toxic effects. This product is typically used when other topical agents have failed and are limited to patients with aphakia or pseudophakia.[31]

▸ *Hyperosmotics*

Glycerin, isosorbide, and mannitol are hyperosmotic agents that increase the osmolality of blood. These agents create an osmotic gradient that draws water from the vitreous humor, thus decreasing IOP. The resulting dehydration of the vitreous humor may cause posterior movement of the lens, which then causes the anterior chamber to deepen, thus opening the anterior angle. If the patient is not vomiting, glycerin (1–1.5 g/kg of a 50%) solution and isosorbide (1.5–2 g/kg) can be given orally. Isosorbide is preferred in patients with diabetes because it is not metabolized into glucose. If the patient has nausea or vomiting, mannitol (20%) can be given IV at a dose of 1 to 2 g/kg over 45 minutes. The hyperosmotic agents are rapid acting, reaching peak effect in 30 to 60 minutes. Headache and thirst are common complaints. Patients who are already dehydrated are at risk of developing CNS dehydration, which can lead to coma. These agents should be used with caution in patients with renal or cardiovascular disease, as extracellular water is increased.[32,45]

SPECIAL CONSIDERATIONS: DRUG-INDUCED GLAUCOMAS

Medications have the potential to cause or exacerbate both POAG and PACG; however, PACG is more likely to be exacerbated by medications than POAG. The use of medications with anticholinergic or sympathomimetic properties can precipitate angle closure. Medications with anticholinergic properties include first-generation antihistamines, tricyclic antidepressants, and antipsychotics. Medications with sympathomimetic properties include phenylephrine and pseudoephedrine. PACG patients who have been treated with laser iridotomy can usually use these agents without causing an exacerbation. Sulfa-based drugs, such as topiramate, acetazolamide, and hydrochlorothiazide, cause swelling of the ciliary body, which causes an anterior displacement of the lens, resulting in a decrease in anterior-chamber depth. Patients with open or closed anterior angles can experience elevated IOP from these drugs. Controlled POAG is rarely exacerbated by anticholinergics and sympathomimetics unless the patient is concomitantly at risk for angle closure. For uncontrolled or untreated POAG, the risk–benefit ratio should be considered before employing these agents. Corticosteroids, through any route of administration, can exacerbate POAG. Corticosteroids increase IOP by causing obstruction of the trabecular meshwork with extracellular material. The increase in IOP appears to increase with potency and intraocular penetration. Ophthalmic corticosteroid preparations carry the highest risk of increasing IOP. However, all administrated routes have been shown to raise IOP in some patients. The onset and extent of IOP elevation is dependent on the specific corticosteroid, dose, route, and frequency. Generally, corticosteroid-induced IOP elevation occurs within a few weeks of beginning steroid therapy. In most cases, the IOP lowers spontaneously to baseline within a few weeks to months upon stopping the steroid. In rare instances, the IOP

Patient Encounter, Part 3

The practitioner and CM agree to start medication therapy. Develop a patient-specific care plan.

Address the patient's (a) drug-related needs, (b) goals of therapy, (c) potential pharmacologic therapies, and (d) plan for follow-up of therapy.

List the monitoring parameters for effectiveness and safety for the chosen therapy.

Explain how you would counsel the patient on the chosen therapy, including the administration of an ophthalmic preparation.

remains elevated. Some patients exhibit clinically significant and dangerously high IOP as a result of steroid use.[46]

OUTCOME EVALUATION

Primary Open-Angle Glaucoma

Evaluate patients 2 to 4 weeks after the initiation or alteration of medical therapy. The clinician should elicit the status of ocular health since the last visit, systemic medical history, medication history, and presence of systemic and ocular adverse effects of medications. IOP measurement, visual acuity assessment, and slit-lamp biomicroscopy at every POAG follow-up visit are necessary. The frequency of visual fields and optic nerve evaluation depends on whether IOP is controlled, the length of time IOP has been controlled, and whether there is progression of the disease. Patients who are at target IOP and have no disease progression should have optic nerve head evaluation and visual field testing every 6 to 12 months. Patients with disease progression and/or who are not at target IOP should receive follow-up evaluation every 1 to 6 months. Assess the patient's ability to use topical eyedrops.[3] (See Application of Ophthalmic Solutions or Suspensions textbox.) Finally, evaluate the patient's adherence to their medical regimen. Nonadherence among patients on topical medical therapy ranges from 5% to 80%. Suspect nonadherence in patients who have visual field and optic nerve progression despite a low IOP measurement, as patients may be more adherent to their medical regimen before their visit. Pharmacy refill histories may be useful in assessing adherence but do not confirm that the patient is actually taking the regimen as prescribed.[47] Specific patient factors related to the risk of nonadherence may include health literacy, medication cost, complicated medication regimens, adverse effects, and ethnicity.[48] Using adherence aids, prescribing the least complex regimen, and educating patients about their glaucoma are ways to reduce nonadherence.[49] Consider providing an eyedrop instillation aid for patients that have dexterity and/or coordination problems.[50]

KEY CONCEPT Target IOP should be revised based on the course of the disease and rate of progression (so-called "velocity of disease"). Adjust therapy if the patient fails to reach target IOP. Patients who have achieved target IOP yet have progressive damage of the optic nerve or worsening of their visual fields should have further adjustment of therapy. Evaluate these patients further for possible reasons of continued disease progression. Consider determining the diurnal pattern of IOP and looking for signs of poor ocular perfusion pressure. Establish a lower target IOP. Adjust therapy in patients who are intolerant, nonadherent, or develop contraindications to their drug therapy regimen. Consider increasing the target IOP and reducing drug therapy for patients who have stable disease and who have maintained a low IOP; closely follow these patients to assess their response.[3]

Primary Angle-Closure Glaucoma

Follow-up of acute angle-closure crisis occurs in the postoperative period. Evaluate the patency of the iridotomy and IOP in the

Patient Care Process

Collect Information:

- Obtain a past medical history, inquiring about previous and current medical problems with eyes.
- Obtain a complete medication history for use of prescription, nonprescription, and dietary supplements.
- Review the medical record for ophthalmic examination findings (applanation tonometry, visual acuity, gonioscopy, visual fields, optic nerve evaluation, pachymetry, and so on).
- Identify socioeconomic factors and health beliefs that affect access to medical care and medications.
- Have patient demonstrate or explain how to instill ophthalmic medications.

Assess the information:

- Determine any recent change or difficulty with vision.
- Determine risk factors for glaucoma.
- Review prescriptions, nonprescriptions, and natural products and determine any potential to exacerbate glaucoma or interact with glaucoma medications.
- Determine presence of ocular or systemic adverse effects from glaucoma medications.
- Determine if patient has achieved goal IOP and if there is evidence of disease progression based on ophthalmic examination findings.
- Identify barriers to medication adherence such as low health literacy, socioeconomic challenges, and physical limitations.

Develop a Care Plan:

- Select medication therapy that will likely achieve target IOP with minimal adverse effects and financial burden.
- Use combination glaucoma eyedrops when possible to improve adherence.
- Safely and appropriately discontinue or minimize the use of medications that could increase IOP.

Implement the Care Plan:

- Educate patient about changes in ophthalmic medication regimen.
- Address patient concerns about glaucoma and its treatment.
- Educate patient on importance of medication adherence and proper instillation and have them demonstrate their technique.
- Educate patient on potential adverse effects, reinforcing proper instillation technique as a strategy to minimize local and systemic adverse effects.

Follow-up: Monitor and Evaluate:

- Follow-up in 2 to 4 weeks to reassess progression of glaucomatous damage, medication effectiveness on IOP, medication adherence, and adverse effects to medication therapy.
- Review interval medical history.
- Perform or review ophthalmic examination findings.
- Determine the need for additional treatment modalities.
- Consider altering follow-up interval based on the progression and control of the disease.

Application of Ophthalmic Solutions or Suspensions

1. Clean hands with soap and water.
2. Avoid touching the dropper tip with your fingers or against your eye to maintain sterility of product; shake dropper bottle if product is a suspension.
3. Tilt head back; pull down the lower eyelid with index finger.
4. Hold the dropper bottle with other hand as close as possible without touching the eye. The dropper should be pointing toward the eye with remaining fingers bracing against the face.
5. Gently squeeze the bottle so that one drop is placed into the pocket.
6. Close eye (do not squint) for 2 to 3 minutes to allow for the maximum corneal penetration of drug.
7. Use a tissue to wipe away excess liquid.
8. Replace and retighten the cap to the dropper bottle.
9. Wait at least 5 minutes before instilling another ophthalmic drug preparation.
10. Application of some ophthalmic preparations (suspension and gels) may cause blurring of vision.

postoperative period. Perform gonioscopy and optic nerve head evaluation if not already performed. Stable patients with PACG should be evaluated at least annually, specifically for the presence of peripheral anterior synechia and optic neuropathy. Treat patients according to POAG guidelines if they have underlying POAG or areas of peripheral anterior synechia with the presence of optic neuropathy.[4]

Abbreviations Introduced in This Chapter

POAG	Primary open-angle glaucoma
PACG	Primary angle-closure glaucoma
IOP	Intraocular pressure
CCT	Central corneal thickness
NTG	Normal tension glaucoma
AAO	American Academy of Ophthalmology

ACKNOWLEDGEMENT

We thank Mikael D. Jones, PharmD, BCPS, Associate Professor of the Department of Pharmacy Practice and Science at the University of Kentucky College of Pharmacy, for his work on this chapter in previous editions of *Pharmacotherapy Principles and Practice*.

Minor Ophthalmic and Otic Disorders

Lauren R. Biehle and Michelle L. Hilaire

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Differentiate between the various ophthalmic disorders based on patient-specific information.
2. Choose an appropriate treatment regimen for an ophthalmic disorder.
3. Discuss the product differences that direct the selection of ophthalmic medications.
4. Assess when further treatment is required based on patient-specific information.
5. Recommend an ophthalmic monitoring plan given patient-specific information, a diagnosis, and a treatment regimen.
6. Educate patients about ophthalmic disease states and appropriate drug and nondrug therapies.
7. Review common otic disorders and appropriate drug and nondrug therapies.

INTRODUCTION

This chapter provides an overview of common ophthalmic and otic disorders and their treatments. **KEY CONCEPT** Many ophthalmic disorders are benign or self-limited, but the clinician must be able to distinguish conditions that lead to serious morbidity, including blindness. Preserving both visual function and cosmetic appearance is the goal.[1] The clinician must understand when referral is appropriate and the proper time frame for follow-up, based on the patient-specific condition. Healthcare professionals should also be aware of common otic disorders that may be encountered.

OCULAR INJURIES

Etiology and Epidemiology

Ophthalmic problems encompass 3% of all emergency department visits.[2] Corneal abrasions are the most common eye injury in children. Scratches, objects, and aggressive eye rubbing may damage the cornea.[3] Healthcare practitioners must know the proper treatment for ocular emergencies and the time frame for follow-up in order to prevent further morbidity (Table 63–1).

CORNEAL ABRASIONS

Treatment

Desired Outcomes

- Complete healing of the corneal abrasion with no scarring or vision impairment
- Prevent infection and pain
- Prevent corneal loss or corneal transplant

General Approach to Treatment

The five layers of the cornea contain no blood vessels but are nourished by tears, oxygen, and aqueous humor. Minor corneal abrasions, also called corneal epithelial defects, heal quickly—typically within 24 hours.[4] Moderate abrasions take 24 to 72 hours to heal. Deep abrasions may scar the cornea. This rarely results in sufficient visual impairment to require corneal transplant. Patients should be instructed not to rub the eye if a corneal abrasion is present. Do not use eye patches to treat uncomplicated corneal abrasion.[3]

Corneal Abrasion Prevention[3]

- Wear eye protection during sports
- Wear industrial safety lenses
- Carefully fit and place contact lenses

Pharmacologic Therapy

Topical NSAIDs Topical nonsteroidal anti-inflammatory drugs (NSAIDs) reduce the need for oral analgesics, but there is not strong evidence available to support their use in the management of corneal abrasions.[4] Available ocular NSAIDs are diclofenac, ketorolac, nepafenac, and bromfenac. The usual dose for

Table 63–1

Ophthalmic Emergencies: Time to Follow Up by Ophthalmologist

Immediate Consult Required	Within 24 Hours
Acute chemical burn	Acute angle-closure glaucoma
Acute, painless loss of vision	Blood in the eye (hyphema)
Blunt trauma to eye	Corneal ulcer
Foreign body in eye	Macular edema
Orbital cellulitis	Sudden congestive proptosis (bulging of eye forward)
Retinal detachment	

Adapted from Shah SM, Khanna CL. Ophthalmic emergencies for the clinician. Mayo Clin Proc. 2020;95(5):1050–1058.

Clinical Presentation and Diagnosis of Corneal Abrasions[3]

Symptoms

- Photophobia
- Pain with eye or eyelid movement
- Foreign body sensation (or gritty feeling)
- Recent ocular trauma

Signs

- Excessive tearing
- Blepharospasm
- Blurred vision
- Conjunctival injection ("red eye")

Diagnostic Test

Use sterile fluorescein dye strips and visualize the cornea under a cobalt-blue filtered light; abrasions appear green; ensure that no foreign body remains in the eye or under eyelid.

diclofenac and ketorolac is one drop four times daily; nepafenac is dosed one to three times daily, and bromfenac is dosed once or twice daily. Use topical NSAIDs with caution in patients with clotting disorders or those who are on systemic NSAIDs or warfarin therapy. Adverse effects typically include discomfort upon administration and conjunctival hyperemia or itching.[4]

Topical Antibiotics Infection slows the healing of a corneal abrasion; therefore, prophylactic antibiotics are often used. However, antibiotic-steroid ophthalmic products are not recommended as the steroid may slow healing of the abrasion. Patients should be asked if any contaminated matter could have entered the eye as this can lead to bacterial keratitis. Discontinue the use of contact lenses until the abrasion is healed and the antibiotic course complete. **KEY CONCEPT** In patients who do not wear contacts, antibiotics active against Staphylococcus, such as erythromycin ointment or trimethoprim-polymyxin B solution, are appropriate choices. In contact lens wearers, choose an ophthalmic antibiotic that has activity against Pseudomonas aeruginosa, such as gentamicin or a fluoroquinolone.[3]

▶ *Outcome Evaluation*

1. Reevaluate patients in 24 hours.
2. If symptoms worsen, recheck for foreign bodies.
3. Refer to ophthalmologist if[3]:
   - Contact lens wearers
   - Decreased vision
   - Lack of improvement or worsening symptoms

OTHER OCULAR INJURIES: TREATMENT

Traumatic Injuries

Attempt to remove loose foreign bodies by gentle irrigation with artificial tears or sterile saline. If removal is successful, a topical broad-spectrum antibiotic, such as erythromycin, will prevent infection. If irrigation is unsuccessful, only ophthalmologists should complete mechanical removal of foreign objects. Protect the eye from further injury with a metal eye shield or a paper cup taped over the eye while awaiting the ophthalmologist.[2]

Splash Injuries and Chemical Exposure

Instruct patients by phone to immediately irrigate the eye with water or saline continuously for at least 15 minutes before seeking a clinician. Irrigation dilutes and removes the chemical agent and is the best way to decrease ocular tissue damage. Patients should then seek immediate care from an ophthalmologist or emergency facility.[5]

Loss of Vision

A variety of disorders may lead to rapid, painless, monocular or binocular vision loss. These include central retinal artery occlusion, acute narrow-angle glaucoma, trauma, and others.[6] The differential diagnosis is complex and should be undertaken by an emergency department or ophthalmologist.

HORDEOLUM

A hordeolum is a common bacterial infection of an oil-producing gland of the eyelid that can be described as external (also called a stye) or internal. Patients will often present with a tender swollen mass and redness of the affected area. *Staphylococcus aureus* is the most common bacteria to cause a hordeolum.[7] A comparison of characteristics and treatment options for external and internal hordeola can be found in Table 63–2.

CONJUNCTIVITIS

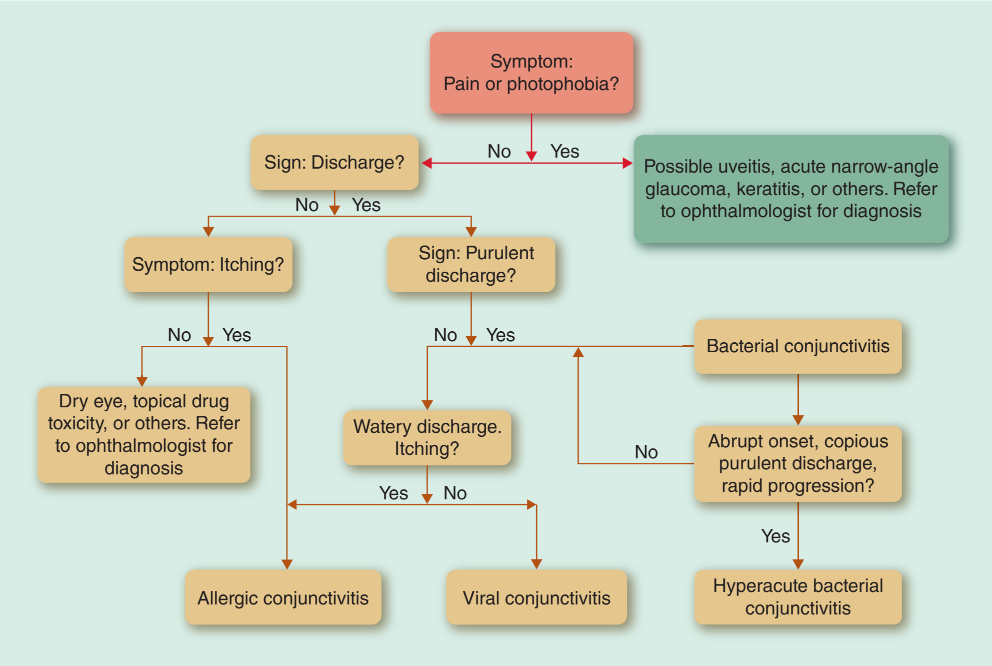
Etiology

Conjunctivitis, also known as red eye, is one of the most common ophthalmic complaints seen by clinicians. An inflamed conjunctiva is the most common cause of red eye.[8] Conjunctivitis cases are most commonly viral in nature. Both viral and

Table 63–2

Comparison of Internal and External Hordeola[7,23,24]

Characteristic	External Hordeolum (Stye)	Internal Hordeolum
Gland	Infection of the Zeis tear gland	Infection of the Meibomian gland
Location	Occurs on eyelid margin	Interior of eyelid
Cause	Often caused by *S. aureus*	Often caused by *S. aureus*
Supportive care	Warm compresses can provide symptom relief	Warm compresses can provide symptom relief
Antibiotics required	Not required	May be required
		Options include topical erythromycin ophthalmic ointment, oral dicloxacillin, or oral trimethoprim–sulfamethoxazole
	Not required, patients may experience recurrent hordeola	If large or unresolving hordeola, patients should be referred to an ophthalmologist for possible incision/drainage



Symptom: Pain or photophobia?

Hyperacute bacterial conjunctivitis

FIGURE 63–1. Differential diagnosis for red eye.

bacterial conjunctivitis are highly contagious. The most common symptoms indicating bacterial conjunctivitis rather than viral are adherence of the eyelids upon waking and presence of mucopurulent discharge. The most common symptom differentiating allergic conjunctivitis from bacterial or viral is itching.[9] Use the differential diagnosis algorithm shown in Figure 63–1 to determine the proper treatment or need for referral.

BACTERIAL CONJUNCTIVITIS

Etiology and Pathophysiology

The primary cause of acute bacterial conjunctivitis (ABC) is gram-positive organisms, *S. aureus, Streptococcus pneumoniae*, and gram-negative *Haemophilus influenzae*.[6] *Pseudomonas* may be a cause of ABC in contact lens wearers.[8] *S. aureus* is a more common cause in adults, while *S. pneumoniae* and *H. influenzae* are more common in children.[8] KEY CONCEPT The pathogens are rarely cultured unless the case is unresponsive to treatment.[6] Patients with bacterial conjunctivitis lasting 4 weeks or more should be referred to an ophthalmologist.[9]

Hyperacute bacterial conjunctivitis is associated with gonococcal *(Neisseria gonorrhoeae)* infections in sexually active patients. Prompt workup and treatment is required, as corneal perforation can occur.[6,8]

Treatment

▶ *Desired Outcomes*

- Complete resolution of the bacterial conjunctivitis
- Prevent adverse consequences of the infection
- Preserve functionality of the eye

▶ *General Approach to Treatment*

ABC may be treated with broad-spectrum antibiotics. Although the condition is usually self-limiting, antibiotic treatment decreases the spread of disease to others and prevents extraocular infection. Additionally, treatment may help decrease the risk of corneal ulceration or other complications that affect sight. Finally, treatment speeds recovery.[6,8]

▶ *Pharmacologic Therapy*

The choice of an antibiotic agent for ABC is largely empiric. The initial treatment needs to include *Staphylococcus* coverage, and cost and side effect profile may be pertinent.[6] In general, ointments are a good dosage form for children. Adults may prefer drops because they do not interfere with vision.

Many broad-spectrum topical antibiotics are approved to treat ABC (Tables 63–3 and 63–4).

- First-line treatments include polymyxin B/trimethoprim solution, polymyxin B with bacitracin ointment, or erythromycin ointment as these provide activity against *S. aureus.*
- The aminoglycosides (tobramycin and gentamicin) are alternatives but have incomplete gram-positive coverage and can cause corneal epithelial toxicity.[8]
- Sulfacetamide has significant resistance and is not highly effective.
- If infection occurs in contact lens users, recurs or is severe, a topical fluoroquinolone is recommended to provide activity against *Pseudomonas*.[8] Moxifloxacin, gatifloxacin, and besifloxacin are newer ophthalmic fluoroquinolones and may have less resistance.[10]
- Treat hyperacute bacterial conjunctivitis with a single dose of intramuscular ceftriaxone 1 g in combination with topical antibiotics and refer the patient to an opthalmologist.[8]
- If concurrent blepharitis is present, add a lid hygiene regimen to antibiotic treatment.[6]

Outcome Evaluation

Significant improvement of acute bacterial conjunctivitis should be seen within 1 week.[8]

Table 63–3

Adult Bacterial Conjunctivitis Dosing Guidelines for Topical Ophthalmic Antibiotics[25]

Azithromycin 1% solution	Days 1 and 2: 1 drop twice daily Days 3–7: 1 drop once daily
Ciprofloxacin 3.5 mg/mL solution	Days 1 and 2: 1–2 drops every 2 hours while awake Days 3–7: 1–2 drops every 4 hours while awake
Ciprofloxacin 0.3% ointment	Apply a ½ in (~1 cm) ribbon of ointment 3 times daily for 2 days, then twice daily for next 5 days
Erythromycin 0.5% ointment	Apply a ½ in (~1 cm) ribbon of ointment up to 6 times daily
Gatifloxacin 0.5% solution	Days 1 and 2: 1 drop every 2 hours while awake up to 8 times daily Days 3–7: 1 drop 4 times per day while awake
Gentamicin 0.3% solution	1–2 drops every 4 hours. In severe infections, may use up to 2 drops every hour
Gentamicin 0.3% ointment	Apply a ½ in (~1 cm) ribbon of ointment 2–3 times daily
Levofloxacin 0.5% solution	Days 1 and 2: 1–2 drops every 2 hours while awake, up to 8 times per day Days 3–7: 1–2 drops every 4 hours while awake, up to 4 times daily
Moxifloxacin 0.5% solution	1 drop 2 times a day for 7 days (Moxeza) 1 drop 3 times a day for 7 days (Vigamox)
Ofloxacin 0.3% solution	Days 1 and 2: 1–2 drops every 2–4 hours while awake Days 3–7: 1–2 drops 4 times daily
Polymyxin B with bacitracin ointment	Apply a ½ in (~1 cm) ribbon of ointment every 3–4 hours for 7–10 days
Polymyxin B/trimethoprim solution	1 drop every 3 hours for 7–10 days
Sulfacetamide 10% ointment	Apply a ½ in (~1 cm) ribbon of ointment every 3–4 hours and at bedtime
Sulfacetamide 10% solution	1–2 drops every 2–3 hours for 7–10 days
Sulfacetamide 10% ointment	Apply a ½ in (~1 cm) ribbon of ointment every 3–4 hours and at bedtime
Tobramycin 0.3% ointment	Mild-to-moderate infections: Apply a ½ in (~1 cm) ribbon of ointment 2–3 times daily; severe infections: Apply every 3–4 hours
Tobramycin 0.3% solution	Mild-to-moderate infections: 1–2 drops every 2–4 hours Severe infections: Initially, 2 drops every hour

Patient Encounter 1

This morning, a 42-year-old male kindergarten teacher presents with eye redness and frequent clear watery discharge. His symptoms started in his left eye 2 days ago and then moved into both eyes. He is not having eye pain or itching, and his symptoms are not affecting his vision. He asks if he needs an antibiotic eyedrop and if he should continue wearing his contact lenses.

What is the probable diagnosis?

Please differentiate between bacterial, hyperacute bacterial, viral, and allergic causes based on physical assessment.

What is a reasonable treatment regimen?

What do you recommend for the patient to do with his contact lenses?

What nonpharmacologic measures should be employed to prevent spreading?

VIRAL CONJUNCTIVITIS

Etiology

Viral conjunctivitis is commonly caused by adenovirus and is often called "pink-eye."[8] Adenovirus is easily spread through daycare centers, nursing homes, swimming pools, camps, and contaminated fingers and medical instruments.[9] Patients often present with an upper respiratory tract infection or recent exposure to viral conjunctivitis.[8] **KEY CONCEPT** Viral conjunctivitis is usually self-limiting, resolving within 2 weeks.[8]

Treatment

Desired Outcomes

- Complete resolution of the viral conjunctivitis
- Prevent adverse consequences of the infection
- Avoid spreading infection to others

Nonpharmacologic Therapy

KEY CONCEPT Nonpharmacologic measures are critical to prevent the spread of viral conjunctivitis. Cold compresses may relieve symptoms.[6,8] Patients should not share towels or other contaminated objects, should avoid close contact with other people, and avoid swimming for 2 weeks.[8,9] Current contact lenses in the infected eyes and their lens case should be discarded. Take care in the medical setting to thoroughly decontaminate instruments and wash hands.[8,9]

Pharmacologic Therapy

Patients may obtain further symptomatic relief by using artificial tears.[8,9] If artificial tear solutions sting, recommend a preservative-free formula.

Topical antivirals are not used to treat adenovirus conjunctivitis. Topical antibiotics are unnecessary and should not be used for a viral infection and to help prevent the development of antibiotic resistance.[9]

Patients with severe subepithelial infiltration may require a topical steroid. However, topical steroids may cause serious ocular complications, increase the period of viral shedding, and may worsen herpetic conjunctivitis, which has similar symptoms as viral conjunctivitis.[9] Only ophthalmologists should prescribe topical steroids.[8]

Outcome Evaluation

Refer patients who do not see improvement within 7 to 10 days or with visual loss to an ophthalmologist to rule out herpetic and other infectious processes.[8,9]

ALLERGIC CONJUNCTIVITIS

Etiology and Clinical Presentation

Ocular allergy is a broad term that includes several diseases with the hallmark symptom of itching, often accompanied by tearing, conjunctival swelling, photophobia, and stringy or sticky mucoid discharge.[11] Allergic conjunctivitis affects up to 40% of patients.[12] Seasonal ocular allergy is the most common type of allergic conjunctivitis. Often, the patient's history is positive for atopic conditions including allergic rhinitis, asthma, or eczema.[8] Perennial allergic conjunctivitis has similar but less severe symptoms and may not be tied to a specific time of year. Finally, conjunctivitis medicamentosa is a drug-induced form of allergic conjunctivitis caused by overuse of topical vasoconstricting agents and sometimes polypharmacy from use of multiple topical glaucoma eyedrops.[11]

Pathophysiology

The conjunctiva of the eye is often the initial site of contact with an environmental allergen. Mast cell degranulation occurs, and the earliest mediator is histamine, which causes itching, redness, and swelling.[12] Leukotrienes and prostaglandins cause cellular infiltration and increased mucus secretion along with chemosis, resulting in conjunctival vasodilation.

Treatment of ocular allergy is aimed at slowing or stopping these processes. Antihistamines block the histamine receptors, prevent histamine release from the mast cells, and stop eosinophil activity.[12] Mast cell stabilizers inhibit the degranulation of mast cells, preventing mediator release. Some topical agents have multiple mechanisms of action, combining antihistaminic, mast cell stabilization, and anti-inflammatory properties (Tables 63–5 and 63–6).[12]

Treatment

Desired Outcomes

- Relief of current allergic symptoms
- Prevention of future allergic symptoms
- No adverse effects from treatment

Table 63–5

Mechanisms of Action of Ocular Allergy Drugs

Drug	Mechanisms
Azelastine	H_1-receptor antagonist
Cromolyn sodium	Mast cell stabilizer
Epinastine	H_1- and H_2-receptor antagonist, mast cell stabilizer
Ketorolac	Inhibitor of prostaglandin synthesis
Ketotifen	H_1-receptor antagonist, mast cell stabilizer, eosinophil inhibitor
Lodoxamide	Mast cell stabilizer
Loteprednol	Corticosteroid
Naphazoline	Decongestant, vasoconstrictor
Nedocromil	Mast cell stabilizer, eosinophil inhibitor
Olopatadine	H_1-receptor antagonist, mast cell stabilizer
Tetrahydrozoline	Decongestant, vasoconstrictor

Table 63–6

Pediatric and Adult Dosing and Common Side Effects of Ocular Allergy Drugs

Drug	Dosing	Common Side Effects
Azelastine 0.05%	Children 3 years of age or older and adults: 1 drop in affected eye(s) twice daily	Ocular stinging, bitter taste, headache
Cromolyn sodium 4%	Children 4 years of age or older and adults: 1–2 drops in each eye 4–6 times daily	Ocular stinging
Epinastine 0.05%	Children 3 years of age or older and adults: 1 drop in each eye twice daily	Ocular burning, ocular itching, cold symptoms
Ketorolac 0.5%	Children 3 years of age or older and adults: 1 drop 4 times a day	Ocular stinging, irritation
Ketotifen 0.025%	Children 3 years of age or older and adults: 1 drop in affected eye(s) twice daily	Red eyes, headache, rhinitis
Lodoxamide 0.1%	Children 2 years of age or older and adults: 1–2 drops in affected eye(s) 4 times daily, for up to 3 months	Ocular stinging, discomfort, foreign body sensation
Loteprednol 0.2%	Adults only: 1 drop in affected eye(s) 4 times daily	Elevated intraocular pressure, cataracts, secondary ocular infections, systemic side effects possible
Naphazoline 0.012%, 0.03%, 0.1%	0.1%: 1–2 drops into affected eye(s) every 3–4 hours as needed 0.012% or 0.03% solution: 1–2 drops into affected eye(s) up to 4 times daily	Burning, stinging on instillation; mydriasis
Nedocromil 2%	Children 3 years of age or older and adults: 1–2 drops in each eye twice daily	Headache, ocular stinging, unpleasant taste, nasal congestion
Olopatadine 0.1%, 0.2%	Children 3 years of age or older and adults (0.1%): 1 drop in affected eye(s) 2 times daily with minimum 6–8-hour interval between doses Children 2 years of age or older and adults (0.2%): 1 drop in affected eye(s) once daily	Headache, blurred vision, ocular stinging
Tetrahydrozoline 0.05%	1–2 drops in affected eye(s) up to 4 times daily	Burning, stinging on instillation; mydriasis

Data from Lexi-Drugs Online™. Lexi-Comp Online™. Hudson (OH): Lexi-Comp, Inc.; 2020. Available from: http://online.lexi.com. Accessed August 16, 2020.

▶ *Nonpharmacologic Therapy*

The primary treatment for ocular allergy is removal and avoidance of the allergen.[8,9] For conjunctivitis medicamentosa, discontinue the offending medication. Patients should be instructed to avoid rubbing their eyes. Apply cold compresses several times daily to reduce redness and itching and to provide symptomatic relief.[11]

▶ *Pharmacologic Therapy*

KEY CONCEPT Use a step-care approach for the treatment of allergic conjunctivitis.

- Step 1: Nonmedicated, artificial tears solution. The solution dilutes or removes the allergen, providing relief while lubricating the eye. The artificial tear solutions may be refrigerated to provide additional topical relief.[13] Solutions are applied two to four times daily as needed. Ointments may be used in the evenings to further moisturize the surface of the eye. Preservative-free formulations may be tried if other products sting or burn, or if the artificial tears need to be used frequently throughout the day.
- Step 2: Topical antihistamine or antihistamine/decongestant combination. Decongestants are vasoconstrictors that reduce redness and seem to have a small synergistic effect with the antihistamine. Topical decongestants used in combination products include naphazoline and tetrahydrozoline. Topical decongestants burn and sting on instillation and commonly cause mydriasis, especially in patients with lighter-colored eyes. Topical decongestant use should be limited to less than 10 days to avoid rebound congestion.
- Step 3: A mast cell stabilizer or a multiple-action (antihistamine-mast cell stabilizer) agent. Use mast cell stabilizers, including cromolyn or nedocromil, prophylactically throughout the allergy season—they are not used for acute relief of symptoms. Full response may take 4 to 6 weeks.
- Step 4: Short-term topical corticosteroids and immunotherapy.[11,12]

Topical antihistamine-mast cell stabilizers are recommended before oral agents in step therapy due to the increased risk of systemic side effects with oral drugs. Topical antihistamines provide faster relief of ocular symptoms. Topical antihistamine-mast cell stabilizers include alcaftadine, azelastine, bepotastine, epinastine, ketotifen, and olopatadine. Topical NSAID ketorolac tromethamine is approved for ocular itching, though it is used less commonly than topical antihistamines.[12]

Outcome Evaluation

Monitor patients for relief of symptoms. Ensure an adequate trial of each agent. Refer severe cases that do not respond to an ophthalmologist.

BACTERIAL KERATITIS

Epidemiology

Thirty thousand cases of microbial keratitis occur annually in the United States.[14] Microbial keratitis encompasses bacterial, fungal, and *Acanthamoeba* keratitis.[14] Only bacterial keratitis, the most common form, is discussed here.

Pathophysiology

Bacterial keratitis is a broad term for a bacterial infection of the cornea including corneal ulcers and corneal abscesses. The cornea in a healthy eye has natural resistance to infection, making bacterial keratitis rare. However, many factors may predispose a

Patient Encounter 2

ST is a 71-year-old woman who presents with eye complaints. She states her eyes are watering off and on and feel like they have sand in them. She has been wearing her glasses, rather than her usual contact lens use. She is able to look up at the light on the ceiling and denies eye pain or itching. She denies any discharge from the eye, except the feeling that they water occasionally. She states now that the spring temperatures have increased; she has recently turned on the fans in her apartment. She tried using artificial tears one time, but they stung, and she did not continue use of them.

Past medical history:

- GERD
- Migraines
- Insomnia

Social history:

- Alcohol use: denies
- Tobacco: 1 pack per day
- Illicit drug use: denies

Medications:

- Doxepin 6 mg at bedtime
- Ibuprofen 400 mg PRN headaches
- Pantoprazole 40 mg Q AM

Which symptoms would distinguish dry eye from conjunctivitis?

What risk factors may contribute to ST's dry eye?

What nonpharmacologic therapies should be recommended for this patient?

What pharmacologic therapies should be recommended for this patient?

Which dosage forms should be recommended for this patient?

How should the patient be monitored?

patient to bacterial infection by compromising the defense mechanisms of the eye (Table 63–7).[14]

The most common pathogens in bacterial keratitis are *Pseudomonas* (including *P. aeruginosa*) and other gram-negative rods, staphylococci, and streptococci.[14] If the keratitis is related to the use of contacts, *Pseudomonas* and *Serratia marcescens* are the most common pathogens.[14] **KEY CONCEPT** Untreated bacterial keratitis can result in corneal scarring and potential loss of vision. Corneal perforation may occur which may require emergent corneal transplant, and the patient could lose the eye.[14] Central corneal scarring may result in vision loss even after successful eradication of the organism.[14]

Clinical Presentation and Diagnosis of Bacterial Keratitis[8,14]

General

The rate of progression of signs and symptoms varies depending on the infecting organism. A differential diagnosis for keratitis must include viral, fungal, and nematodal infections in addition to bacterial causes.

Symptoms

- Photophobia
- Rapid onset of ocular pain

Signs

- Red eye
- Conjunctival discharge
- Decreased vision

Laboratory Tests

Culture if keratitis is severe or sight-threatening, chronic, or unresponsive to broad-spectrum antimicrobial therapy.

Table 63–7

Risk Factors for Bacterial Keratitis

Exogenous Factors

- Contact lenses
- Loose sutures from ocular surgeries
- Previous corneal surgery
- Previous ocular or eyelid surgery
- Trauma, including foreign bodies, chemical and thermal injuries, and local irradiation

Ocular Surface Disease

- Abnormal lid anatomy or function
- Misdirection of eyelashes
- Ocular infection (eg, conjunctivitis, blepharitis)
- Tear film deficiencies

Systemic Conditions

- Atopic dermatitis
- Connective tissue disease
- Diabetes mellitus
- Gonococcal infection
- Immunocompromised
- Stevens-Johnson syndrome
- Substance abuse
- Vitamin A deficiency

Ocular Medications

- Anesthetics
- Antimicrobials
- Contaminated ocular medications
- Glaucoma medications
- Preservatives
- Steroids
- Topical NSAIDs

Corneal Epithelial Abnormalities

- Corneal epithelial edema
- Predisposition to recurrent erosion of the cornea
- Viral keratitis (eg, herpes simplex or zoster keratitis)

Data from Lin A, Rhee MK, Akpek EK, et al. Bacterial Keratitis Preferred Practice Pattern®. Ophthalmology. 2019;126(1):P1–P55.

Treatment

▶ *Desired Outcomes*[14]

- Resolution of infection and corneal inflammation
- Reduced corneal pain
- Restored corneal integrity with minimal scarring
- Restored visual function

▶ *General Approach to Treatment*

All cases of suspected bacterial keratitis require prompt ophthalmology consultation to prevent permanent vision loss.[8]

▶ *Pharmacologic Therapy*

Dosage Considerations Topical antibiotic drops are preferred. Consider subconjunctival antibiotics if compliance is a concern. Systemic therapy is useful in cases of systemic infection (eg, gonorrhea) or if the sclera is infected. Reserve ointments for minor cases or adjunctive nighttime therapy.[14]

Drug Choice Start topical broad-spectrum antibiotics empirically. Use a loading dose for severe keratitis (Table 63–8). Single-drug therapy with a fluoroquinolone is as effective as combination therapy. Resistance is seen with some fluoroquinolones, choose moxifloxacin or gatifloxacin in severe keratitis cases.[14] Antibacterials should be continued until positive response, then tapered. Fortified antibiotic therapy is an option for severe or unresponsive cases but may increase toxicity to the cornea and surrounding tissues. Fortified antibiotics are compounded products that are a higher concentration than the commercially available formulations.

Topical corticosteroids are employed in some cases of bacterial keratitis. The suppression of inflammation may reduce corneal scarring. However, local immunosuppression, increased ocular pressure, reduced epithelial healing and reappearance of the infection are disadvantages to their use. Topical steroids may be beneficial in bacterial keratitis if initiated early (within 72 hours of antibiotic therapy) but may lead to worse outcomes in keratitis caused by fungi or *Acanthamoeba*.[15]

Table 63–8

Pharmacologic Therapies for Bacterial Keratitis[14]

Organism	Drug
Unknown or multiple types of organisms	Cefazolin 50 mg/mL *and* tobramycin/ gentamicin 9–14 mg/mL *or* Fluoroquinolones (various strengths)
Gram-positive cocci	Cefazolin 50 mg/mL *or* Vancomycin[a] 10–50 mg/mL *or* Bacitracin[a] 10,000 international unit *or* Fluoroquinolones (various strengths)
Gram-negative rods	Tobramycin 9–14 mg/mL *or* Gentamicin 9–14 mg/mL *or* Ceftazidime 50 mg/mL *or* Fluoroquinolones (various strengths)
Gram-negative cocci	Ceftriaxone 50 mg/mL *or* Ceftazidime 50 mg/mL *or* Fluoroquinolones (various strengths)

Adult Topical Dosing

Severe keratitis: Loading dose every 5–15 minutes for the first hour, then every 15 minutes to 1 hour around the clock. Less severe keratitis may use less frequent dosing.

[a] Use for resistant *Enterococcus* and *Staphylococcus* species and penicillin allergy. Due to the absence of gram-negative activity, do not use vancomycin or bacitracin for single-agent empiric therapy in bacterial keratitis.

Data from Lin A, Rhee MK, Akpek EK, Amescua G, Farid M, Garcia-Ferrer FJ, et al. Bacterial Keratitis Preferred Practice Pattern®. Ophthalmology. 2019;126(1):P1–P55.

Outcome Evaluation[14]

- Symptomatic improvement is indicative of therapeutic efficacy.
- Adjust treatment based on culture and sensitivity reports.
- Modify the treatment regimen if the patient does not show improvement within 48 hours.
- Gram-negative keratitis will have increased inflammation in the first 24 to 48 hours, even on appropriate therapy.
- Taper therapy based on clinical response.
- Reculture if negative clinical response; discontinue antibiotics 12 to 24 hours before culturing for best results.
- Contact lenses wearers should be educated about the increased risk of infection overnight and continuous wear and the importance of adherence to contact lens hygiene.

DRY EYE

Epidemiology and Etiology

Dry eye is a frequent cause of eye irritation. The lack of a single diagnostic test for the condition limits the available epidemiologic data. Dry eye affects millions worldwide, being more frequent in elderly patients.[16] The risk factors for dry eye are listed in Table 63–9. Dry eye that is left untreated can cause loss of vision, structural damage, an increased risk for infection, and compromised efficacy of ocular surgery.[17]

Pathophysiology

The surface of the eye and the tear-secreting glands work together as an integrated unit that refreshes the tear supply and clears away used tears. Dry eye may be caused by impaired tear secretion and/or increased tear evaporation.[17]

Dysfunction of tears may be caused by aging, systemic inflammatory diseases, a decrease in androgen hormones, surgery, ocular surface diseases, systemic diseases, or medications that affect the efferent cholinergic nerves. Dysfunctional tear film may result in an inflammatory response on the ocular surface called keratoconjunctivitis sicca.[17]

Table 63–9

Risk Factors for Dry Eye[17]

- Androgen deficiency
- Antihistamine use
- Connective tissue disease
- Estrogen replacement therapy
- Female gender
- Hematopoietic stem cell transplantation
- Hepatitis C infection
- LASIK and refractive excimer laser surgery
- Low dietary intake of omega-3 fatty acids
- Older age
- Radiation therapy
- Vitamin A deficiency

Data from Akpek EK, Amescua G, Farid M, Garcia-Ferrer FJ, Lin A, Rhee MK, et al. Dry Eye Syndrome Preferred Practice Pattern®. Ophthalmology. 2019;126(1):P286–P334.

Table 63–10

Associated Conditions That Cause or Worsen Dry Eye[17]

Ocular Conditions	Environmental Factors
Blepharitis	Air travel
Eyelid malposition	Air conditioning or heating
Lagophthalmos	Contact lenses
Meibomian gland dysfunction	Exogenous irritants or allergens
Systemic Diseases	Prolonged use of computer or reading
Amyloidosis	Reduced humidity
Bell palsy	Smoke exposure
Epstein-Barr virus	Wind and/or use of fans
Graft-versus-host disease	**Local Trauma**
Hemochromatosis	Injury/scarring
Hepatitis C infection	Orbital surgery
Human immunodeficiency virus infection	Radiation
Lymphoma	**Medications**
Neuromuscular Diseases	Anticholinergics
Ocular mucous membrane pemphigoid	Antidepressants
Parkinson disease	Antihistamines
Rosacea	β-Blockers
Rheumatoid arthritis	Diuretics
Sarcoidosis	Hormone therapy
Scleroderma	Systemic retinoids
Sjögren syndrome	Frequent administration of ophthalmic medication
Stevens-Johnson syndrome	
Systemic lupus erythematosus	

Data from Akpek EK, Amescua G, Farid M, Garcia-Ferrer FJ, Lin A, Rhee MK, et al. Dry Eye Syndrome Preferred Practice Pattern®. Ophthalmology. 2019;126(1):P286–P334.

Clinical Presentation and Diagnosis of Dry Eye[16,17]

General

Many other ocular diseases have similar symptoms. Patients with suggestive symptoms without signs should be placed on a treatment trial. Repeated observations may be required for a clinical diagnosis.

Symptoms

- Dry or foreign body sensation
- Mild itching
- Burning or stinging
- Photophobia
- Ocular irritation or soreness
- Blurry vision and/or variable vision
- Contact lens intolerance
- Diurnal fluctuation or symptoms worsening later in the day

Signs

- Redness
- Mucus discharge
- Increased blink frequency
- Intermittent tearing

Other Diagnostic Tests

- The tear break-up time test assesses the stability of precorneal tear film. Break-up times of less than 10 seconds are considered abnormal.
- Ocular surface dye staining assesses the ocular surface and will show blotchy areas in the dry eye.
- Schirmer test evaluates aqueous tear production but is not diagnostic. Results of 5 mm or less are considered abnormal.
- Assess corneal sensation if trigeminal nerve dysfunction is suspected.
- Consider an autoimmune disorder if significant dry eyes, other signs and symptoms, or family history are present.

Environmental causes (Table 63–10) and an abnormal blink reflex are common causes of increased evaporative loss of tears and worsening of dry eye.[17]

Treatment

Desired Outcomes[17]

- Relief of the symptoms of dry eye
- Maintain or improve visual acuity
- Prevention of long-term adverse effects from dry eye

General Approach to Treatment

KEY CONCEPT Dry eye is a chronic condition. Symptoms can be improved with treatment, but unless dry eye is secondary to a disease, it is not usually curable. Because of this, patient education is important, and a periodic reassessment of the efficacy of the treatment is appropriate. If the patient is unresponsive to treatment, refer to an ophthalmologist for additional options. If the dry eye is secondary to a systemic disease, the disease should be managed by the appropriate medical specialist.[17]

Nonpharmacologic Therapy

Behavioral and environmental modifications may significantly improve dry eye, especially in mild cases. Patients should be counseled to increase their frequency of blinking, use eyelid hygiene and warm compresses, and stop smoking. Reduce air drafts and consider adding a humidifier in low-humidity areas. Schedule regular breaks from computer work, other electronic screens, or reading. These activities promote decreased blinking and can increase dry eye symptoms. Lower the computer screen to below eye level to decrease lid aperture. Evaluate medication profile and therapeutically substitute medications that do not exacerbate dry eye. Moisture chamber spectacles or goggles may reduce tear evaporation.[16,17]

If pharmacologic and other therapies are not sufficient, punctal occlusion or lateral tarsorrhaphy may be an option for more severe cases.[16,17] Punctal occlusion is the plugging of the punctal drainage sites with collagen or silicone plugs. Lateral tarsorrhaphy sutures portions of the lid margins together to decrease evaporative tear loss.

Pharmacologic Therapy

The mainstay of treatment for dry eye is artificial tears. Artificial tears augment the tear film topically by increasing viscosity and provide symptom relief. If a patient uses artificial tears more than four times daily, or develops an allergy to ophthalmic preservatives, recommend a preservative-free formulation. Artificial tears are available in gel, ointment, and emulsion forms that provide a longer duration of relief. Ointment use is appropriate at bedtime as it may cause blurry vision.[17]

Preliminary data suggest dietary or supplemental intake of omega-3 fatty acids may be beneficial. Omega-3 fatty acids may block the production of inflammatory cytokines and proinflammatory mediators.[16,17]

Anti-inflammatory agents may be used in conjunction with artificial tears. The first approved agent was cyclosporine emulsion. Cyclosporine emulsion increases tear production in some patients. Cyclosporine emulsion may require several months for full results, so it should not be used for acute relief.[16]

An additional treatment for the signs and symptoms of dry eye is twice-daily lifitegrast 5% ophthalmic solution. Lifitegrast is a lymphocyte function-associated antigen-1 (LFA-1) antagonist. LFA-1 is a protein that interacts with an intracellular adhesion molecule (ICAM-1). ICAM-1 may be overexpressed in patients with dry eye disease and can promote inflammation of the ocular surface. By blocking the interaction of LFA-1 to ICAM-1, lifitegrast may reduce ocular surface inflammation. The duration of therapy in clinical trials was 12 weeks. The most common adverse effects of lifitegrast include eye irritation, distortion of taste, and reduced visual acuity.[18,19] Use of topical corticosteroids for short periods (2 weeks) may suppress inflammation and ocular irritation symptoms but should be used with caution.[17] (Table 63–11).

Table 63–11

Pharmacologic Therapies for Dry Eye[17]

Drug	Dosing
Cyclosporine ophthalmic emulsion 0.05%	1 drop in each eye twice daily
Lifitegrast 5% ophthalmic solution	1 drop in each eye twice daily
Loteprednol etabonate suspension 0.5%	1–2 drop(s) in affected eye(s) 4 times daily; short term use only

Data from Akpek EK, Amescua G, Farid M, Garcia-Ferrer FJ, Lin A, Rhee MK, et al. Dry Eye Syndrome Preferred Practice Pattern®. Ophthalmology. 2019;126(1):P286–P334.

Outcome Evaluation[17]

- Monitor patient for relief of symptoms and ocular damage.
- Periodically reassess the patient's compliance with therapy and understanding of the disease.

Patient Care Process: Dry Eye

Collect information:

- Collect relevant information about medical history of dry eye.
- Collect information about the patient's signs and symptoms related to dry eye.
- Collect relevant information about the patient's behaviors, such as smoking, and environmental risk factors for dry eye.
- Collect an updated medication list including prescription medications, nonprescription medications, herbal products, and dietary supplements.

Assess information:

- Assess the patient's signs and symptoms of dry eye for potential need for referral.
- Assess the patient's reported behaviors and environmental risk factors for potential intervention.
- Assess each medication in the patient's medication list for appropriateness and risk of exacerbation of dry eye.

Develop a care plan:

- Address the patient's risk factors for dry eye, including potential nonpharmacologic interventions related to smoking and other environmental risk factors.
- Address the patient's medication-related problems and optimize the patient's medication therapy by recommending alternatives to medications that can exacerbate symptoms of dry eye.
- Determine an appropriate care plan based on the patient's frequency of symptoms. The care plan may include treatment options such as over-the-counter formulations of artificial tears, omega-3 fatty acids, or prescription therapies such as cyclosporine or lifitegrast.
- Plan to counsel the patient on appropriate use of ophthalmic solutions that may be utilized as part of the recommended therapy for dry eye.

Implement a care plan:

- Engage the patient in discussion about his/her risk factors for dry eye, including potential nonpharmacologic interventions related to smoking and other environmental risk factors.
- Recommend alternatives to medications that can exacerbate symptoms of dry eye.
- Initiate an appropriate care plan based on the patient's frequency of symptoms. The care plan may include treatment options such as over-the-counter formulations of artificial tears, omega-3 fatty acids, or prescription therapies such as cyclosporine or lifitegrast.
- Counsel the patient on appropriate use of ophthalmic solutions with the steps below:
    - Wash hands before and after instilling medication(s) into the eye.
    - Contact lenses should be removed prior to instilling eye medication, and the patient should wait 10 minutes before reinserting contact lenses.
    - Do not touch the tip of the container with anything.
    - Use of **nasolacrimal occlusion** decreases systemic absorption and may increase ocular bioavailability of the drug. After instilling the eyedrop, the patient should close the eye and press a finger gently against the nasolacrimal duct (tear duct) for 2 to 3 minutes.
    - Contribute to the coordination of care by referring the patient to an ophthalmologist if self-care is not appropriate.

Monitor and Evaluate:

- Monitor patient for relief of symptoms and ocular damage.
- Assess adherence and recommend alternative formulations of artificial tears if necessary.
- Periodically reassess the patient's compliance with therapy and understanding of the disease.

Patient Encounter 3

BE, a 45-year-old Black man, presents with an irritation to his right ear that started about 24 hours ago. He has recently started wearing new waterproof headphones when he does his intense cardiovascular workouts and swimming at a local pool for his triathlon training. PMH: seasonal allergies

PE:

BP 130/76 mm Hg

P 72 beats/min

R 16 breaths/min

Ht. 6′6″ (198 cm)

Wt. 215 lb (98 kg)

Medications:

- Cetirizine 10 mg daily as needed for allergies
- Multivitamin daily

Does BE have any potential risk factors for acute otitis externa?

What pharmacologic options are available?

What nonpharmacologic therapies could BE do to decrease the likelihood of this happening again?

- Cyclosporine or lifitegrast may take up to 3 months for full improvement.
- If a patient presents with vision loss, moderate or severe pain, corneal ulceration, or a lack of response to therapy, refer the patient to an ophthalmologist for prompt evaluation.

DRUG-INDUCED OCULAR DISORDERS

Many systemic medications can cause ocular adverse effects. Patients presenting with ocular complaints should have their medication profile evaluated.

OTIC DISORDERS

OTITIS EXTERNA

Epidemiology and Etiology

KEY CONCEPT Acute otitis externa (AOE), or what is commonly referred to as swimmer's ear, is an infection of the external auditory canal that potentially involves diffuse inflammation that may extend distally to the pinna and proximally to the tympanic membrane.[20,21] Otitis externa has a lifetime prevalence of approximately 10% and can be considered chronic rather than acute if it lasts 3 months or longer.[20]

A diffuse acute otitis media is diagnosed by a rapid onset, generally within 48 hours, in the past 3 weeks of symptoms and signs of inflammation such as intense or disproportionate tenderness of the tragus, pinna, or both.[21] Patients with a nonintact tympanic membrane, tympanostomy tube, diabetes, immunocompromised state, or prior radiotherapy are at risk for more serious infections and are not treated the same as an uncomplicated acute otitis externa.

Pathophysiology

In North America, the vast majority of acute otitis externa cases are bacterial caused by pathogens such as *P. aeruginosa* and *S. aureus*.[20,21] Otitis externa can be polymicrobial, and it should be treated with topical antibiotics if uncomplicated.[21]

Otitis externa can be caused by a variety of different factors such as water exposure, self-cleaning, soapy deposits, alkaline eardrops, dermatologic conditions, trauma, sweating, allergies, genetics, climate, and stress.[21]

Treatment

▶ *Desired Outcomes*

- Relief of the symptoms of otitis externa
- Prevention of long-term adverse effects from otitis externa

▶ *General Approach to Treatment/ Nonpharmacologic Therapy*

Removing obstructing cerumen; using acidifying eardrops shortly before swimming, after swimming, at bedtime, or all three; drying the ear canal with a hair dryer; using ear plugs while swimming; and avoiding trauma to the external auditory canal are recommended by the guidelines as therapy options for preventing otitis externa.[21]

▶ *Pharmacologic Therapy*

Otitis externa in a patient with a perforated tympanic membrane needs to be treated with medications that are not ototoxic as compared to an uncomplicated case. There are not significant differences in efficacy of the topical agents; therefore, patient and provider preferences, cost, adherence, and adverse effects are priority.[21] Refer to Table 63–12 for common otic preparations.

Cortisporin (bacitracin, neomycin, polymyxin B, hydrocortisone) is typically used first in patients with an intact tympanic membrane. Ofloxacin and ciprofloxacin/dexamethasone (Ciprodex) are used with a perforated tympanic membrane or if it cannot be visualized. A total of 7 to 10 days of topical therapy is recommended.[21] Also, pain is very common with otitis media, and it needs to be managed accordingly. Anesthetic otic drops are not recommended for pain management. If there is no improvement with the drops within 48 to 72 hours, then the diagnosis of otitis externa should be reviewed.

Outcome Evaluation

- Monitor patient for relief of symptoms and otic damage.

Table 63–12

Pharmacologic Therapies for Otitis Externa

Drug	Considerations
Acetic acid 2.0% solution	Pain and irritation, may be less effective beyond a week of treatment; not with perforated tympanic membrane
Acetic acid 2.0%, hydrocortisone 1.0% solution	Pain and irritation; not with perforated tympanic membrane
Ciprofloxacin 0.2%, hydrocortisone 1.0% solution	Twice daily adequate
Ciprofloxacin 0.3%, dexamethasone 0.1% solution	Twice daily adequate
Neomycin, polymyxin B, hydrocortisone solution	Ototoxic; four times daily; not with perforated tympanic membrane
Ofloxacin 0.3% solution	Twice daily adequate, potentially daily

Adapted from Schaefer P, Baugh RF. Acute otitis externa: an update. Am Fam Physician. 2012;86(11):1055–1061; Rosenfeld RM, Schwartz SR, Cannon CR, et al. Clinical practice guideline: acute otitis externa. Otolaryngol Head Neck Surg. 2014;150(1 Suppl):S1–S24.

CERUMEN IMPACTION

Epidemiology and Etiology

One of the most common reasons for patients seeking care for auditory problems is obstruction of the ear. Ear canal obstruction is most commonly caused by cerumen. Twelve million people in the United States annually seek care for cerumen impaction, 8 million cerumen removal procedures occur annually, and "…one in 10 children, 1 in 20 adults and more than one-third of the geriatric and developmentally delayed populations…" have excessive or impacted cerumen.[22]

Pathophysiology

Obstruction can lead to more serious problems including hearing loss, tinnitus, fullness, itching, otalgia, discharge, odor, and cough. Hearing loss can range from 5 to 40 dB depending on the degree of occlusion of the canal with cerumen.[22] Cerumen impaction can also prevent a provider from viewing the external auditory canal and/or tympanic membrane and performing auditory diagnostic tests that are vital components of any physical examination. Common symptoms include pain, itching, sensation of fullness, tinnitus, odor, drainage, and cough.

Treatment

▶ *Desired Outcomes*

- Relief of the symptoms of cerumen impaction

▶ *General Approach to Treatment*

Prevention of cerumen impaction includes education in proper ear hygiene. Proper ear hygiene does not include using cotton-tipped swabs to clean ears. Cotton-tipped swabs have been implicated in increasing cerumen impaction.[22] Alcohol or hydrogen peroxide drops or irrigation, topical earwax-softening agents, and irrigation are all potential options for secondary prevention of impacted cerumen.[22]

Only patients who are symptomatic should receive treatment. Patients with cerumen that prevent assessment of the ear should also be treated. Treatment for cerumen impaction may include cerumenolytic agents, irrigation, or manual removal.[22] Cerumenolytics work by thinning the cerumen to decrease the need for irrigation and manual removal. All cerumenolytic agents have been shown to be equally efficacious including water. The different cerumenolytic agents available include water based, oil based, and non-water- and nonoil based. Water-based agents work by breaking up the cerumen while oil-based preparation soften without breaking up the cerumen. Irrigation uses a jet of warm water to flush out the cerumen. A curette, probe, hook, forceps, or suction may be used for manual removal. All treatment regimens have been shown to be efficacious and none are preferred over another.

Side effects, although rare, can occur with treatment for cerumen impaction. Some side effects include tympanic membrane perforation, ear canal laceration, infection of the ear, bleeding, or hearing loss. The number of side effects from cerumen impaction treatment that occur in the United States is around 8000 yearly.[22]

Outcome Evaluation

- Monitor patient for relief of symptoms from excess cerumen.

Abbreviations Introduced in This Chapter

ABC	Acute bacterial conjunctivitis
NSAID	Nonsteroidal anti-inflammatory drug

Nose, Mouth, and Throat Disorders

Alexandra Hintz, Phu Trinh, and Luke Dearden

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Compare and contrast clinical presentations of various nose, mouth, and throat disorders.
2. Identify common medications that cause xerostomia and sialorrhea.
3. Evaluate when pharmacologic treatment is necessary for treatment of nose, mouth, and throat disorders.
4. Compare and contrast the mechanisms of action of common medications used to treat nose, mouth, and throat disorders.
5. Develop a treatment plan, including nonpharmacologic and pharmacologic interventions, for the treatment of nose, mouth, and throat disorders.
6. Educate patients about nose, mouth, and throat disorders and the pharmacologic and nonpharmacologic therapies used to treat them.
7. Create a monitoring plan for treatment of nose, mouth, and throat disorders.

NONALLERGIC RHINITIS

Introduction

Allergic rhinitis refers to inflammation of the nasal mucous membrane when exposed to allergens. In contrast, nonallergic rhinitis (NAR) refers to a condition of chronic symptoms of nasal congestion and rhinorrhea, unrelated to a specific allergen.[1] Symptoms may be constant or may only present for a brief period of time. Symptoms may develop and resolve year-round. NAR can be divided into acute rhinitis, chronic rhinitis, atrophic rhinitis, and vasomotor rhinitis. NAR was previously referred to as nonallergic vasomotor or vasomotor rhinitis but was renamed because of a lack of evidence showing a vascular origin. The pathophysiology of NAR is complex and mainly unknown.

Epidemiology and Etiology

NAR is thought to be associated with dysregulation of sympathetic, parasympathetic, and nociceptive nerves innervating the nasal mucosa. Rhinitis affects roughly 20% of the population of industrialized countries.[2] Annual healthcare costs for this average $1.9 billion in the United States. Symptoms occur most commonly between 30 and 60 years of age and affect women more than men.[2]

Clinical Presentation and Diagnosis

KEY CONCEPT NAR is clinically diagnosed by performing a complete medical history, physical examination, and diagnostic testing to rule out other possibilities.[3] The most important factor in attaining a proper diagnosis of NAR is a comprehensive medical history and complete physical. Common symptoms that present with both allergic rhinitis (see Chapter 65) and NAR are headache, facial pressure, postnasal drip, coughing, and throat clearing.[3-5] Environmental triggers may also affect NAR, such as strong odors, cold air exposure, alcohol, tobacco smoke, and/or spicy foods to name a few.[6] If a skin test is performed, patients will typically have a negative skin test and serum antibodies for relevant allergens.[6]

Treatment

▶ *Desired Outcomes*

Minimize or prevent symptoms and prevent long-term complications.

▶ *General Approach to Treatment*

The best overall treatment of NAR is the avoidance of an identified trigger while utilizing medical therapy as an adjunct option. Management of NAR first requires educating the patient on avoiding environmental triggers. Once the causative allergens and the specific symptoms are identified, management consists of three possible approaches: allergen avoidance, nonpharmacologic therapy, and pharmacotherapy for prevention or treatment of symptoms. Limiting exposure to factors such as perfumes, tobacco, spicy foods, and various cleaning items may significantly reduce symptoms. A stepwise approach is implemented when using pharmacologic agents.[1]

▶ *Nonpharmacologic Therapy*

Avoiding environmental triggers, preventing poor air quality in home, avoidance of offending allergen, avoidance of tobacco smoke, avoidance of house dust mites, and saline rinses are nonpharmacologic options to utilize for treatment of NAR.

▶ *Pharmacologic Therapy*

Generally, patients with chronic NAR are less responsive to pharmacologic therapy than those with allergic rhinitis. Topical agents often have better efficacy in these patients compared to oral formulations. Typically, treatment avoids oral agents. **KEY CONCEPT** Use

Patient Encounter 1

LJ is a 39-year-old man who presents with a runny nose, congestion, sneezing, itchy eyes for the past 2 weeks. He states that he has to blow his nose several times throughout the day and that his mucus is clear. He denies any sinus pressure and cough. Upon a thorough workup, the patient does not have any triggers that produces these symptoms.

Past medical history:

- Hypertension
- Diabetes
- GERD

Social history:

- Alcohol use: 1 to 2 drinks/week
- Tobacco: denies (wife smokes)
- Illicit drug use: denies

Which symptoms does LJ present to suggest nonallergic rhinitis?

What environmental or medical risk factors may contribute to LJ's symptoms?

What nonpharmacologic therapies should be recommended for this patient?

What pharmacologic therapies should be recommended for this patient?

a stepwise pharmacologic approach for management of NAR (Table 64–1). Topical nasal corticosteroids are often first-line treatment, especially for those with congestion and obstruction.[1,7] Topical anticholinergics, such as ipratropium, may be used as first line for those experiencing rhinorrhea.[1,7] Topical antihistamines have a limited role in NAR. However, they may be helpful in patients with rhinorrhea and nasal congestion.[1,7]

Outcome Evaluation

Major outcomes to evaluate include quality of life, the efficacy and tolerability of treatment, and patient satisfaction. Nasal symptom scores may be utilized to assess outcomes and health-related quality of life. Patient-reported instantaneous and reflective total nasal symptom scores have been used to assess the level of efficacy of

Table 64–1

Pharmacologic Doses of Medications for Nonallergic Rhinitis[1,4,5,7]

Drugs	Brand Names	Dosages	Special Populations	Adverse Effects
Topical Antihistamines				
Azelastine	Astepro	1–2 sprays twice daily	Pediatrics: 5–11 years: 1 spray twice daily	Headache, drowsiness
Olopatadine	Patanase	2 sprays twice daily	Pediatrics: 6–11 years: 1 spray twice daily	
Topical Decongestants				
Oxymetazoline (OTC)	Afrin, various	2–3 sprays twice daily		Epistaxis, headache, cough, pharyngitis, rhinitis medicamentosa
Phenylephrine (OTC)	Various	2–3 sprays every 4 hours	Pediatrics: > 12 years: 0.25%–0.5% 2–3 sprays every 4 hours 6–12 years: 0.25% 2–3 sprays every 4 hours 2–6 years: 0.125% 1 drop every 2–4 hours	
Intranasal Steroid				
Beclomethasone	Beconase AQ, Qnasl	1–2 inhalations in each nostril twice daily (Beconase AQ) 2 inhalations (160 mcg) in each nostril once daily (Qnasl)	Pediatric: Beconase AQ: 6–11 years: 1 inhalation in each nostril twice daily Qnasl: 4–11 years: 1 inhalation (40 mcg) in each nostril once daily	
Budesonide	Rhinocort Aqua	1 spray each nostril daily; max: 4 sprays/day		
Fluticasone (OTC)	Flonase, various	2 sprays in each nostril once daily	Pediatrics: > 4 years: 1 spray in each nostril daily (Flonase)	
Topical Antimuscarinics				
Ipratropium	Atrovent	2 sprays in each nostril 2–4 times a day	Pediatrics: 5–11 years: 2 sprays in each nostril 2–3 times a day	Epistaxis, nasal drying

Data from Lexi-Drugs Online™. Lexi-Comp Online™. Hudson, OH: Lexi-Comp, Inc.; 2017. Available from: http://online.lexi.com.proxy.hsc.unt.edu. Accessed August 7, 2020.

Patient Care Process: Nonallergic Rhinitis

Collect information:

- Duration of symptoms
- Any concomitant signs and symptoms
- Medication list
- Past medical history (eg, other conditions, medications trialed in past, triggers to allergens)
- Social history (eg, smoking history/exposure to secondhand smoke, occupation)
- Perform physical examination
- Perform skin prick test, if allergic rhinitis suspected

Assess information:

- Determine whether the rhinitis is allergic or nonallergic.
- Determine whether the rhinitis is acute or chronic.
- Assess potential causes of NAR and identify any underlying conditions.

Develop a care plan:

- Select nonpharmacologic therapy (eg, avoiding environmental triggers, preventing poor air quality in home, avoidance of offending allergen, avoidance of tobacco smoke, avoidance of house dust mites, and saline rinses).
- If symptoms do not resolve with nonpharmacologic therapy, select pharmacologic treatment targeted toward the predominant symptom (eg, corticosteroids for congestion and obstructive symptoms, anticholinergic medications for rhinorrhea, antihistamines for rhinitis).

Implement a care plan:

- Educate the patient regarding nonpharmacologic treatment for NAR.
- Counsel patients regarding any new medications used to treat NAR.
- Counsel patient when to follow-up if symptoms do not resolve.

Follow-up:

- Monitor for resolution of NAR.

treatment. Instantaneous scores refer to assessment of symptoms within 1 hour or less. Reflective scores refer to assessment of symptoms over the 12 hours prior to the recording of the score. Scores are given on a 0 to 3 scale, with 0 being no symptoms, 1 being mild symptoms, 2 being moderate symptoms, and 3 being severe symptoms. The main goal is to minimize or prevent symptoms, and success will be driven by a collaborative effort with the patient and the clinician.

POSTNASAL DRIP/UPPER AIRWAY COUGH SYNDROME

Introduction

Postnasal drip is the drainage of secretions from the nose or paranasal sinuses into the pharynx.[8] The ACCP Clinical Practice Guidelines recommends the term upper airway cough syndrome (UACS) be used, rather than postnasal drip, for patients with chronic cough related to upper air abnormalities.[8] UACS includes all upper airway abnormalities causing cough. Increased mucous production that drips to the back of the throat may be the leading cause. Cough reflex is related to inflammatory conditions of the nose and sinuses.

Pathophysiology

Clinical studies have suggested that the pathogenesis of cough from UACS is due to the mechanical stimulation of the afferent limb of the cough reflex in the upper airway.[9] Stimulation by secretions from the nose and sinuses may cause cough. Patients with UACS-induced cough may have a more sensitive cough reflex in the upper airway. Causes of UACS may include colds, flu, allergies, sinus infection or sinusitis, nasal obstruction, rhinitis (allergic, nonallergic, chronic), pregnancy, medications, deviated septum, changes in weather, certain foods, and fumes.

Clinical Presentation and Diagnosis

The clinical presentation of patients with UACS includes cough, drainage in throat, nasal congestion, and nasal discharge. Patients may report having the sensation of having something drip down the throat or frequent throat clearing.[8,9] Medical histories often have findings of an upper respiratory illness or wheezing. Diagnosis of UACS-induced cough should be determined by consideration of symptoms, physical examination, radiographic findings, and response to therapy.

Treatment

▶ *Desired Outcomes*

Minimize or prevent symptoms of cough and respiratory issues.

▶ *General Approach to Treatment*

KEY CONCEPT The general approach to treatment of UACS is to treat the patient's presenting symptoms as well as any underlying causes. Identifying UACS may be difficult. Respiratory tract infections are the most common cause of acute cough. Chronic cough may stem from asthma, UACS, bronchitis, and gastroesophageal reflux disease (GERD). If a patient presents with cough with concurrent dyspnea, the patient should be evaluated by a medical provider.

▶ *Nonpharmacologic Therapy*

Options for patients in treatment of UACS are nasal saline irrigation, vaporizers, humidifiers, reduction of exposure to dust, and utilization of HEPA air filters. If patient has chronic cough that is related to GERD, options include diet modifications for weight loss in overweight or obese patients, elevating the head of the bed and avoiding meals within 3 hours of bedtime.

Patient Care Process: Postnasal Drip/Upper Airway Cough Syndrome

Collect information:

- Duration of cough, drainage in throat, nasal congestion, and nasal discharge
- Any concomitant signs and symptoms
- Medication list
- Past medical history (eg, other conditions, medications trialed in past)
- Social history (eg, smoking history/exposure to secondhand smoke, occupation)
- Perform physical examination

Assess the information:

- Determine whether cough contributed to conditions or triggers (eg, colds, flu, allergies, sinus infection or sinusitis, nasal obstruction, pregnancy, medications, deviated septum, changes in weather, certain foods, and fumes).
- Assess potential causes of cough and identify any underlying conditions.

Develop a care plan:

- Select nonpharmacologic therapy (eg, nasal saline irrigation, vaporizers, humidifiers, reduction of exposure to dust, and utilization of HEPA air filters).
- If symptoms do not resolve with nonpharmacologic therapy, select pharmacologic treatment (eg, intranasal glucocorticoids, oral and nasal antihistamines, oral decongestants, or oral leukotriene receptor antagonists).

Implement the care plan:

- Educate the patient regarding nonpharmacologic treatment for UACS.
- Counsel patients regarding any new medications used to treat UACS.
- Counsel patient when to follow up if symptoms do not resolve.

Follow-up: monitor and evaluate

- Monitor patient for resolution of UACS.
- Reevaluate the patient if UACS does not improve or worsens.

► *Pharmacologic Therapy*

For patients experiencing cough attributed to allergic rhinitis, empiric therapy of intranasal glucocorticoids may be effective in symptom reduction within the first few days. However, maximal effect may take up to 2 weeks to achieve. Therapy is continued for approximately 3 months if patient responds.[10] Other options for cough due to allergic rhinitis includes oral and nasal antihistamines, oral decongestants, oral leukotriene receptor antagonists, and other agents. See Chapter 65 for more details on the medications and dosing.

When cough may be linked to nonallergic rhinitis, an oral first-generation antihistamine or a combined antihistamine decongestant may be trialed. First-generation antihistamines are preferred over second-generation antihistamines due to the stronger anticholinergic effect.

Other options include intranasal azelastine, glucocorticoid, and ipratropium. Lack of improvement after 1 to 2 weeks of empiric therapy suggests UACS is not the cause of cough.[10]

Outcome Evaluation

Patients may have more than one cause for chronic cough and may only resolve when all causes treated concurrently. Treatments for cough may be stopped once cough has resolved while closely monitoring and observing the patient.

DYSGEUSIA

Introduction

Dysgeusia refers to taste and smell disorders that can lead to decreased quality of life due to decreased detection of aroma and flavors of foods, as well as fragrances in the environment.[1] Consequences of dysgeusia include consuming spoiled foods, injury or death from delayed detection of environmental hazards, and reduced nutritional intake.[11] Dysgeusia may also be a symptom related to COVID-19; please refer to Chapter 74 for more information.

Epidemiology and Etiology

A study performed by the United States National Health and Nutrition Examination Survey (NHANES) showed that 12.4% of US adults 40 years or older had some degree of olfactory dysfunction.[12] Advanced age was associated with increasing prevalence of both taste and smell disorders. Dysgeusia is more prevalent in elderly patients who are hospitalized and institutionalized (13.9%) than in those living in the community (3.2%).[13] Medications that can cause dysgeusia are macrolides, antimycotics, fluoroquinolones, protein kinase inhibitors, angiotensin-converting enzyme (ACE) inhibitors, statins, and proton pump inhibitors (PPIs).

Clinical Presentation and Diagnosis

Patients may be reluctant to disclose a history of smell impairment unless there is a specific complaint. Underreporting of this phenomenon may lead to undiagnosed dysgeusia and nontreatment. Symptoms may include a decreased ability to taste and smell. Patients may also complain of having an unpleasantly sweet, bitter, metallic, or salty taste. Patients who experience any of these symptoms warrant further evaluation. Diagnosis may include a smell or taste test, imaging, laboratory studies, and a thorough history and physical examination.[11] Office smell or taste tests such as the University of Pennsylvania Smell Identification Test (UPSIT) may identify symptoms associated with dysgeusia. Other tests include threshold, discrimination, identification test (TDIT), chemosensory tests, butanol threshold tests, whole-mouth taste tests, spatial tests, flavor discrimination tests, and somatosensory tests.

Treatment

► *Desired Outcomes*

The main goal of treatment is to restore the sense of taste and smell, if able.

► *General Approach to Treatment*

Treatment depends on etiology; nasal sinus diseases are the most common olfactory disorders to cause dysgeusia. Nasal sinus

Patient Care Process: Dysgeusia

Collect information:

- Duration of dysgeusia
- Any concomitant signs and symptoms
- Medication list
- Past medical history (eg, other conditions, medications tried in past)
- Social history (eg, smoking history/exposure to secondhand smoke, alcohol use, occupation)
- Physical examination

Assess the information:

- Determine whether loss of taste and smell can be attributed to medications or conditions (eg, advanced age).
- Identify potential causes of dysgeusia and identify any underlying conditions.

Develop a care plan:

- Select nonpharmacologic therapy (eg, removing exposure to allergens, desensitization therapy, surgery to remove offending obstruction when medical therapy for nasal and sinus disease ineffective, mouth rinses, and smell training).
- Select pharmacologic treatment (eg, intranasal glucocorticoids, antihistamines, or leukotriene inhibitors) if symptoms do not resolve with nonpharmacologic therapy.

Implement the care plan:

- Educate the patient regarding nonpharmacologic treatment for dysgeusia.
- Counsel patients regarding any new medications used to treat dysgeusia.
- Counsel patient when to follow up if symptoms do not resolve.

Follow-up: monitor and evaluate

- Monitor patient for resolution of dysgeusia.
- Reevaluate the patient if dysgeusia does not improve or worsens.
- Refer to specialist if symptoms persist.

diseases may be either obstructive or nonobstructive. Obstructive disorders require relief of the obstruction and the treatment of infection, if present in the patient. Patients without obstruction may have damage to olfactory receptors due to inflammation. Physicians should refer patients to a smell and taster disorder center or to an otolaryngologist if the patient's quality of life is significantly decreased.

▶ *Nonpharmacologic Therapy*

Nonpharmacologic therapy consists of removing exposure to allergens, desensitization therapy, surgery to remove offending obstruction when medical therapy for nasal and sinus disease is ineffective, mouth rinses, and smell training.

▶ *Pharmacologic Therapy*

Intranasal glucocorticoids are useful in treatment of dysgeusia with rhinitis, nasal edema, and polyps.[11] Examples include two sprays in each nostril twice daily of either beclomethasone dipropionate 42 mcg, flunisolide 25 mcg, or mometasone furoate 50 mcg. Antihistamines may be useful for patients experiencing dysgeusia accompanied with allergic rhinitis (see Chapter 65 for options). Leukotriene inhibitors, such as montelukast 10 mg by mouth once daily, are beneficial in patients with nasal polyps, anosmia, and hyposmia.[14]

Outcome Evaluation

Patients may recover from dysgeusia when sense of taste and smell recovers. Improvements may be seen after treatment is initiated if damage is reversible. Performing tests above to assess sense of taste and smell will identify improvement.

EPISTAXIS

Introduction

Epistaxis refers to the loss of blood from tissues that line the inside of the nose. Anterior bleeds are the most common at 90%, which occurs in the Kiesselbach plexus, a vascular watershed area of nasal septum.[15] Posterior bleeds may lead to more severe cases which is caused by the posterolateral branches of the sphenopalatine artery.[15]

Epidemiology and Etiology

Causes of epistaxis may be due to trauma, medications (eg, anticoagulants, nonsteroidal anti-inflammatory drugs [NSAIDs], and nasal steroids), bleeding disorders, vascular conditions, neoplasms, hypertension, alcohol, allergies, or heart failure.[15,16] Patients may experience epistaxis at any age; however it is common in patients under the age of 10 and patients between 45 and 65 years of age.[15] Hospitalizations increase with age. Seasonal changes may also affect the incidence of epistaxis. Factors include incidence of upper respiratory infections, allergic rhinitis, and mucosal changes associated with fluctuations in temperature and humidity.[16]

Clinical Presentation and Diagnosis

Nosebleeds will be evident by performing an assessment of the patient. Patients may undergo coagulation studies, an initial tamponade procedure, or physical examinations to identify causes. Distinguishing between anterior and posterior bleeds may be performed by placing bilateral anterior nasal packing and them examining the patient. Continued bleeding may suggest a posterior bleed which will require hospitalization with cardiac monitoring.

Treatment

▶ *Desired Outcomes*

Locating the source of bleeding and stopping the bleeding to prevent further complications.

▶ *General Approach to Treatment*

Initial management includes compression of nostrils and plugging the affected nostril with cotton or gauze. The patient

Patient Care Process: Epistaxis

Collect information:

- Severity and duration of epistaxis
- Any concomitant signs and symptoms
- Medication list
- Past medical history (eg, other conditions)
- Social history (eg, smoking history/exposure to secondhand smoke, alcohol use, occupation)
- Perform physical examination

Assess the information:

- Determine whether nosebleeds are caused by medications or conditions (eg, anticoagulants, NSAIDs, nasal steroids, bleeding disorders, vascular conditions, neoplasms, hypertension, alcohol, allergies, or heart failure).
- Assess potential causes of epistaxis and identify any underlying conditions.
- Determine whether bleeding requires hospitalization.

Develop a care plan:

- Initially select compression of nostrils and plugging affected nostril with cotton or gauze.
- If above does not control bleeding, select nasal packing, balloon catheters, electrocautery, thrombogenic foams and gels, vasoconstriction with pharmacologic agents, or tranexamic acid if patient has a refractory case by a medical professional.

Implement the care plan:

- Educate the patient regarding when to seek medical attention.
- Educate the patient on initial management of compression and plugging of nostrils.

Follow-up: monitor and evaluate:

- Monitor patient for resolution of epistaxis.
- Monitor if hospitalization is required.

should then sit up straight and lean forward slightly. Do not have the person lie down or tilt the head backward. With thumb and index finger, firmly pinch the nose just below the bone up against the face. Apply pressure for 5 minutes. If bleeding continues after 5 minutes, repeat process. **KEY CONCEPT** Call a healthcare provider if a nosebleed does not stop after 10 minutes of home treatment, if the patient is having difficulty breathing, uses blood thinners, or has a nosebleed after a severe head injury.[16]

▶ *Nonpharmacologic Therapy*

Nasal packing, which includes nasal tampons or gauze packing, is a common option for treatment of epistaxis. This includes ribbon gauze impregnated with petroleum jelly or polymyxin B-bacitracin zinc-neomycin ointment, or petroleum jelly and 3% bismuth tribromophenate (Xeroform). Nasal balloon catheters are also often utilized, but mainly in more severe posterior bleeding. Electrocautery is used in larger vessels that are found to be the cause of the bleed. Electrocautery is utilization of a special electrical tool to cauterize blood vessels in the nose. Electrocautery must be performed with caution to avoid excessive destruction of health tissues.

▶ *Pharmacologic Therapy*

Oxymetazoline nasal spray often is utilized to manage single anterior bleeds due to its vasoconstriction properties. Patients may utilize oxymetazoline two to three sprays in each nostril twice daily. Vasoconstriction using 4% cocaine solution or phenylephrine 0.25% to 1% solution topically may manage single anterior bleeds, but use is limited. Cocaine is a controlled substance and with cardiovascular effects. Phenylephrine also has cardiovascular effects when absorbed systemically. If bleeding is more severe, local anesthetics such as 4% cocaine or tetracaine or 2% lidocaine solution should be used. Lastly tranexamic acid may be utilized in refractory cases. A Merocel tampon saturated with 500 mg of the IV formulation of tranexamic acid is used to treat this form of epistaxis.[16] Thrombogenic foams and gels such as Quixil fibrin glue, Floseal thrombin gel, Surgicel, Gelfoam, and Avitene are all products that may be used for controlling epistaxis.[16]

Outcome Evaluation

Determining the origin of bleeding is paramount to treatment success. Nosebleeds that are managed in the outpatient setting will stop after proper treatment. If origin is suspected to be posterior, hospitalization is required.

COLD SORES

Introduction, Epidemiology, and Etiology

Cold sores are reoccurring, painful lesions caused by the herpes simplex virus type 1 (HSV-1) and most commonly present on the vermillion border of the lip. Approximately 48% of the US population is seropositive for HSV-1, which is usually transmitted via oral secretions or direct contact with a lesion.[17] Cold sores are the most common manifestation of HSV-1.

Pathophysiology

Upon initial infection, HSV-1 rapidly replicates at the site of contact, which may lead to illness (including a lesion) within days of transmission. It resides in the sensory neurons where it remains for life. Although HSV-1 lies dormant for most of the time, cold sores can reoccur upon viral reactivation. Reactivation is often associated with identifiable triggers including sun exposure, stress, or immunodeficiency.[18]

Clinical Presentation and Diagnosis

Cold sores are often first identifiable by a prodrome tingling sensation at the site of lesion development.[18] If left untreated, the lesion rapidly develops leading to pain and inflammation. Blisters often form and lyse, creating ulceration, scabbing, and finally healing. The entire process may last up to 2 weeks. Diagnosis occurs via clinical evaluation; however, most patients are capable of self-diagnosis.

Treatment

▶ *Desired Outcomes*

The two primary goals of cold sore treatment are:

1. Shorten the duration of, or eliminate, the lesion while limiting pain or discomfort.
2. If prophylaxis is indicated, reduce lesion reoccurrence to allow for improved quality of life.

Depending on the frequency of virus reactivation, the cold sore severity, and other patient-specific factors, successful treatment can include chronic prophylaxis or episodic treatment with oral antivirals, most commonly acyclovir or valacyclovir. No treatment, in the case of mild cases, is also an acceptable approach.

► *Episodic Treatment*

As-needed antiviral treatment upon onset of symptoms:

- All treatment with antivirals should be initiated as early as possible, ideally during the prodrome phase.
- Appropriate for less frequent reactivation, or if the patient can clearly identify prodrome symptoms.

► *Prophylactic Treatment*

Daily suppressive antiviral treatments are appropriate when:

- Patient does not have prodrome (cannot tell when symptoms are initially appearing).
- Episodes cause significant disfigurement or pain.
- Reoccurrence is associated with significant systemic complications, which could include fever, malaise, or ocular involvement.
- Patient is immunocompromised (eg, HIV, malignancies).
- Patient-specific factors, including quality of life and cost.

► *Nonpharmacologic Therapy*

Avoiding triggers (if easily identifiable) can be moderately successful. Excessive sun exposure is a commonly reported trigger and may be mitigated via sunscreen or SPF lip balm.[19] Additional triggers could include fatigue, stress, trauma to the affected region, or illness. Some triggers (eg, stress or illness) may be more difficult to avoid than others, and pharmacologic therapy may be required.

► *Nonprescription Pharmacologic Therapy*

Numerous over-the-counter (OTC) products containing topical pain relievers (eg, benzocaine, menthol) and skin protectants are marketed as cold sore treatments. Although they may provide symptomatic relief, they are often costly and do not treat the underlying infection. Docosanol prevents viral entry into the host cell and is the only topical antiviral product available OTC. It has demonstrated ability to reduce lesion duration in certain studies, though results are largely inconsistent.[20]

► *Prescription Pharmacologic Therapy*

KEY CONCEPT Oral antivirals, including acyclovir, famciclovir, and valacyclovir disrupt DNA synthesis of the herpes simplex virus and are highly effective for treatment and suppression, especially when started early in the disease course.[20] These agents are well-tolerated and are used first line, especially when the patient reports significant disruption in daily life. While all three oral antiviral medication are equally effective for the episodic treatment of cold sores, acyclovir and valacyclovir are also used regularly for prevention (Table 64–2).[21]

Outcome Evaluation

Episodic treatment with oral antivirals can completely eliminate lesion formation if initiated early enough. However, even if initiated after lesion formation, treatment can significantly lessen the cold sore duration, discomfort, and severity. No routine monitoring is recommended with episodic treatment.

Daily prophylaxis is successful if cold sore reactivation is reduced to a level acceptable with the individual patient's lifestyle. Assess hepatic and renal function at least annually.

XEROSTOMIA AND SIALORRHEA

Introduction, Epidemiology, and Etiology

Xerostomia (dry mouth) is a nonspecific symptom resulting from salivary gland hypofunction.[22] Hypofunction may be disease related. Sjögren syndrome, for example, is an autoimmune disease

Table 64–2

Pharmacologic Treatment Used for Cold Sores

Drug	OTC/Rx	Episodic	Prophylaxis	Pros and Cons
Oral Antivirals				
Acyclovir	Rx	**Adults:** 400 mg TID for 5–10 days **Peds:** 20 mg/kg TID for 5–10 days. Max 400 mg/dose	400 mg BID	• Low cost • Frequent dosing • Safe for chronic suppression
Famciclovir	Rx	**Adults:** 500 mg orally twice daily for 5–10 days (initial) **OR** 1500 mg once (recurrent) **Peds:** Dosing not established	N/A	• Simple dosing regimen • Higher cost, reduced availability
Valacyclovir	Rx	**Adults/Peds:** 2 g BID for 1 day	500 mg daily	• Simple dosing regimen • Higher cost • Safe for chronic suppression
Topical Antivirals				
Acyclovir 5% ointment/cream	Rx	Apply 5 times daily for 4 days	N/A	• Limited effectiveness
Docosanol 10% cream	OTC	Apply 5 times daily until healed	N/A	• No prescription required • Consistent effectiveness not established • Higher cost
Penciclovir 1% cream	Rx	Apply every 2 hours while awake for 4 days	N/A	• Limited effectiveness • Frequent dosing

Patient Care Process: Cold Sores

Collect information:

- About the onset of the cold sore, including possible triggers
- About the history related to cold sores (eg, how frequently do cold sores occur, severity, and what treatment has been tried)
- About past medical history (eg, is the patient immunocompromised)
- About social history (eg, how does the cold sore affect the patient's quality of life)

Assess the information:

- Determine whether the patient will require episodic treatment, preventive treatment, or no treatment.
- Assess potential triggers and evaluate nonpharmacologic way to prevent cold sore onset.

Develop a care plan:

- If patient presents with a recently active or oncoming cold sore, initiate oral antiviral (valacyclovir, acyclovir, or famciclovir).

Implement the care plan:

- Recommend avoidance of triggers, if identifiable.
- Educate the patient to take the oral antiviral during the prodrome phase of the cold sore, if possible.

Follow-up: monitor and evaluate:

- Monitor patient for complete lesion healing.
- Discuss preventive therapy with oral antivirals (acyclovir or valacyclovir), if cold sores occur frequently, are severe, or greatly affect the patient's quality of life.

that reduces salivary gland function directly. Dry mouth, however, is also commonly a side effect of medications, including anticholinergics, opioids, antidepressants, and many others (Table 64–3). Prolonged salivary gland hypofunction leads to deterioration of dental hygiene including dental caries, oral candidiasis, halitosis, and gingivitis. Dry mouth resulting from medication use must also be commonly managed within a palliative care setting.

Sialorrhea (drooling) is also a nonspecific symptom that may result from salivary gland dysfunction; however, it is more commonly attributed to neuromuscular dysfunction.[23] Patients at the end of life, as well as those with Parkinson disease, cerebral palsy, stroke, and amyotrophic lateral sclerosis (ALS) are most likely to experience sialorrhea. Nevertheless, antipsychotics (particularly clozapine) and benzodiazepines can contribute to drooling as well. The primary risk associated with drooling is aspiration pneumonia.

Upon presentation for drooling or dry mouth, a thorough history and medication reconciliation must be obtained.

Table 64–3

Medications That Commonly Cause Dry Mouth

Medication Class	Examples of Medications
Anticholinergic medications	Diphenhydramine (Benadryl), oxybutynin (Ditropan), solifenacin (Vesicare), tolterodine (Detrol)
Antidepressants	**SNRIs**—duloxetine (Cymbalta), venlafaxine (Effexor) **SSRIs**—sertraline (Zoloft), fluoxetine (Prozac), paroxetine (Paxil), citalopram (Celexa), escitalopram (Lexapro) **Tricyclics**—amitriptyline (Elavil), nortriptyline (Pamelor)
Antipsychotics	**Atypical**—aripiprazole (Abilify), olanzapine (Zyprexa), quetiapine (Seroquel) **Typical**—haloperidol (Haldol), chlorpromazine (Thorazine), fluphenazine (Prolixin)
Opioids	Fentanyl (Duragesic), tramadol (Ultram), buprenorphine (Subutex), morphine (MS Contin)
Muscle relaxants	Baclofen (Lioresal), tizanidine (Zanaflex), cyclobenzaprine (Flexeril)

Treatment

▶ *Xerostomia Overview*

KEY CONCEPT A critical first step in treating xerostomia should include a thorough review of medications. Elimination of an offending agent should take priority, if possible. Table 64–3 includes a list of common medications that contribute to dry mouth. If elimination of the offending agent is not possible, or xerostomia is not related to medication, nonpharmacologic and pharmacologic options are available and will be discussed below (Table 64–4).

▶ *Sialorrhea Overview*

For sialorrhea, the medications should also be reviewed, primarily looking for clozapine use. Other atypical antipsychotics and benzodiazepines may also contribute to sialorrhea. If medication use is ruled out as the primary cause, treatment should be centered around pharmacologic management, especially if aspiration is a risk. Pharmacologic management is outlined in Table 64–4.

Desired Outcomes

▶ *Xerostomia*

Treatment of xerostomia aims to alleviate symptoms and prevent complications such as dental caries, periodontal disease, halitosis, salivary gland calculi, dysphagia, and oral candidiasis.

▶ *Sialorrhea*

Treatment of sialorrhea aims to control drooling to maintain quality of life and prevent aspiration.

Nonpharmacologic Therapy

Oral hygiene minimizes the long-term risks associated with dry mouth and also decreases the risks of aspiration associated with sialorrhea. Appropriate dental care needs to be prioritized and should include[22]:

1. Brushing teeth with fluoride toothpaste at least twice per day. For those at high risk of dental cavities use fluoride 1.1% gel daily. Alternatively, 5% fluoride varnish or 38% silver diamine fluoride can be applied at a dentist's office every 3 months.
2. Using alcohol-free mouthwash to decrease bacteria and eliminate halitosis.

Table 64–4

Pharmacologic Treatments for Xerostomia and Sialorrhea[24]

Indication	Medication	Dosage Form	Dosing Regimen	Mechanism
Xerostomia	Artificial saliva	**Spray** (Aquoral, Mouth Kote, Oasis Spray) **Orally disintegrating tablet or lozenge** (SalivaSure, Caphosol, Salivate Rx) **Liquid** (Biotene, Numoisyn, Oasis Mouthwash) **Gel** (Biotene Oral Balance Gel)	Use as needed	Topical lubricant that mimics saliva
Xerostomia (Sjögren syndrome)	Cevimeline (Evoxac)	Tablet	30 mg orally TID	Cholinergic agonist
	Pilocarpine (Salagen)	Tablet	5 mg orally QID	Cholinergic agonist
Sialorrhea	Glycopyrrolate (Cuvposa, Glycate)	Oral liquid Injection	0.1 mg sublingually as needed OR 0.2 mg subcutaneously every 4–6 hours (palliative care)	Anticholinergic agent
	Atropine (Isopto Atropine)	Ophthalmic 1% drops (used orally)	1–2 drops placed under the tongue as needed	Anticholinergic agent
	Tropicamide (Mydriacyl)	Ophthalmic 1% drops (used orally)	1–2 drops placed under the tongue as needed	Anticholinergic agent

3. Appropriate denture care, if applicable.
4. Avoid carbonated soft drinks or other sugary foods/beverages where possible.

Proactiself-care to stimulate saliva secretion also include the following:

1. Ensure hydration with water or sugar-free liquids. Avoid caffeine, nicotine, or alcohol.
2. Chew on sugar-free gum or suck on sugar-free hard candies/lozenges.
3. Avoid "mouth-breathing" by making sure the nasal passage is clear.
4. Use humidifiers in dry environments if necessary.

Pharmacologic Therapy

▶ *Xerostomia*

Pharmacologic therapy for dry mouth should be pursued if offending medication cannot be reduced or discontinued, and if nonpharmacologic therapy is inadequate. Artificial saliva is most commonly used, is available over the counter, and is associated with little risk.[25] Dry mouth that is a result of medication use rarely requires cholinergic agonists (pilocarpine or cevimeline), however they are likely to be required in the setting of Sjogren syndrome.[22] Doses for pilocarpine and cevimeline can be found in Table 64–4.

▶ *Sialorrhea*

Atropine ophthalmic drops, up to two drops four times daily, used sublingually are first-line treatment for sialorrhea, especially in the setting of palliative care. If atropine is unavailable, tropicamide ophthalmic drops should be used. Additional options include oral anticholinergic medications including glycopyrrolate, scopolamine, or benztropine.[23]

Outcome Evaluation

Treatment of dry mouth and drooling should be evaluated regularly by the patient's primary care and dental teams. Evaluation should include swallowing assessment, physical inspection, and presence of infection (candidiasis for dry mouth or aspiration pneumonia for drooling). Successful treatment involves improving patient's quality of life and elimination of complications.

Patient Care Process: Medication-Related Xerostomia

Collect information:

- Accurate medication list
- Past medical history, including onset and duration of xerostomia

Assess the information:

- Determine which medications are most likely to cause xerostomia.

Develop a care plan:

- Discontinue or reduce the dose of medications that could exacerbate xerostomia, if possible.
- Select nonpharmacologic options (eg, chewing sugar-free gum) to stimulate saliva.
- If medications are unable to change, and nonpharmacologic therapy is ineffective, select appropriate pharmacologic treatment, beginning with artificial saliva products.

Implement the care plan:

- Educate the patient regarding any nonpharmacologic therapies.
- Educate regarding the importance of dental hygiene, and ensure the patient is engaged with a dentist, if applicable.
- Monitor for worsening of other disease states if treating medication is discontinued or reduced.

Follow-up: monitor and evaluate:

- Monitor patient for improved salivary production.
- Reevaluate the patient if xerostomia does not improve or worsens.

APHTHOUS STOMATITIS (CANKER SORES)

Introduction, Epidemiology, and Etiology

Canker sores are common, recurrent, and painful ulcerative lesions that develop on the oral mucosa. In North America, about 20% of people experience canker sores. While sores may develop infrequently in most, some experience near continuous ulcer activity. The sores tend to occur most frequently in younger individuals and typically occur less and less as one ages.

Pathophysiology

The cause of canker sores is largely unknown, though are thought to occur as a result of immune dysregulation.[26] However, it is likely a combination of numerous factors that may include food allergies, micronutrient deficiencies, and infection. There is evidence that trauma (eg, chewing on insides of cheeks) and stress are triggers.[27]

Clinical Presentation and Diagnosis

Diagnosis is made via physical examination, as canker sores are distinct, round, ulcerations with an erythematous rim surrounding a yellowish center. They are painful and may make eating or drinking uncomfortable. Typically, they are between 3 and 6 mm in diameter. Ulcers are classified into three groups[28]:

1. Minor ulcers, less than 1 cm, usually 3 to 5 mm (most common).
2. Major ulcers greater than 1 cm.
3. Herpetiform ulcers, 1 to 2 mm, present in clusters.

The disease course from onset to healing lasts between 10 and 14 days.

Treatment

Unlike cold sores, there is not a widely effective treatment option available for canker sores. Approach to management should focus on prevention, if possible, and symptomatic management. Most canker sores do not require treatment and are self-limiting.

Patient Encounter 2

A community pharmacist is approached in the store by a 30-year-old woman who has questions about treatments for a "painful and embarrassing cold sore." Upon observation the pharmacist recognizes the cold sore is quite noticeable, has already blistered, lysed, and has scabbed over. The patient reveals that she is a saleswoman, and the cold sore has decreased her confidence when interacting with potential clients. She has been battling this cold sore for 8 days.

Realizing that this cold sore is diminishing this patient's confidence, and possibly damaging her career, what are the most important questions to ask?

What treatment strategy is appropriate to recommend for this patient's current cold sore?

What strategy should be discussed with this patient for cold sore reoccurrences?

▶ *Desired Outcomes*

The primary goals of canker sore treatment are to:

1. Reduce lesion duration and limit pain or discomfort.
2. Reduce lesion frequency to allow for improved quality of life.

▶ *Nonpharmacologic Therapy*

Similar to cold sores, avoidance of triggers (if easily identifiable) can be moderately successful. Avoiding trauma (chewing on inside cheek, dental restorations, hard candies) should be prioritized. Maintaining appropriate dental hygiene may also reduce reoccurrence. In the case of an active ulcer, acidic and spicy foods can increase irritation and should be avoided if possible.

▶ *Pharmacologic Therapy*

Pharmacologic therapy is not curative and is aimed to reduce duration and relieve pain.

Pain Relief Topical anesthetics, namely lidocaine 2% viscous solution, are first-line pain relievers and are applied directly to the lesion. Additional topical anesthetics, including benzocaine and dyclonine as mouth rinses, gels, or lozenges are widely available over the counter.

First-Line Treatment KEY CONCEPT Moderate-to-high-potency topical corticosteroids contribute to quicker ulcer healing and are first-line treatment for individuals who require disease-modifying treatment.[29] These should be initiated as early as possible within the disease course. Dexamethasone elixir (0.5 mg/5 mL) is commonly swished for 5 minutes and spit four times daily. Other high- or mid-potency topical corticosteroids including clobetasol 0.05% ointment and triamcinolone 0.1% may be applied directly to the lesions three times daily. Notably, the ulcer should be thoroughly dried with gauze prior to application.[29]

Oral treatment in Complex Aphthosis Oral treatment should be reserved for complex cases, including lesions greater than 1 cm in diameter and when oral ulcerations occur simultaneously with genital ulcerations. The drug of choice should be oral prednisone 20 to 40 mg daily for up to 7 days.[30] Alternatively, dapsone 25 to 50 mg daily or colchicine 0.6 mg daily has been used, though there is limited evidence demonstrating their effectiveness. Oral prednisone, in combination with the previously mentioned topical corticosteroids, is a first-line treatment.

Treatment of Secondary Infection Although the pathophysiology of canker sores is unlikely of infectious origin, secondary candida infection is possible in severe cases. For this, chlorhexidine rinse, nystatin, or clotrimazole troches are indicated.

Outcome Evaluation

Most canker sores completely resolve without treatment after 10 to 14 days. In cases where topical corticosteroids are needed, no routine monitoring is recommended.

COUGH

Introduction

Cough is the single most common complaint for which patients seek medical care in the primary care setting. It can present due to a number of underlying causes of either infectious or noninfectious origin.

Patient Care Process: Canker Sores

Collect information:

- Onset of the canker sore.
- History related to canker sores (eg, how frequently do they occur, severity, and what treatment has been tried).
- How does the canker sore affect the patient's quality of life?

Assess the information:

- Determine whether the canker sore will require pain relief, topical treatment, or no treatment.

Develop a care plan:

- Select nonpharmacologic therapy as applicable (eg, avoidance of acidic and spicy foods).
- Select topical pain relievers.
- Select a topical corticosteroid if quality of life is significantly hindered.

Implement the care plan:

- Educate the patient regarding any nonpharmacologic therapies.
- Educate that the canker sore will likely heal without treatment in 10 to 14 days.
- Counsel patient when to follow up if symptoms do not resolve.

Follow-up: monitor and evaluate:

- Monitor patient for resolution of canker sore.
- Follow up as necessary for additional episodes.
- Educate the patient that severity and frequency of canker sores lessen as age increases.

Pathophysiology

Cough is an important defense mechanism that the body uses to clear the airways of excessive secretions and foreign material. A complex sensorimotor reflex arc is activated when cough receptors are irritated by stimuli such as accumulated secretions, postnasal drip, or inflammation.[31]

Clinical Presentation and Diagnosis

Cough is classified based on duration of symptoms (Table 64–5). When assessing cough, it is important to gather an accurate patient history with information regarding any environmental or occupational factors and travel exposures as these may be contributing factors to the cough. It is also important to assess whether there are any red flags that could possibly indicate a life-threatening condition (eg, hemoptysis, prominent dyspnea, etc.). If present, these should be addressed and evaluated immediately.[32]

Treatment

▶ *Desired Outcomes*

1. Treat the underlying cause of the cough when possible (refer to appropriate chapters in this book for more information).
2. Promote the safe use of OTC products when used for symptomatic treatment of cough.
3. In patients with an ineffective cough, clear the airways of tenacious secretions and prevent complications such as pneumonia.[33]

▶ *General Approach to Treatment*

When treating the underlying cause of cough, recommendations are consistent with guidance for specific disease states. For example, treatment of cough due to upper airway cough syndrome (UACS) should be treated as discussed in the section of this chapter "Postnasal Drip/Upper Airway Cough Syndrome," and treatment of cough due to an upper respiratory tract infection (URTI) should be treated as discussed in Chapter 72. KEY CONCEPT OTC cough and cold products should be safely chosen based on patient-specific factors, preferably with guidance from a healthcare professional. A description of the most common cough medications as well as some patient considerations can be found in Table 64–6.

In pediatric patients, treatment of cough with OTC medications should generally be avoided, especially in those under the age of 2 years. Per the American College of Chest Physicians (CHEST) guidelines, when cough medications are used for pediatric patients

Table 64–5

Common Etiologies for Cough Based on Classifications[33]

Classification	Duration	Possible Causes
Acute	< 3 weeks	**Most common causes** URTI, also known as the common cold **Other causes** Life-threatening diagnoses: pneumonia, severe exacerbation of asthma or COPD, PE, heart failure Non–life-threatening diagnoses: LRTI, asthma, **bronchiectasis**, UACS, COPD
Subacute	3–8 weeks	Same life-threatening and non–life-threatening diagnoses as acute cough Postinfectious cough GERD Bronchitis
Chronic	> 8 weeks	**Most common causes** UACS secondary to rhinosinusitis Asthma NAEB GERD **Other causes** Smoking ACE inhibitors

ACE, angiotensin-converting enzyme; COPD, chronic obstructive pulmonary disease; GERD, gastroesophageal reflux disease; LRTI, lower respiratory tract infection; NAEB, nonasthmatic eosinophilic bronchitis; PE, pulmonary embolism; UACS, upper airway cough syndrome, URTI, upper respiratory tract infection

Table 64–6

Common Medications used for Cough Treatment

Drug	Dosing	Considerations
Antihistamines		
Diphenhydramine (Benadryl)	Oral: 25 mg every 4–6 hours or 50 mg every 6–8 hours as needed	Primarily reduce postnasal drip; do not directly suppress cough
Loratadine (Claritin)	Oral: 10 mg once daily	There are several antihistamines (See Table 64–4), but diphenhydramine (first generation) is commonly used for cough. Second-generation antihistamines, such as loratadine, may be preferred due to less sedating side effects Avoid first-generation antihistamines in elderly patients due to anticholinergic side effects such as sedation, blurry vision, dry mouth, constipation, and urinary retention
Decongestants		
Phenylephrine (Sudafed PE Sinus Congestion)	Oral: 10 mg every 4 hours as needed	Primarily reduce postnasal drip; do not directly suppress cough
Pseudoephedrine (Sudafed Sinus Congestion)	Oral: 30–60 mg every 6 hours as needed	Oral decongestants should not be used for longer than 7 days Use with caution in patients with cardiovascular disease, including hypertension
Opioid Agonists		
Codeine with promethazine (Schedule V controlled substance)	Oral: 5 mL (promethazine 6.25 mg/codeine 10 mg) every 4–6 hours (max 30 mL [promethazine 37.5 mg/codeine 60 mg] per 24 hours)	Effective for cough suppression but used primarily for severe cough due to the risk for respiratory depression Avoid use in pediatric patients < 12 years old
Expectorant		
Guaifenesin XR (Mucinex)	Oral: 600–1200 mg every 12 hours as needed	The primary mechanism of action is to remove mucus by reducing viscosity
Antitussives		
Benzonatate (Tessalon Perles) (Rx only)	Oral: 100–200 mg 3 times daily as needed	There have been reports of serious hypersensitivity reactions with benzonatate, such as bronchospasm, laryngospasm, and cardiovascular collapse
Dextromethorphan (Delsym)	Oral: 10–20 mg every 4 hours or 20–30 mg every 6–8 hours; XR: 60 mg twice daily (max 120 mg/24 hours)	Dextromethorphan can reduce cough severity by decreasing the sensitivity of cough receptors and interrupting cough impulse transmission Dextromethorphan comes in several formulations such as capsules, liquid, lozenges, suspensions, syrups, strips, and gel Higher doses of dextromethorphan can increase risk of serotonin syndrome when used with other serotonergic agents. It also carries an increased risk for abuse/misuse which can lead to death, brain damage, etc.

Data from Lexi-Drugs Online™. Lexi-Comp Online™. Hudson, OH: Lexi-Comp, Inc.; 2017. Available from: http://online.lexi.com. Accessed August 8, 2020.

under the supervision of a healthcare professional, dextromethorphan has proven superior to honey for symptom relief; however, honey may provide more relief in comparison to diphenhydramine or placebo.[34] It is also important to note certain safety concerns within the pediatric population. For example, honey should not be used in children less than 1 year old due to the risk of infantile botulism, and medications containing codeine should be avoided in all children due to the risk of respiratory distress.[35]

▶ *Nonpharmacologic Therapy*

Nonpharmacologic therapies that are often used for treatment of cough include the use of a neti pot, mentholated chest rub, honey, demulcents, cough drops, gelatin, and chicken soup. The evidence for these therapies in the treatment of acute cough from the common cold were reviewed in the 2017 CHEST guidelines, but no specific recommendations were made regarding their effectiveness.[35] If honey is used for pediatric patients, the amount of honey given during clinical trials has been dependent on patient age with those between the ages of 2 to 5 years receiving ½ teaspoon, ages 6 to 11 receiving 1 teaspoon, and ages 12 to 18 receiving 2 teaspoons.[36] Additionally, nonpharmacologic therapies should target underlying conditions when applicable (eg, lifestyle modifications for GERD, smoking cessation, etc.). In patients with cystic fibrosis who have an ineffective cough, airway clearance techniques, such as chest physiotherapy or oscillating devices, are often used, but the effect on long-term outcomes is not known.[33]

▶ *Pharmacologic Therapy*

See Table 64–6.

Outcome Evaluation

Monitor patients with chronic cough for symptom resolution after 4 to 6 weeks of optimal treatment. If symptoms persist, consider further investigations.[32]

CROUP

Introduction

Croup is a distinct cough that occurs primarily in children between 6 months and 3 years of age and is most prominent during the fall

Patient Care Process: Cough

Collect information:

- Duration of cough
- Signs and symptoms related to cough
- Past medical history
- Occupational or environmental exposures
- Current medication list

Assess the information:

- Whether the cough is acute, subacute, or chronic.
- Determine severity and acuity of cough to determine need for immediate investigation or hospital admission (ie, any "red flags" that could suggest a life-threatening illness).
- Assess potential causes of cough (eg, infectious, underlying conditions, occupational exposures).
- Assess appropriateness of medication list by ensuring adequate control of underlying conditions and identifying medications that could potentiate cough.
- Ensure patient is an appropriate candidate for OTC medications (eg, avoid cough/cold medications in children lees than 2 years; avoid NSAIDs in patients with cardiovascular history).

Develop a care plan:

- Select appropriate nonpharmacologic therapy as applicable (eg, smoking cessation).
- Optimize therapy for underlying conditions that could potentiate cough.
- Discontinue medications that could potentiate cough.
- Select appropriate treatment of cough symptoms when applicable (eg, antibiotics for bacterial infection).

Implement the care plan:

- Educate the patient regarding any nonpharmacologic therapies.
- Counsel patients regarding indication, duration, directions, adverse effects, and any other applicable information for new medications used to treat cough.
- Advise patient when to follow up if symptoms do not resolve.

Follow-up: monitor and evaluate

- Monitor patient for relief of cough symptoms.
- Monitor patient for safety of new medications used to treat cough.
- Reevaluate patient if symptoms do not resolve after 4 weeks of optimal treatment.

and winter months. It is typically caused by viruses, and the most common viral pathogens are parainfluenza viruses (types 1–3).[37]

Pathophysiology

Croup develops when immune responses to an infection cause swelling in the larynx, trachea, and bronchi. This leads to obstruction of the upper airway and consequent inspiratory stridor and barking cough.[37]

Clinical Presentation and Diagnosis

Croup is primarily a clinical diagnosis. It is characterized by a high-pitched, whistling sound when breathing in (stridor) and a barking cough. Symptoms typically develop abruptly, peak after 24 to 48 hours, and then spontaneously resolve within 1 week.[37]

Treatment

▶ *Desired Outcomes*

1. Achieve symptom improvement within 4 hours of treatment.
2. Achieve complete resolution of symptoms within 1 week.

▶ *General Approach to Treatment*

Treatment of croup is determined by severity of the illness. Scoring systems, such as the Westley Croup Score, are sometimes used to assess the severity of croup. Westley Croup Scores are based on level of consciousness, cyanosis, stridor, air entry, and retractions with higher scores indicating worse croup severity. Patients with mild illness can often be managed at home after receiving a single dose of a corticosteroid, usually dexamethasone, orally or parenterally. Patients with moderate or severe illness should receive a single dose of a corticosteroid along with nebulized epinephrine. Oxygen can also be given if the patient is hypoxic.[37]

▶ *Nonpharmacologic Therapy*

Because croup symptoms can be exacerbated by emotional distress, it can be helpful to minimize agitation in a symptomatic child. Humidified air inhalation has traditionally been used for croup management, but studies have not demonstrated a statistically significant effect on croup scores or hospital admissions when used in patients with moderate croup.[37]

▶ *Pharmacologic Therapy*

Outcome Evaluation

Patients with mild croup can be sent home after receiving a single dose of a corticosteroid if they are stable with no stridor. Patients with moderate or severe croup should be observed for up to 4 hours after receiving treatment. If symptoms do not improve, hospitalization should be considered (Table 64–7).[37]

SORE THROAT

Introduction

Sore throat is a common complaint in the outpatient setting. It is most commonly attributed to pharyngitis, which is inflammation of the mucous membranes of the oropharynx. It is characterized by throat pain, especially when swallowing. This chapter focuses mainly on supportive management of viral and noninfectious sore throat, which does not require antibiotic treatment. For a detailed description of bacterial pharyngitis treatment, please see Chapter 75, Upper Respiratory Tract Infection.

Epidemiology and Etiology

Pharyngitis is a very common complaint, accounting for over 2% to 5% of all primary care visits and approximately 1.8 million annual visits to the emergency room.[38,39] The etiology of sore throat is generally categorized as either infectious or noninfectious, with

Table 64–7

Medications Used for Croup Treatment

Drug	Dosing
Dexamethasone	0.15–0.60 mg/kg orally or parenterally, single dose[38]
Nebulized epinephrine	Up to 0.5 mL of racemic epinephrine 2.25% or Up to 5 mL of L-epinephrine 1:1000; repeat as needed[38]

infectious being the most common origin. Most infectious causes (50%–80%) are viral in nature while a smaller portion (5%–36%) are caused by the bacteria group A β-hemolytic streptococci (GAS). The most common viral pathogens include rhinovirus, coronavirus, influenza, parainfluenza, and adenovirus while less common viral causes include herpes, Epstein-Barr virus, and human immunodeficiency virus (HIV).[39]

Examples of noninfectious causes of sore throat include allergic rhinitis or sinusitis, postnasal drainage, irritation from smoke exposure or dry air, and GERD.[39] Less commonly, severe sore throat can indicate epiglottitis, which is a potentially life-threatening inflammation of the epiglottis, most frequently caused by *Haemophilus influenza* type B (HiB).[40]

Patient Care Process: Croup

Collect information:

- Demographic information (eg, age)
- Onset of cough
- Observe the nature of the cough (eg, stridor, barking cough)

Assess the information:

- Distinguish croup from other etiologies such as cough from bacterial infection.
- Assess severity of the croup as either mild, moderate, or severe by examining level of consciousness, cyanosis, stridor, air entry, and retractions (ie, Westley Coup Score).

Develop a care plan:

- Select a single dose of a corticosteroid such as dexamethasone.
- For patients who have moderate or severe croup, select nebulized epinephrine in addition to dexamethasone.
- Consider giving oxygen if indicated.

Implement the care plan:

- Administer the medications (ie, dexamethasone with or without nebulized epinephrine).
- Counsel parents about the illness.
- Counsel parents on when symptom resolution can be expected.
- Counsel parents on when to seek medical attention if necessary.

Follow-up: monitor and evaluate

- Monitor patient for relief of croup symptoms.
- If patient is stable with no stridor after receiving treatment, consider sending the child home.
- Consider hospitalization if symptoms do not improve.

Clinical Presentation and Diagnosis

Sore throat can be associated with several different etiologies. While symptoms alone cannot determine the etiology of sore throat, understanding symptoms that are commonly associated with different etiologies can help focus the evaluation and exclude life-threatening illnesses (Table 64–8). Different tools, such as the Centor Score, can be used to estimate the probability that the etiology is GAS (see Chapter 75 for more detail).[39]

Treatment

▶ *Desired Outcomes*

1. Treat the underlying cause of sore throat when possible.
2. Avoid improper use of antibiotics.
3. Alleviate pain associated with sore throat.

▶ *General Approach to Treatment*

Patients with signs or symptoms suggesting life-threatening illnesses from severe or invasive infections and upper airway obstruction should be referred to the emergency room immediately. Patients determined to have epiglottitis should have their airway immediately secured and then transferred to an intensive

Table 64–8

Concomitant Symptoms With Sore Throat Based on Etiology

Etiology	Possible Symptoms
Life-threatening illnesses ("red flags")[39]	Respiratory distress Neck pain or stiffness Unilateral throat pain **Trismus**
Epiglottitis[40]	High fever Severe sore throat Difficulty or painful swallowing Shortness of breath Stridor Drooling
Viral infection[38]	Cough Rhinorrhea Conjunctivitis Fatigue Diarrhea Redness or swelling in the back of the throat
GAS infection[39]	Acute onset Fever Tonsillar exudates **Cervical adenopathy**
Fungal infection[38]	Loss of taste Mouth numbness White curd-like plaques Smooth red patches
Tonsillitis[41]	Swollen tonsils Tonsillar exudates Tender lymph nodes Fever Sore throat/difficulty swallowing Bad breath

GAS, group A β-hemolytic streptococci.

Patient Encounter 3

LM is a 10-year-old girl who presents to the pharmacy with her mom. Her mom states they are on their way home from the doctor's office where LM was just diagnosed with influenza A. The mother, who seems agitated that the doctor did not give her daughter any antibiotics to help with the pain, holds up a product with "flu" on the label and asks you if it will help her daughter's sore throat. After looking at the product, you find that it contains aspirin, chlorpheniramine, and dextromethorphan.

Is the product that LM's mother has an appropriate treatment option for LM? Why or why not?

If not, what other medications could you recommend to help with symptomatic relief of LM's sore throat?

What nonpharmacologic recommendations could LM's mother try to ease the sore throat pain?

What would be the best way to address this mother's frustrations with not receiving antibiotics for her daughter?

care unit (ICU). For infectious causes of epiglottis, antibiotics such as second- or third-generation cephalosporins are typically given to cover HiB and then adjusted as needed based on culture and sensitivity results.[40]

Patients with signs or symptoms suggesting tonsillitis should be referred to their primary care provider. Removal of the tonsils (ie, tonsillectomy) is typically reserved patients who have at least seven episodes per year, five episodes per year for 2 consecutive years, or three episodes per year for 3 consecutive years.[41]

For uncomplicated sore throat, the underlying cause should be the target of therapy. Bacterial etiologies should be treated with antibiotics (see Chapter 75), but infectious causes of viral origin will resolve with supportive care alone. Supportive care usually involves pain relief using oral and topical analgesics as well as nonpharmacologic measures.[38] Often, antibiotics are inappropriately prescribed for viral or noninfectious sore throat, largely due to patient concerns of pain. Managing patient's sore throat pain may help to alleviate patient concern and discourage improper antibiotic prescribing.

▶ *Nonpharmacologic Therapy*

Nonpharmacologic therapies used for symptomatic relief of sore throat most commonly involve consuming hot or cold foods and beverages such as tea with honey, soups, melted ice chips, or popsicles. Patients can also use salt-water rinses. Avoiding triggers that cause sore throat, such as secondhand smoke, is also helpful. If a sore throat is due to dry air, a humidifier can also be used. There is very little literature supporting these recommendations, but they are likely not harmful.

▶ *Pharmacologic Therapy*

There is currently a lack of evidence-based recommendations for therapeutic management of noninfectious sore throat. Data from nonantibiotic treatments of infectious sore throat is often extrapolated for treatment of noninfectious sore throat. **KEY CONCEPT** Pharmacologic treatment for sore throat typically includes a systemic oral analgesic with or without a topical agent for pain relief (Table 64–9).[38]

Single-dose oral corticosteroids (OCS), such as dexamethasone, can reduce the duration of pain in sore throat; however, the

Table 64–9

Oral and Topical Analgesics

Drug	Dosing	Considerations
Oral Analgesics		
Acetaminophen (Tylenol)	Oral: 325–650 mg every 4–6 hours (max 4 g/day)	Oral analgesics have a slower onset of action but longer duration of action compared to topical analgesics Both acetaminophen and NSAIDs have demonstrated benefits such as sore throat pain relief; however, patient-specific factors must be considered (eg, avoid NSAIDs in patients with high risk of cardiovascular or GI adverse effects)[39] Aspirin is contraindicated in pediatric patients <18 years old who have or are recovering from chickenpox or flu symptoms due to the risk of Reye syndrome
Acetaminophen/caffeine (Excedrin Tension Headache)	Oral: 1 g/130 mg every 6 hours as needed (max 3 g/390 mg per 24 hours)	
Ibuprofen (Advil)	Oral: 200–400 mg 3–4 times daily (max 3200 mg/day)	
Aspirin (Bayer Aspirin)	Oral: 325 mg to 1 g every 4–6 hours as needed (max 4000 mg/day)	
Topical Analgesics		
Phenol (Chloraseptic)	Lozenges: Use 2 lozenges every 2 hours as needed Spray: Apply one spray to the affected area, keep in place for 15 seconds, then expectorate; may repeat every 2 hours as needed Rinse: Gargle or swish for 15 seconds, then expectorate; repeat every 2 hours as needed (max 12 times/day)	Quicker onset of action and shorter duration than oral analgesics The phenol lozenges can be used in pediatric patients starting at age 6, the spray starting at age 3, and the rinse starting at age 4 months (if using Ulcerease with a clean swab).
Benzocaine (Hurricaine, Cepacol)	Lozenge (with menthol): Allow 1 lozenge to dissolve slowly; may repeat every 2 hours as needed Spray: Apply one spray on affected area or throat up to 4 times daily	
Menthol (Vicks VapoDrops)	Drops: Dissolve 1 drop slowly in the mouth; repeat every 2 hours as needed

Patient Care Process: Sore Throat

Collect information:

- Past medical history (eg, allergic rhinitis or sinusitis, postnasal drainage, irritation from smoke exposure or dry air, GERD)
- Current medication list
- Concomitant signs and symptoms to determine etiology of sore throat

Assess the information:

- Assess severity of sore throat to exclude potentially life-threatening causes such as epiglottis.
- Assess potential causes of sore throat (eg, infectious or noninfectious).
- Ensure patient is an appropriate candidate for OTC medications (eg, avoid NSAIDs in patients with high cardiovascular or gastrointestinal risk).

Develop a care plan:

- Select nonpharmacologic therapy as applicable (eg, tea with honey, soups, melted ice chips, popsicles).
- Avoid antibiotic therapy for noninfectious causes of sore throat.
- Determine medications that could potentiate sore throat.
- Select appropriate treatment of sore throat symptoms when applicable (eg, oral analgesics with or without topical analgesics) based on patient-specific factors.

Implement the care plan:

- Discontinue medications that could potentiate sore throat if possible.
- Educate the patient regarding any nonpharmacologic therapies.
- Institute treatments determined to be appropriate.
- Counsel patients regarding indication, duration, directions, adverse effects, and any other applicable information for OTC medications.

Follow-up: monitor and evaluate

- Monitor patient for relief of sore throat symptoms.
- Monitor patient for safety of new medications used to treat sore throat.
- Refer the patient for further investigation if symptoms do not resolve after 7 to 10 days.

absolute benefit is lower in patients with less severe sore throat. Therefore, OCS are generally reserved for symptomatic relief of severe sore throat.[42] Other treatments that have been studied for sore throat, specifically in the postoperative setting, include inhaled fluticasone propionate, intravenous dexamethasone, lidocaine, ketamine gargle, topical NSAIDs, and perioperative amylmetacresol/dichlorobenzyl lozenges.[43] These agents do not have a clear place in therapy for routine treatment of sore throat. There is inconsistent evidence for the management of sore throat using alternative treatments such as zinc, herbals, and acupuncture. Ibuprofen 25-mg lozenges have proven effective in clinical trials for relief of sore throat; however, the lozenge formulation is not yet available.[44]

Outcome Evaluation

Most cases of pharyngitis spontaneously recover within 7 to 10 days. Symptoms associated with streptococcal pharyngitis typically resolve after 24 to 72 hours of antibiotics.[39] If symptoms do not improve, patients should be reevaluated for other underlying causes of sore throat.

LARYNGITIS

Introduction

Laryngitis is defined as inflammation of the larynx and vocal fold mucosa. Dysphonia, or impaired voice production, is the most common sign of laryngitis. Most episodes of laryngitis are acute, which can be defined as lasting less than 3 weeks.[45] Chronic episodes, which last longer than 3 weeks, can also occur. While there are several different possible etiologies, this chapter will focus on the most common causes of both acute and chronic laryngitis.

Epidemiology and Etiology

Dysphonia-related disorders, such as laryngitis, are very common and can produce direct costs somewhere between \$577 and \$953 per patient per year.[46]

Acute laryngitis is self-limited and most often caused by voice misuse, URTIs, or the influence of weather conditions.[46] Infectious causes are usually due to viral pathogens such as parainfluenza, rhinovirus, influenza, and adenovirus. However, bacterial causes have also been identified in acute laryngitis.

Chronic laryngitis is most commonly caused by voice overuse but can also be caused by irritants such as purulent sinus drainage or tobacco.[46] Laryngitis is associated with GERD and is considered an extraesophageal syndrome; however, it is important not to assume GERD as the sole cause since laryngitis can have multiple etiologies.[47] Other less common etiologies of chronic dysphonia can be neurologic (eg, Parkinson disease, spasmodic dysphonia), musculoskeletal (eg, muscle tension dysphonia), rheumatologic (eg, rheumatoid arthritis), or pulmonary (eg, chronic obstructive pulmonary disease [COPD]).[46]

Clinical Presentation and Diagnosis

Physical examination and patient history are essential to identify both acute and chronic causes of laryngitis (Table 64–10). If dysphonia is associated with red flags such as stridor, neck mass, unexpected weight loss, or concomitant neurologic symptoms, the patient should be further evaluated using laryngoscopy to visualize the larynx. In less alarming scenarios, laryngoscopy is only necessary if dysphonia does not improve or resolve after 4 weeks of observation.[46]

Other symptoms can be observed in combination with dysphonia and can be used in assessing the underlying cause of laryngitis. For example, patients with acute laryngitis resulting from an infection will experience symptoms that are consistent with an URTI. Patients who have laryngitis that is associated with GERD will typically have concomitant manifestations that are characteristic of esophageal syndrome (Table 64–10).[47]

Table 64–10

Assessment of Patients Presenting With Laryngitis

Signs/symptoms	Throat discomfort, change in voice, cough, dysphagia, secretion If caused by infection: Sore throat, painful swallowing, rhinorrhea, dyspnea, postnasal discharge, and congestion[46] If associated with reflux: Heartburn, chest pain, regurgitation, dysphagia[47]
Physical examination[46]	Full head and neck examination Evaluation of patient's voice Inspection and palpation of the neck for masses or lesions Observation of swallowing and breathing Indirect mirror laryngoscopy if possible
History[47]	Tobacco use Occupation (eg, teacher, singer) Surgical history involving the head, neck, or chest or recent intubation
Procedures/ imaging[47]	Laryngoscopy CT or MRI *not* recommended prior to laryngoscopy

Treatment

▶ *Desired Outcomes*

1. Achieve improvement or complete resolution of dysphonia as soon as possible, usually within 4 weeks for acute laryngitis, although preferably sooner.
2. Improve the patient's quality of life and restore effective verbal communication.

▶ *General Approach to Treatment*

Appropriate treatment begins with identifying the underlying cause of laryngitis. After assessing the patient through history, physical examination, and laryngoscopy, if needed, treatment can be directed accordingly.

▶ *Nonpharmacologic Therapy*

KEY CONCEPT There are several nonpharmacologic interventions that can be recommended for the prevention and supportive treatment of laryngitis. These include maintaining adequate hydration, resting the voice, using a humidifier in dry air environments, and avoiding smoking or secondhand smoke exposure. Patients should also be encouraged not to strain their voice even by whispering. Throat clearing/coughing, alcohol, caffeine, and anticholinergic medications, such as antihistamines, antipsychotics, or tricyclic antidepressants, can worsen dysphonia.[46]

In chronic reflux laryngitis, common nonpharmacologic recommendations include avoidance of certain foods (eg, coffee, alcohol, chocolate, fatty food, acidic food), smoking cessation, and weight loss.[47]

Other nonpharmacologic therapies, such as voice therapy or surgery, are less commonly used and depend on the underlying etiology. For example, voice therapy is effective for the treatment of muscle tension dysphonia, and surgery can be used in cases of malignancy or benign vocal fold lesions.[46]

▶ *Pharmacologic Therapy*

Antibiotics should *not* typically be prescribed for the treatment of acute laryngitis. While erythromycin has shown subjective improvement in the treatment of patients with laryngitis, no studies have demonstrated objective improvement with the

Patient Care Process: Laryngitis

Collect information:

- Duration of dysphonia
- Any concomitant signs and symptoms
- Medication list
- Past medical history (eg, other conditions, voice misuse, exposure to weather conditions)
- Social history (eg, smoking history/exposure to secondhand smoke, occupation)
- Perform physical examination
- Perform laryngoscopy if there are any alarming symptoms or concomitant neurologic symptoms

Assess the information:

- Determine whether the laryngitis is acute or chronic.
- Assess potential causes of laryngitis and identify any underlying conditions.
- Assess medication list to determine if any could be worsening dysphonia (eg, antihistamines, antipsychotics, tricyclic antidepressants).

Develop a care plan:

- Select nonpharmacologic therapy (eg, maintaining adequate hydration, resting the voice).
- Determine medications that could worsen dysphonia.
- Select appropriate pharmacologic treatment for any underlying conditions (eg, proton pump inhibitor for laryngitis associated with GERD).
- For persistent dysphonia, refer to otolaryngology or a voice clinic with laryngologists and SLPs.

Implement the care plan:

- Discontinue medications that could worsen dysphonia, if possible.
- Institute appropriate treatments.
- Educate the patient regarding nonpharmacologic treatment for laryngitis.
- Counsel patients regarding any new medications used to treat underlying conditions.
- Advise patient when to follow up if symptoms do not resolve.

Follow-up: monitor and evaluate

- Monitor patient for resolution of dysphonia.
- Refer patient for further investigation if symptoms with an unknown cause persist after 4 weeks.

use of antibiotics. Most cases are viral, and the use of antibiotics can potentiate adverse effects, increased costs, and antibiotic resistance.[45] Steroids also should not be routinely prescribed due to lack of evidence showing beneficial outcomes and increased adverse events. However, there may specific situations based on laryngoscopy results or other conditions that may justify their use.[46]

For laryngitis that is associated with GERD, twice-daily dosing of a proton pump inhibitor (PPI), such as omeprazole 20 or 40 mg twice daily, may be used. The use of a PPI should only be considered in patients who have concomitant esophageal GERD syndrome, and a step down of therapy should be initiated after 2 months of treatment.[47]

Botulinum toxin is sometimes used for the off-label treatment of certain types of laryngeal dystonia such as spasmodic dysphonia (SD). This is not curative for SD but is used primarily for symptom control.[46]

Outcome Evaluation

Most episodes of acute laryngitis will resolve spontaneously within 7 to 10 days regardless of treatment. If symptoms do not improve or resolve within 4 weeks, the patient should undergo laryngoscopy. Referral to otolaryngology or a voice clinic with laryngologists and speech-language pathologists (SLPs) should not be delayed in patients with persistent dysphonia.[46]

Abbreviations Introduced in This Chapter

ACE inhibitors	Angiotensin-converting enzyme inhibitors
ALS	Amyotrophic lateral sclerosis
COPD	Chronic obstructive pulmonary disease
GERD	Gastroesophageal reflux disease
HSV-1	Herpes simplex virus-1
NHANES	National Health and Nutrition Examination Survey
NSAIDs	Nonsteroidal anti-inflammatory drugs
OCS	Oral corticosteroids
OTC	Over the counter
PE	Pulmonary embolism
PPI	Proton pump inhibitors
SD	Spasmodic dysphonia
SPF	Sun protection factor
TDIT	Threshold, discrimination, identification test
UPSIT	University of Pennsylvania Smell Identification Test

Allergic Rhinitis

Hanna Phan and Michael Daines

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the basic pathophysiology of allergic rhinitis (AR).
2. Define mild versus moderate–severe AR, persistent versus episodic, and differentiate between seasonal, perennial, and episodic AR.
3. Differentiate the categories of pharmacotherapy choices for treatment of AR based on mechanism, efficacy on symptom type (eg, ocular, nasal congestion), and side effect profile.
4. Identify situations in which a referral to an allergy specialist is needed.
5. Describe an approach for treatment and monitoring for treatment of mild and moderate–severe AR based on patient-specific factors.
6. Identify the differences in approach to the treatment of AR for children, pregnant women, and the elderly compared with the routine approach in adults.

INTRODUCTION

Rhinitis is inflammation of the lining of the nose and contiguous parts of the upper respiratory tract. Allergy is only one of numerous causes of rhinitis. Signs and symptoms of allergic rhinitis are noted in Table 65–1. Some patients suffer concurrently from both allergic rhinitis (AR) and one or more types of nonallergic rhinitis (NAR). This is sometimes called mixed rhinitis (MR). Because ocular symptoms (eg, itching and/or redness of eyes, tearing) frequently occur in association with AR, some sources use the term allergic rhinoconjunctivitis. This acknowledges involvement of the bulbar and palpebral conjunctivae in the allergic process.[1-4]

AR will be emphasized in this chapter, but some mention will be made of NAR (see chapter 64 for further information about nonallergic rhinitis). The most common causes of NAR are shown in Table 65–2. KEY CONCEPT AR is an allergen-induced, immunoglobulin E (IgE)-mediated inflammatory condition of the lining of the nose and upper respiratory tract. This pathophysiologic feature differentiates AR from NAR. AR has traditionally been categorized as either seasonal or perennial.[5-8] Seasonal allergic rhinitis (SAR) is attributed to inhaled allergens (**aeroallergens**) that have a seasonal variation. These allergens are usually encountered outdoors and are most often grass, tree, or weed pollens and substances from molds and fungi. Length of seasonal exposure depends on geographic location and climatic conditions. Perennial allergic rhinitis (PAR) is attributed to aeroallergens that are present in the patient's environment year-round and are usually encountered indoors.[6-8] Common perennial allergens are the house dust mite, indoor molds and fungi, insects (especially cockroaches), and companion animals (pets). Some patients are affected by AR year-round, but have seasonal exacerbations. These people are probably allergic to both seasonal and perennial aeroallergens. Other patients have only episodic manifestations. These people are probably allergic to aeroallergens that are only episodically encountered (eg, cat at a friend's house).

Because these traditional categories of seasonal and perennial AR are imperfect and help little with therapeutic management decisions, another system for categorizing AR has been suggested by guidelines.[6-10] This alternative system categorizes the manifestations by a combination of frequency and severity. There are two divisions of frequency: intermittent and persistent. Intermittent frequency is defined as AR manifestations occurring less often than 4 days per week or for fewer than 4 consecutive weeks. Persistent frequency is defined as AR manifestations occurring for 4 or more days per week *and* for 4 or more consecutive weeks. Severity is categorized as either mild or moderate–severe based on presence of the following symptoms: sleep disturbance, impairment of daily activity (including leisure and/or sports), impairment of work/school, and troublesome symptoms. Mild manifestations are those of which none of the listed symptoms are present. Moderate–severe severity includes those patients with manifestations of AR with at least one of the listed symptoms present. Additionally, AR impact on comorbidities such as asthma and sinus disease which can also be considered when evaluating a patient's AR severity. Clinicians should consider referring patients with comorbid conditions, such asthma, to an allergy specialist. See Table 65–3 for a summary of these categories of AR.

EPIDEMIOLOGY AND ETIOLOGY

Prevalence of AR is up to 40% depending on geographic location, with highest incidence in children, usually manifesting after age 2 years. AR remains the most common immunological disease, which is still relatively underrecognized and managed. It can reduce quality of life, interfering with attendance and performance at school and work, impacting overall societal as well as healthcare expenditures.[9]

Table 65–1

Clinical Presentation and Diagnosis of Allergic Rhinitis[1-4]

Typical Symptoms

- Rhinorrhea (usually clear and bilateral; primarily anterior but may be posterior [postnasal drip])
- Sneezing
- Itching (mostly nasal, but also palate, throat, eyes, ears)
- Nasal congestion (not in all patients, but when present, usually the most troublesome symptom)

Other Symptoms

- Ocular manifestations (itch, redness, tearing, **chemosis**, periorbital edema)
- Sleep disturbances often with fatigue, asthenia, malaise, and irritability
- Presenteeism (impaired performance at work or school)
- Absenteeism from work or school
- Quality-of-life impairment (including social function)
- Headache, mild facial or ear pain or fullness
- Cough (especially in those with concurrent asthma)
- Children (especially): snorting, sniffling, clearing the throat, learning or attention problems, poor appetite

Signs (Especially Common in Children)

- Pale, boggy nasal mucosa
- Rubbing the nose upward (allergic salute; may create horizontal crease just above tip of nose)
- Rubbing/scratching of eyes
- Mouth breathing
- Dark circles under the eyes (allergic shiners)
- **Dennie-Morgan** lines or folds under the eyes

Diagnosis

- Typical symptoms, confirmatory signs, especially in association with exposure to allergen triggers
- Other diagnostic testing usually optional but may be necessary to rule out nonallergic causes or if immunotherapy is considered (appropriate physical examination, specific IgE antibody testing by either skin testing or in vitro serum testing, other specialized testing)
- Several sources particularly good for differential diagnosis of nonallergic rhinitis[3,13,15]
- Vasomotor rhinitis—sneezing and itch less common than AR; anosmia more common
- Unilateral symptoms—refer for possible obstruction, anatomic abnormality, tumor, cerebrospinal fluid (CSF) leak
- Atrophic rhinitis—older adults, history of nasal surgery

Etiology of AR is multifaceted, both genetic and environmental in nature. Some studies have suggested that in addition to possible genetic predisposition, inadequate environmental exposure (eg, to animals) in early life may increase risk for AR.[11,12] The major risk factors for AR are a family history of atopy (AR, asthma, eczema, or food allergies); elevated serum IgE levels (especially before the age of 6 years); higher socioeconomic class; positive skin test results; exposure to particulate air pollution; maternal smoking; firstborn status; and emigration into a Western industrialized environment.[3,6,8,9,11,12,] Certain disorders commonly occur with AR. The most important example is asthma. While different percentages are reported, most patients with asthma have rhinitis symptoms (many of which are AR), and only somewhat fewer with AR have asthma.[3,13] In fact, there is evidence that AR can predispose to the development and/or worsening of asthma.[1,3,13] Other conditions that can occur with AR include allergic conjunctivitis, eczema, sinusitis, sleep disorders, otitis media with effusion, and the oral food allergy syndrome.[3,9]

Table 65–2

Types of Rhinitis[1-3]

Allergic (see Table 63–3 for details)

Nonallergic

- Vasomotor (also known as perennial nonallergic, idiopathic, and autonomic rhinitis) (triggered by irritants, cold air, exercise/running, or unidentified factors)
- Food/meal related (gustatory)
- Infectious
- NARES (nonallergic rhinitis with eosinophilia syndrome)
- Occupational (caused by protein allergens [IgE-mediated] or by irritants [probably non–IgE-mediated])
- Hormonally related (hypothyroidism, pregnancy, menstrual cycle related, and some drugs [see below])
- Drug-induced
  - Angiotensin-converting enzyme inhibitors (ACEIs)
  - α_1-blockers (used for treatment of BPH and HTN)
  - Phosphodiesterase-5 inhibitors (used for treatment of ED)
  - Aspirin and other NSAIDs (as an isolated side effect of AERD)
  - Oral contraceptives and hormone replacement therapy
  - Miscellaneous agents have been implicated (calcium channel blockers, some diuretics, centrally acting α_2 agonists, risperidone, gabapentin)
- Atrophic rhinitis
- Rhinitis associated with inflammatory or immunologic diseases (eg, granulomatous infections, SLE, Wegener granulomatosis, sarcoidosis, Churg–Strauss syndrome)
- Malignancy

Mixed

Combination of allergic and nonallergic manifestations

AERD, aspirin-exacerbated respiratory disease; BPH, benign prostatic hyperplasia/hypertrophy; ED, erectile dysfunction; HTN, hypertension; IgE, immunoglobulin E; NSAIDs, nonsteroidal anti-inflammatory drugs; SLE, systemic lupus erythematosus.

Table 65–3

Categories of Allergic Rhinitis[7-9]

Based on Etiologic Category

- Seasonal—symptoms due to seasonal aeroallergens; present only during specific portions of the year, with length of exposure dependent on geographic location and climate conditions
- Perennial—symptoms present throughout the year due to environmental aeroallergens, such as indoor allergens (eg, dust mites)
- Episodic—symptoms present only during intermittent exposure to allergen trigger (eg, exposure to a friend's pet)

Based on ARIA 2016 Update

- Symptoms: sleep disturbance, interference with daily activities (including leisure or sport), impairment of school/work, and troublesome symptoms
- Mild versus moderate–severe
  - Mild—none of the above symptoms present
  - Moderate–severe—presence of any one of the above symptoms
- Intermittent versus persistent
  - Intermittent—symptoms are present for less than 4 days/week, or for less than 4 consecutive weeks
  - Persistent—symptoms are present for 4 or more days/week and for more than 4 consecutive weeks
  - Any one of the four possibilities of these variables can occur: mild intermittent, mild persistent, moderate–severe intermittent, and moderate–severe persistent

PATHOPHYSIOLOGY

AR is an IgE-mediated disorder of people who are allergy prone. Initial contact is required to sensitize the patient to subsequent exposures. Patients with an inherited tendency to allergic disorders produce T-helper lymphocyte type 2 (Th-2)-directed responses, including production of specific IgE antibodies, to one or more allergens. Many types of cells, mediators, and intermediate substances (including cytokines) are involved. In response to subsequent exposures to the trigger antigen(s), there is an early-phase and often a late-phase allergic response. This distinction has therapeutic implications.[1,3,5,6,8,9]

During the early phase, the trigger allergen becomes bound to IgE that is fixed to mast cells in the nasal mucosa. This occurs within minutes of subsequent exposure to the antigen. Mast cells degranulate and release preformed mediators, the most important of which is histamine. This stimulates more mast cells, as well as macrophages, eosinophils, and basophils to produce more substances, including cysteine leukotrienes and prostaglandin D_2. These mediators bind to receptors in the nose and facilitate many of the manifestations of AR. The resultant vasodilation, mucosal edema, and hypertrophy all contribute to nasal congestion. Clear, watery, and often profuse rhinorrhea is also characteristic in this early phase, a result of mucous secretion and increased vascular permeability. Sneezing and nasal itch are other prominent features of the early phase. Many patients also have ocular symptoms.[1,3,5,6,8,9]

The late phase occurs in about 50% of AR sufferers. It can begin as soon as 2 hours after the early phase and usually peaks between 6 and 12 hours. The late phase involves a second release of many of the mediators of the early phase. In addition, the late phase is characterized by an inflammatory component caused by infiltration of several cell types into the nasal mucosa. The most significant manifestation during the late phase is nasal congestion that is often severe and long lasting.[1,3,5,6,8,9]

A phenomenon known as the priming response or nasal hyperresponsiveness is also of importance. This means that prolonged and/or repeated allergen exposure makes it easier to stimulate mediator release and symptoms. A vicious cycle results in which smaller doses of allergen can create symptoms (ie, the threshold is lowered). Thus, even when pollen exposure is decreased, symptoms may continue. In some patients, the threshold is lowered to the degree that even irritant substances (eg, formaldehyde, tobacco smoke, perfumes, automobile exhaust, and other environmental pollutants) may cause symptoms, on a nonallergic basis.[1,3,5,6,8,9]

TREATMENT

General Approach and Desired Outcomes

Guideline documents have been published on AR.[6-9,14] They provide some of the basis for the sections that follow. Although guideline documents are highly regarded by many, the patients enrolled in the randomized clinical trials that are a major basis for their conclusions and recommendations are not always representative of patients in a primary practice population.[15] **KEY CONCEPT** The general approach for treatment of AR is fourfold: avoidance of allergen triggers, patient/caregiver education, pharmacotherapy, and immunotherapy.[3,6,7,8,9,10,13] Recommended approaches to AR management begin with allergen avoidance and patient/family education. If allergen avoidance is not sufficient and/or symptoms necessitate treatment, pharmacotherapy is utilized. Failure to respond to first-line over-the-counter (OTC) or prescription AR medication may warrant referral to an allergy specialist for further assessment. Based on assessment by a specialist, immunotherapy may also be an option in selected patients.

Education of the patient and the patient's support system is essential.[6] All parties need to understand the potential seriousness of AR (including complications such as asthma) and the chronic, recurrent nature of AR. All should be told about the treatment options, including their relative advantages and disadvantages. Proper understanding and use of current medication in the patient's regimen should be assured. A better educated patient and support system will result in a better relationship with healthcare providers and hopefully will optimize patient outcomes.

KEY CONCEPT The goals of treatment of AR are to minimize the frequency and severity of symptoms, prevent comorbid disorders and complications, improve the patient's quality of life, improve work attendance and productivity and/or school attendance and performance, and minimize adverse effects of therapy. Until a cure is established, these are the only realistic goals.

Patient Encounter 1, Part 1

Mrs. K, a regular customer in your community pharmacy, asks your advice about helping her 7-year-old son, LK. She states, LK has "constant" sneezing, runny nose, watery and itchy eyes, as well as "throat" itching. You determine LK has AR that could benefit from treatment.

What additional information is needed to make a recommendation in treatment?

Nonpharmacologic Therapy

Avoidance of allergen triggers is a core component of nonpharmacologic therapy of AR. Patient and caregiver education is fundamental in reducing preventable allergen exposure. Avoidance of allergen triggers, to the extent they have been identified and to the extent such avoidance is possible, underlies the treatment for all patients with AR (Table 65–4).[6-9]

▶ *Saline*

Nasal administration of saline is an alternative and often used as an adjunctive, nonpharmacological treatment of AR.[3,6,16,17] This therapy may benefit any patient with rhinitis, including those with vasomotor rhinitis.[5] Saline may be administered as drops or a spray, but the irrigation mode of administration is popularly known by several terms, including neti pot, nasal wash, nasal douche, nose bidet, and as nasal irrigation. Although less effective than intranasal corticosteroids (INCSs), it has been shown to improve sneezing and nasal congestion. It can be used either alone or as add-on therapy. The formula provided by the American Academy of Allergy, Asthma and Immunology (AAAAI) should be followed for those making their own saline nasal irrigation solution.[16] Iodized salt is not recommended as it may be irritating. Hypertonic saline seems to have no advantage over 0.9% sodium chloride. Tap water should not be used as it is not adequately filtered or treated; thus, there is risk for bacteria and protozoas (eg, amoebas) containimation. Instead, distilled, or sterile water should be used. Or, alternatively, boiled, and cooled tap water (boil for 3–5 minutes, then cooled to lukewarm).[17] Administration can be accomplished while the patient is in the shower or leaning over a sink. The head is bent forward and downward, then

Table 65–4

Allergen Avoidance Measures[6,8-10]

Allergen avoidance underlies all other treatments of AR

There are several limitations to allergen avoidance:
- Allergen(s) must be identified.
- Literature support for a clinically significant improvement in symptoms from allergen avoidance is meager.
- Quality of life may be negatively impacted by forced removal of a pet from the household.

Outdoor plant pollen and mold/fungi parts:
- Limit outdoor exposure, especially during high pollen conditions (warm sunny days with wind and low humidity) and during mold/fungi spore release (shortly after rains).
- Wear a face mask during activities that disturb soil and decaying vegetation.
- Keep windows and doors closed.
- Use central air conditioning, maintain clean equipment, and change appropriate air filters regularly. Avoid use of an evaporative cooler (eg, swamp cooler).

Indoor allergens (house dust mite, mold/fungi, cockroaches, and pets):
- Use central air conditioning, maintain clean equipment, and change appropriate air filters regularly. Avoid use of an evaporative cooler (eg, swamp cooler).
- Maintain humidity below 50% and maintain clean equipment.
- Clean frequently to prevent mold growth (dilute bleach with detergent).
- Avoid exposed food and garbage to deter insects.
- Clean kitchen frequently.
- Use roach traps that facilitate their removal.
- Vacuum frequently and use a high-efficiency particulate air (HEPA) filter.
- Minimize carpeting, fabric covered furniture, and fabric wall/window coverings.
- Cover bedding (pillows, mattresses, box springs) with allergen-proof, zippered cases.
- Launder bedding frequently, in hot water (> 130°F or 54°C) to kill mite ova.
- Consider **acaricide** (eg, benzyl benzoate) treatment of carpets to kill mites and ova.
- Put items that cannot be laundered (eg, soft toys) in a plastic bag and freeze.
- Keep pets out of bedroom and bathe cats weekly, if possible.

Irritants:
- Avoid, as possible, all exposure to smoke, chlorine fumes, formaldehyde fumes, and other substances identified as irritant triggers (eg, perfumes, newspaper ink).

Table 65–5

Intranasal and Oral Medications for AR[6-8,13,14,18,19]

Corticosteroids
Intranasal[a] (budesonide [OTC], beclomethasone, ciclesonide, flunisolide, fluticasone [propionate and furoate] [OTC], mometasone, triamcinolone [OTC])
Oral (rarely used, eg, prednisone)

Antihistamines
Intranasal[a] (azelastine, olopatadine)
Oral[b]
- First generation/sedating (cautious use in selected patients) (most OTC depending on strength: diphenhydramine, chlorpheniramine, clemastine, and others)
- Second generation/low- or nonsedating[a]: loratadine (OTC), cetirizine (OTC), fexofenadine (OTC), levocetirizine (OTC), desloratadine

Combination antihistamine/corticosteroid
Intranasal (azelastine and fluticasone propionate)

Mast cell stabilizer/cromone
Intranasal (cromolyn [OTC])

LTRA
Oral (montelukast)

Antimuscarinic
Intranasal (ipratropium)

Decongestant
Intranasal (short-term use) (tetrahydrozoline, phenylephrine [OTC], naphazoline [OTC], oxymetazoline [OTC])
Oral[b] (phenylephrine [OTC]; pseudoephedrine [BTC[c]])

[a] First-line choices.

[b] Some products combine an antihistamine with a decongestant, sometimes with other ingredients.

[c] Behind the counter (OTC plus other requirements necessary; see the Decongestants section of text).

Note: All products are prescription unless indicated as OTC.

tilted to the side opposite the treated nostril. Then, with a bulb syringe or similar device, slowly introduce about 4 oz (118 mL) of the warm saline solution into one nostril. Soon, the solution will run out of the opposite nostril. The position of the head should be adjusted as necessary to avoid the solution running into the ears or down the throat. Devices for nasal irrigation should be also cleaned appropriately and regularly to minimize possible microbial growth.[17]

Nasal irrigation is one delivery method, although the optimal method (spray, drops, nebulizer, or irrigation) is not known. Optimal frequency of administration is also not known. Nasal irrigation is usually given twice daily, but use of smaller volumes as spray products may be given up to four times daily. Side effects are usually limited to minor local nasal irritation, but nausea has been reported.

Pharmacologic Therapy

KEY CONCEPT Routine first-line agents for the treatment of AR are intranasal corticosteroids (INCSs) and oral (or possibly intranasal) antihistamines. Secondary agents, each of which may have a first-line role in selected patients, include oral (and rarely intranasal) decongestants, an intranasal mast cell stabilizer (ie, cromolyn), an oral leukotriene receptor antagonist (LTRA) (ie, montelukast), an intranasal antimuscarinic (ie, ipratropium), and intranasal saline irrigation. See Table 65–5 for intranasal and oral medications for the treatment of AR. Treatment selection, among common medications for AR, can vary based on best available evidence (ie, guidelines, clinical trials, etc) for a given medication in addition to the severity of AR of a given patient.[3,6-9,12] See Figure 65–1. In all cases, therapy must be individualized, in cooperation with the patient. Considerations include frequency and severity of specific symptoms, realistic avoidance measures, patient age, patient preferences for route of administration, tolerance of side effects, adherence issues, comorbid disorders, and concurrent therapy. Some clinicians may elect to use an action plan for AR with their patients, similar to that used for asthma.[6] Some patients may benefit from having an AR action plan, depending on their AR severity and complexity of therapy.

▶ *First-Line Agents*

Corticosteroids Corticosteroids are usually administered by the intranasal route for the treatment of AR. Occasionally, a short

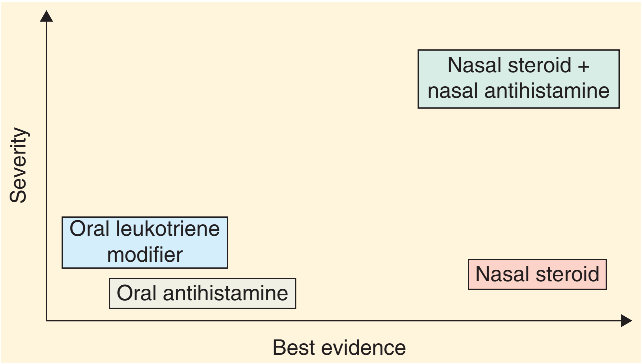

FIGURE 65–1. Evidence-based treatment options for AR based on current guidelines.[7-10]

course of oral therapy (eg, prednisone burst and taper) is necessary. Oral corticosteroids may be used to overcome severe nasal congestion, particularly due to rhinitis medicamentosa (see the section on Decongestants). Parenteral administration of corticosteroids for AR is discouraged due to side effects.[5,8,13]

INCSs provide very good relief for sneezing, itching, and rhinorrhea, and even nasal congestion and ocular symptoms. Nasal congestion is often the most bothersome symptom of AR, and the most difficult to control. This is probably because it results from inflammation that predominates in the late phase of the allergic response. **KEY CONCEPT** INCSs are the most effective therapy for AR, especially for nasal congestion. Their anti-inflammatory mechanism of action probably contributes to this superiority.[3,5,13] The majority of contemporary literature suggests that INCSs are superior to intranasal antihistamines, to oral antihistamines even when combined with a leukotriene antagonist, and to a leukotriene antagonist alone.[3,6,8-10] In recent guidelines by the American Academy of Allergy, Asthma, and Immunology (AAAAI) and American College of Allergy, Asthma, and Immunology (ACAAI), and British Society for Allergy and Clinical Immunology (BSACI), INCSs are recommended as monotherapy versus in combination with an oral antihistamine for initial treatment of nasal symptoms of seasonal allergic rhinitis in patients ages 12 years and older.[6-9,14] Additionally, in patients ages 15 years and older with moderate-to-severe SAR, INCSs are recommended over an LTRA such as montelukast, for initial treatment.[8,14]

There are currently eight INCS products available in the United States, including two different salt forms of fluticasone. Most (budesonide, ciclesonide, fluticasone furoate, mometasone, and triamcinolone) are used once daily. However, fluticasone propionate may be given either once or twice daily, beclomethasone is usually given twice daily, and flunisolide is given two or three times daily. There is no good evidence that any single product is superior in efficacy. INCSs are best given regularly, as the onset of action usually takes up to 12 hours and the maximum effects may be delayed up to 14 days.[3,6-9,13,14,18] In some people the onset is within 3 to 4 hours, so these agents may even be used on an as-needed basis.[6,19] When nasal congestion is severe, intranasal administration may not be effective due to limited exposure to the nasal mucosa. Short-term use of intranasal decongestants may facilitate better exposure. See Table 65–6 for INCS products.

The correct technique for administration of intranasal medication is important for optimum efficacy. Consult the individual product labeling for specific instructions. Also see Table 65–7 for

Table 65–6

Intranasal Corticosteroids

Generic (Brand) Name	mcg/dose	Adult Dosages (Each Nostril)	Pediatric Dosages (Each Nostril)[a]
Beclomethasone dipropionate (Beconase AQ)	42	1–2 sprays twice daily	6 years and older: 1–2 sprays twice daily, once symptoms are controlled decrease dose to 1 spray twice daily 12 years and older: 1–2 sprays twice daily
Beclomethasone dipropionate (Qnasl [HFA MDP])	40 80	— 2 sprays once daily	4–11 years: 1 spray once daily 12 years and older: 2 sprays once daily
Budesonide[a] (Rhinocort Aqua)	32	1–4 sprays once daily	6–11 years or older: 1–2 sprays once daily 12 years and older: see adult dosing
Ciclesonide (Omnaris)	50	2 sprays once daily	2–11 years: 1–2 sprays once daily (perennial AR)
Ciclesonide (Zetonna [HFA MDP])	37	1 spray once daily	6 years and older: 2 sprays once daily (seasonal AR) 12 years and older: 2 sprays once daily (perennial AR) 12 years and older: 1 spray once daily (seasonal AR)
Flunisolide	25	2 sprays two or three times daily	6–14 years or older: 1 spray three times daily or 2 sprays twice daily 15 years and older: 2 sprays two or three times daily
Fluticasone furoate[a] (Flonase Sensimist)	27.5	2 sprays once daily	2–11 years or older: 1–2 sprays once daily 12 years and older: 2 sprays once daily
Fluticasone propionate[a] (Flonase)	50	1–2 sprays once daily or 1 spray twice daily	4–11 years or older: 1 spray once daily
Mometasone[a] (Nasonex)	50	2 sprays once daily	2–11 years or older: 1 spray once daily 12 years and older: 2 sprays once daily
Triamcinolone acetonide[a] (Nasacort AQ)[b]	55	2 sprays once daily	2–5 years: 1 spray once daily 6–12 years: 1–2 sprays once daily

[a]Available OTC.

mcg, micrograms; HFA, hydrofluoroalkane (propellant); MDP, metered-dose pump.

From Ref. 19, includes any off-label dosing.

Table 65–7

Administration Instructions for Intranasal Sprays[20,21]

1. Clear the nose of mucus and debris.
2. Consult product labeling for preadministration instructions (eg, shaking the container, priming the spray pump).
3. Do not tilt head backward. This increases drug lost down the esophagus. This decreases efficacy and increases the potential for systemic absorption and thus systemic side effects.
4. For non-pump nasal sprays, keep head upright. For nasal pump sprays, bend the head forward (flex the chin onto the chest) so that the nose is the lowest portion of the head.
5. Use the contralateral hand to insert the spray nozzle into one nostril (ie, the left hand for right nostril).
6. Use the other hand to occlude the opposite nostril (the one not being medicated).
7. Aim the spray or drops toward the outer (lateral) inside surface of each nostril and away from the nasal septum.
8. Breath in slowly but deeply through the medicated nostril.
9. Repeat this procedure to apply medication to the other nostril.
10. Consult the product labeling for instructions on cleaning the device.
11. See the text for information about preparation and use of saline irrigation.

general instructions for the optimal administration of intranasal sprays. The technique described maximizes exposure of the drug to the nasal mucosa to optimize efficacy and minimizes both exposure to the nasal septum and loss of medication down the esophagus.[20,21]

Most patients tolerate INCSs very well. Local side effects include nasal burning, irritation, and dryness, which may occur in 2% to 10% of patients.[3,19,22] Also, 2% to 8% of patients may experience mild epistaxis.[3,22] This may be partly due to administration technique. Perforation of the nasal septum is very rare. This can be minimized by proper administration technique (see Table 65–7), specifically, directing the spray laterally and away from the (medial) nasal septum.[20-22]

The older INCSs (beclomethasone, flunisolide, and budesonide) have significant absorption, whereas, among the newer products, including fluticasone, ciclesonide, and mometasone have bioavailability of less than 1% to 2%.[22] The decreased absorption minimizes systemic side effects. However, there is still some concern for hypothalamic–pituitary–adrenal (HPA) axis suppression (eg, growth suppression), osteoporosis, and ocular effects (eg, glaucoma, cataracts), especially in cases with multiple sources of steroid exposure. There is no confirmation that INCSs *cause* posterior subcapsular cataracts, increased intraocular pressure, or decreased bone density; however, those with risk factors for these conditions should be monitored carefully for their development.[3,22,23] The consensus about INCSs, when used alone, and systemic side effects, even those related to HPA axis suppression, is that most products are safe. Clinicians should examine total corticosteroid exposure (ie, from all sources, nasal, inhaled, oral, etc) in assessing potential risk for adverse effects from systemic exposure.[22,23] Ultimately, patient preference for a specific INCS may be determined more by cost, availability, and formulation differences that affect odor and aftertaste.

Antihistamines Antihistamines used for AR treatment are administered by either the oral or the intranasal route. These agents interact with the histamine type 1 (H_1) receptor. They are technically inverse agonists, not competitive antagonists; however, there may be little clinical significance to the difference. These drugs bind H_1 receptors, keeping them in the inactive state. This downregulation of H_1 receptor activity results in a decrease in end-organ effects.[24]

Activation of H_1 receptors in the nose, upper airway mucosa, and the eye produce the common manifestations of AR (sneezing, itching, rhinorrhea, nasal congestion, and ocular symptoms). The antihistamines are very effective for the sneezing, itching, and rhinorrhea. There is some improvement of nasal congestion, but less so than for the other symptoms. There is also benefit for the ocular symptoms (eg, itching, redness, tearing). Intranasal administration is more effective than oral administration for the nasal congestion but less effective for the ocular symptoms. The onset of action by oral administration is usually within 1 to 2 hours and for intranasal administration within 15 minutes.[3,5,13] Antihistamines probably provide better relief when used continuously during symptomatic periods, but they are also effectively used only when needed for mild and/or intermittent or episodic AR.

The oral agents are divided into first- and second-generation drugs. The first-generation agents are distributed among six chemical classes, including the more sedating ethanolamine class (eg, diphenhydramine) and the least sedating alkylamine class (eg, chlorpheniramine). Most sources now discourage the routine use of the first-generation agents for AR. This is due to their central nervous system (CNS) and antimuscarinic side effects. The CNS effects are primarily sedation and impairment of cognitive function and performance of tasks. Decision making and driving or work/school performance can be impaired even when the patient is unaware of any overt effects.[5,6] The major antimuscarinic effects include blurred vision, dry mouth, urinary retention, and constipation. The only possible advantage of the antimuscarinic properties is an additional effect to decrease rhinorrhea. Another disadvantage of the first-generation antihistamines is that most are administered three to four times daily due to shorter half-life. Patients who take other sedative substances may have an additive effect from the antihistamine. Those taking any other medications with antimuscarinic properties may experience additive effects from the antihistamine. The elderly are, in general, more sensitive to both types of adverse effects.[3,5,13]

Currently available oral second-generation H_1 antihistamines are cetirizine, loratadine, and acrivastine. All except acrivastine are available as a single agent, and some are marketed in combination with the decongestant pseudoephedrine. As these agents are active metabolites of preceding agents, fexofenadine (preceding agent was terfenadine, removed from marked due to cardiac toxicity), levocetirizine, and desloratadine are informally labeled as "third-generation" antihistamines, but sometimes classified as "second-generation" antihistamines. The second-generation antihistamines have less antimuscarinic activity than the first-generation agents. Based on current literature, no single H_1 antihistamine (first- or second-generation) is clearly superior in efficacy; however, very few head-to-head comparative studies have been conducted. Individual variation is likely, and patients may need to try more than one product to realize optimal benefit. The oral second-generation antihistamines are effective for the sneezing, itching, and rhinorrhea of AR but less effective for the nasal congestion. They also improve ocular symptoms. Intranasal antihistamines are somewhat better for nasal congestion.[5,10]

Fexofenadine has virtually no sedative effects, even at doses higher than recommended. Loratadine and desloratadine are not sedative at recommended doses but can be at higher doses. Cetirizine, levocetirizine, and acrivastine have some sedative effects, even at recommended doses. All the oral second-generation agents require some dosage reduction with impaired renal function, but specific recommendations vary with creatinine clearance.[19] Most of the oral second-generation antihistamines can be administered once daily (except for the lower dosage forms of fexofenadine and the acrivastine combination product).

There are only two intranasal antihistamine products available in the US market as of December 2020, azelastine and olopatadine. These are considered second-generation agents, although they also have anti-inflammatory effects.[25] Both are available only by prescription. The most common side effect of these products is a bitter taste. This is more common with the original formulation of azelastine (Astelin) and less common with olopatadine. A specific formulation of azelastine (Astepro) has less bitter taste.[26] There is also an available combination product with azelastine and fluticasone propionate. There is enough systemic absorption to cause sedation in some patients using intranasal antihistamines, with possible greater incidence with azelastine compared to olopatadine. See Table 65–8 for the single-agent second-generation antihistamine products.

KEY CONCEPT Second-generation antihistamines are often effective alone, specifically for mild or intermittent AR. They are preferred over first-generation antihistamines because of fewer side effects. Although effective for most symptoms of AR, they are less

Patient Encounter 1, Part 2

Additional history from Mrs. K and LK reveals the following information.

LK's symptoms began about 2 month ago after they moved into a new home in the countryside. Both Mr. and Mrs. K have seasonal allergies and are treated with oral antihistamines. LK's symptoms have become problematic in that he had to miss school today due to his inability to stop itching his eyes and the constant runny nose. Mrs. K reports that symptoms are daily and caused LK to not sleep well for the past 2 months. Mrs. K states that LK was not recently sick (ie, no fever, aches), and he is not congested. His nasal secretions are clear. Mrs. K tried using something over-the-counter, she could not remember the name but remembered the pink color of the oral liquid. She reports that it made LK "super hyper" and has not since been given medication for his symptoms.

How would you classify LK's presumed allergic rhinitis? Why?

What OTC-specific recommendations would you make for initial management of LK's presumed AR?

Table 65–8

Single-Agent Second-Generation Antihistamine Products (Oral and Intranasal)

Oral Dosage Forms

Generic (Brand) Name	Formulation	Usual Adult Dosage	Usual Pediatric Dosage
Cetirizine[a,b] (Zyrtec, generic)	5, 10 mg tabs/chew tabs; capsule 5 mg/5 mL syrup	5–10 mg once daily	6–11 mo; 2.5 mg once daily 12–23 mo; 2.5 mg once or twice daily 2–5 yo; 2.5–5 mg once daily or 2.5 mg twice daily
Desloratadine[b] (Clarinex)	5 mg tabs; 2.5 mg/5 mL syrup 2.5, 5 mg orally disintegrating tabs	5 mg once daily	6–11 mo; 1 mg once daily 1–5 yo; 1.25 mg once daily 6–11 yo; 2.5 mg once daily
Fexofenadine[a,b] (Allegra, generic)	60, 180 mg tabs, 6 mg/mL suspension 30 mg orally disintegrating tabs	60 mg twice daily or 180 mg once daily	2–11 yo; 30 mg twice daily
Levocetirizine[a] (Xyzal)	5 mg tabs 2.5 mg/5 mL solution	5 mg once daily	6 mo–5 yo; 1.25 mg once daily 6–11 yo; 2.5 mg once daily
Loratadine[a,b] (Claritin; Alavert, generic)	10 mg tabs and cap; 5 mg/5 mL syrup and susp; 10 mg disintegrating tabs; 5 mg chewable tab	10 mg once daily	2–5 yo; 5 mg once daily

Intranasal Sprays

Generic (Brand) Name	mcg/spray	Usual Adult Dosage (Each Nostril)	Usual Pediatric Dosage (Each Nostril)
Azelastine (Astelin, Astepro)[c]	137	1–2 sprays twice daily	5–11 yo; 1 spray twice daily
Olopatadine (Patanase)	665	2 sprays twice daily	6–11 yo: 1 spray twice daily

[a] Available OTC.

[b] Available in combination with pseudoephedrine (consult labeling for pediatric dosage).

[c] Available in combination with fluticasone propionate (consult labeling for dosage)

Note: Acrivastine is available only with pseudoephedrine and so is not included in this table.

mo, months old; yo, years old.

Data from Lexi-Comp OnlineTM , Pediatric & Neonatal Lexi-Drugs OnlineTM , Hudson, Ohio: Lexi-Comp, Inc.; December 31, 2020, includes any off-label dosing.

effective than INCSs for nasal congestion. Intranasal administration is more effective than oral administration for nasal congestion. Most patients can use oral second-generation products. Others may prefer the intranasal route of administration, but they require a prescription. If nasal congestion is not relieved, addition of a decongestant is reasonable, either alone or as a combination product (see Decongestant section). Perhaps even the combination of an oral with an intranasal antihistamine is reasonable for some patients, depending on their preferences. Other pharmacologic agents can be combined with oral and/or intranasal antihistamines, as necessary for optimal control of symptoms. The intranasal combination product of azelastine and fluticasone may be appropriate for some patients. In recent guidelines, for patients age 12 years and older for initial management of moderate-to-severe SAR, use of both INCS and intranasal antihistamine may be considered.[6-10,13,14]

▶ *Adjunctive or Secondary Choice Agents*

Decongestants Decongestant drugs are useful only for nasal congestion. This results from their α_1-adrenergic agonist activity, which causes vasoconstriction in the nasal mucosa. They provide no benefit for the sneezing, itching, rhinorrhea, or the ocular manifestations. Decongestants can be given alone, either by the oral or by the intranasal route.[3,10,13] Also, numerous combination products are available, consisting of a decongestant with an antihistamine (and sometimes other ingredients). There are some special considerations for use of decongestants in pediatric and pregnant patients (see the Special Populations section).

Oral decongestant products are currently limited to pseudoephedrine and phenylephrine. Pseudoephedrine has been changed from truly OTC to a more controlled "behind-the-counter" (BTC) status because it is an ingredient in the illicit manufacture of methamphetamine. Some manufacturers changed the ingredients of their products by replacing pseudoephedrine with phenylephrine to maintain shelf presence in the OTC area. However, much controversy surrounds the efficacy of oral phenylephrine. Most contemporary literature suggests that the currently recommended adult dose is minimally effective as a nasal decongestant, even compared to placebo in SAR.[3,27]

The side effects of orally administered decongestants most often affect cardiovascular function or the CNS. The side effects are primarily due to sympathetic stimulation and are usually dose-related. Some elevation of blood pressure may occur, but in normotensive and well-controlled hypertensive patients, the elevation is usually small, especially when used briefly or intermittently. In patients with known cardiovascular disease, such as hypertension, use of intranasal agents is recommended to minimize systemic exposure and side effects. Insomnia, nervousness, irritability, and anxiety are relatively common CNS side effects. Some patients may have decreased appetite, tremors, headache, and even hallucinations. Men with benign prostatic hyperplasia (BPH) and other patients with disorders causing bladder outlet obstruction may have increased urinary retention due to α_1 stimulation of the urethral sphincter.[28]

The intranasal agents currently available in the United States include the OTC products phenylephrine, oxymetazoline, and naphazoline. Intranasal application of decongestants provides rapid and effective relief of nasal congestion. This therapy may provide relief for nasal congestion, even for those patients already on INCSs. However, the continuous use of intranasal decongestants often causes a paradoxical rebound phenomenon of persistent nasal congestion, called rhinitis medicamentosa.[29] Although some patients do not develop rhinitis medicamentosa, even after several weeks of continuous use of intranasal decongestants, the usual recommendation is to use them for no more than 3 consecutive days.[28,29] Intranasal decongestants can cause local side effects, including stinging, burning, dryness, and even sneezing. These are usually mild and well-tolerated. Due to very limited absorption, the intranasal route rarely causes systemic side effects.[3,28] Administration technique should be optimized as described in Table 65–7. Should rhinitis medicamentosa occur, the best management is first to discontinue the decongestant, possibly with a taper to minimize worsening the situation. However, the response to withdrawal is often delayed for days. Therefore, it may be necessary to start INCSs and/or begin a short course of oral corticosteroid.[29] KEY CONCEPT Whenever possible, intranasal decongestants in AR should be limited to short-term use to overcome severe nasal congestion and to facilitate improved efficacy of other intranasal agents. The intranasal administration of decongestants should usually not exceed 3 consecutive days. Despite the usual good tolerance of recommended doses of oral decongestants, caution is warranted when they are used in patients with cardiac disease (dysrhythmias, angina pectoris, heart failure), hypertension, cerebrovascular disease, bladder outlet obstruction (including BPH), glaucoma (especially closed angle), hyperthyroidism, and possibly diabetes.[3,28] The choice between the two routes of administration is often based on several considerations, including cost, convenience, patient preference, speed of onset (within 30 minutes orally, within 5–10 minutes intranasally), and side effects.

Mast Cell Stabilizer Cromolyn is available as an OTC intranasal product. The mechanism of action in AR is mast cell stabilization. The drug binds to mast cells and prevents release of the mediators of AR that would otherwise result from allergen exposure. The drug is moderately effective, but less so than both INCSs and oral or intranasal antihistamines. It does have effects on both early and late phases of AR. Its effects begin within 4 to 7 days of use but may not be maximal for up to 2 weeks. However, it can be used effectively on an as-needed basis for episodic exposures to allergen. Cromolyn is very well-tolerated. The most common side effects are mild local stinging and/or burning, sneezing, unpleasant taste, and possibly nosebleed. A disadvantage is the frequency of administration. At least initially, it should be used four times daily. Some patients may need only two or three daily doses when used continuously after the first few weeks at four times daily. It is most useful for patients with mild or intermittent symptoms, especially in the pediatric population and in pregnant women.[3,10,13,30]

Leukotriene Receptor Antagonist Leukotrienes are involved in the pathophysiology of AR and, in particular, contribute to the nasal congestion in the late phase. There is some difference of opinion about benefits of LTRAs. LTRAs are recommended by some guidelines in the case of PAR (not SAR) over oral antihistamines.[8] Most sources indicate good benefit for nasal congestion and rhinorrhea, some benefit for ocular symptoms but less for nasal itch and sneezing compared to INCSs and antihistamines.[31] Montelukast is the only LTRA approved for treatment of AR. It is marketed as oral granules and as both chewable and regular tablets and is administered once daily. The combination of montelukast with an oral antihistamine may have improved efficacy over either agent alone, according to some sources; however, even the combination is probably not better than INCSs.[3,6,8,14] The onset of action of montelukast is delayed for a day or more. The drug is usually considered to be very well-tolerated. However, there are postmarketing reports of neuropsychiatric events,

Patient Encounter 1, Part 3

Mrs. K and LK come back to speak with you. It has been over 6 months since you last spoke with them about LK's allergies. LK is getting nosebleeds occasionally and stopped wanting to use any nasal product and only uses the OTC antihistamine you originally recommended. About 6 months ago, LK was diagnosed with asthma and was started on fluticasone 44 mcg HFA MDI 2 puff twice a day and as-needed albuterol. LK is due to see his pediatrician for a follow-up visit this week, and he still has nasal symptoms (rhinorrhea, some congestion) and eye itching. LK's allergies are now beginning to affect his breathing with some additional use of his albuterol over the last couple of weeks (ie, used once each week at night, with relief of symptoms).

What suggestions would you offer for control of LK's symptoms, now? What should be monitored?

including sleep disturbances, depression, and suicidal ideation, as well as headache, gastrointestinal (GI) disturbances, skin rash, and Churg–Strauss syndrome.[19] A boxed warning was added by the Food and Drug Administration (FDA) for montelukast, strengthening existing warning about behavioral and mood-related changes. Use of this medication for allergic rhinitis should be reserved for those who are not treated effectively with or cannot tolerate first-line agents (eg, INCS, oral or inhaled antihistamines). Clinicians should consider benefits and risks of its use in a given patient.[32]

Antimuscarinic Agent Ipratropium is currently the only antimuscarinic agent indicated for treatment of AR. Systemic absorption is minimal. It is available by prescription as an intranasal spray. Its use is limited to those patients whose rhinorrhea has not been controlled by other therapy (antihistamines and/or INCSs).[3,13] There are two strengths available: 0.03% and 0.06%. The 0.03% product is approved for AR in children as young as 6 years of age. This agent may be particularly helpful for patients who have vasomotor (idiopathic, autonomic) rhinitis or those who may have a mixed etiology.[5] Local side effects are usually limited to nasal and oral dryness, throat irritation, and mild epistaxis.[3,10,13,19]

Biologic Agents Biologic agents such as omalizumab are currently not FDA approved for AR nor are they recommended for routine use in treatment of AR. Omalizumab is a monoclonal antibody that binds to IgE. The product is approved for moderate-to-severe persistent asthma with a positive skin test or in vitro reactivity to a perennial aeroallergen and symptoms that are inadequately controlled with inhaled corticosteroids in patients ages 6 years and older. Omalizumab is not approved for treatment of AR as of September 2020. It is administered by subcutaneous injection. Dosage is determined by the patient's circulating IgE levels. The cost is high compared with that of other modes of therapy. Investigational use has demonstrated possible efficacy in AR, although relative efficacy is unknown. Its use is best limited to those with concurrent asthma and AR until further data are known.[33] Dupilumab, an anti-IL-4 receptor α-antagonist, is approved as an add-on maintenance treatment for inadequately controlled chronic rhinosinusitis with nasal polyps as well as moderate-to-severe persistent atopic dermatitis where topical prescription therapies are not adequately effective or not tolerated and as add-on maintenance treatment for moderate-to-severe asthma that is eosinophilic or oral corticosteroid dependent. It is not approved for AR as of September 2020; however, there are data describing efficacy and safety of its use in adults with PAR and comorbid asthma.[34,35] Data regarding safety and efficacy of biologic agents, such as omalizumab and dupilumab, for routine use in the treatment of AR are currently lacking.

Immunotherapy Immunotherapy could be considered a type of pharmacotherapy. Allergen-specific immunotherapy (SIT) involves repetitive dosing of allergen(s). This approach to treatment can be considered for patients with moderate–severe AR, especially those who have limited response to usual therapy (eg, intranasal steroid, antihistamine) and limiting environmental exposure.[36-39] Immunotherapy is almost always initiated by an allergist or otolaryngologist, after referral for specific allergen testing to determine individualized therapy. This type of therapy is intended for patients with IgE-mediated AR by history and confirmed with specific allergen testing. Historically, immunotherapy was considered for patients in three categories.[3] The first were those with severe, complicated, or worsening rhinitis. This was partly for additional diagnostic testing to rule out nonallergic causes of rhinitis. The second were those patients with AR who did not tolerate or responded poorly to appropriate pharmacotherapy. The third were those patients who had a single, or one major allergen identified, for which there was an immunotherapy product available for treatment. In addition, some patients requested immunotherapy based on superior and durable effectiveness.

Currently, the role of any other healthcare provider is limited to referral of appropriate candidates to allergy specialists.

Currently, SIT can be done via subcutaneous immunotherapy (SCIT) or sublingual immunotherapy (SLIT). The major advantage of SLIT over SCIT is ease of administration. Possible adverse effects of SLIT include oral or ear pruritis, throat irritation, tongue pruritis, and mouth edema, with decrease in occurrence and severity of such events in subsequent years of treatment. Potential adverse effects of SCIT include local injection reactions, systemic reactions, and rare, allergic, anaphylaxis reactions. The first dose of immunotherapy is given in the prescriber's office, for purposes of safety. Subsequent doses are self-administered by the patient. SCIT is always done under medical supervision, requiring regular clinic visits and observation after SCIT administration.[39,40] Potential risk factors for SLIT-associated anaphylaxis include previous systemic reaction to SCIT, severe or uncontrolled asthma, acute infection, interruption of dose regimen, and oral lesions.[36] Both SCIT and SLIT can induce long-term symptom remission and have been found to be effective for SAR as well as perennial mite allergy. Comparisons between SCIT and SLIT as well as use

Patient Encounter 2, Part 1

Mr. J is a 35-year-old man. He works full time as an assistant coach for the local college basketball team. He reports that he has had allergies since starting his position and moving to town about 1 year ago. He moved from New York City to Ann Arbor, Michigan, and since his move, he reports daily sneezing, itchy, watery eyes. He is currently on loratadine 10 mg daily and fluticasone nasal spray daily. He reports his treatment worked initially but has not worked as well in the last few months.

What additional information do you need to better evaluate Mr. J?

of some available agents in pediatric populations are currently lacking.[41]

As of September 2020, four products have been FDA approved for administration as SLIT. There are currently two products for grass pollen: Oralair and Grastek. Oralair contains a mixture of pollens from Sweet Vernal, Orchard, Perennial Rye, Timothy, and Kentucky Blue Grass and is approved for adults and children ages 5 to 65 years.[42] Grastek, which contains only Timothy grass pollen, is approved for adults and children ages 5 to 65 years.[43] Ragwitek is a SLIT for short ragweed pollen, approved for adults ages 18 to 65 years.[44] Odactra, the SLIT for house dust mites, is approved for adults ages 18 to 65 years.[45]

Complementary and Alternative Medicine Therapy Complementary and alternative therapy (CAM) for AR has been reviewed.[46] For example, capsaicin (Capsicum annuum), once regarded as CAM, in the form of a nasal spray, is being investigated as a possible agent in treatment of AR. Previous data behind this compound were inconclusive, citing the need for future studies.[47] Consistent evidence for efficacy has not been established, and there are some safety concerns. In general, data regarding efficacy and safety of CAM products for routine treatment of AR are currently limited.

Special Populations

▶ *Children*

KEY CONCEPT Generally, the treatment of AR in children is the same as it is for adults. There are, however, limitations in terms of FDA-approved products for different age groups. Also, depending on the age of the patient, there may be administration issues with some products. Most children affected by AR are more than 2 years old, because usually, several years of antigen exposure is required to establish sensitization. Children who have rhinitis before the age of 2 should be evaluated for other etiologies.[48]

There has been concern about use of combination cough and cold products (many contain an antihistamine and a decongestant) in children due to side effects. Most negative outcomes have resulted from inadvertent overdosage, often by giving the same drug from more than one product concurrently. These products are discouraged in children less than 4 years old.[48]

First-generation H_1 antihistamines are discouraged for children as they are for adults, due to the possible detrimental effects on school performance and learning. They may also cause paradoxical CNS stimulation in the very young age (< 2 years old). Second-generation (less sedating) H_1 antihistamines (primarily for mild or intermittent symptoms) or INCSs (for moderate–severe or persistent manifestations) are first-line modes of therapy. Antihistamines may need to be used even for more severe and/or persistent symptoms in those children who have difficulty with use of intranasal products. If necessary, these two classes can be combined.[48] See Table 65–8 for dosages of second-generation antihistamines by age groups for which they are indicated. Special care should be given to avoid administration of the same medication from different (especially combination) products. The side effects of second-generation antihistamines in children are similar to those for adults.

See Table 65–6 for dosages of INCSs by age groups. The consensus about INCSs and systemic side effects, especially delay in growth, is that most products are safe. Three INCSs, mometasone, fluticasone furoate, and triamcinolone, are FDA approved for children as young as 2 years of age. The local side effects of INCSs are the same in children as for adults.[22,48]

Other therapy options may be worth consideration for some pediatric patients. Montelukast provides an oral alternative, especially for those who are too young to cooperate with intranasal administration of corticosteroids. It may be used in combination with an oral antihistamine for additional efficacy. Another option for mild or intermittent symptoms is intranasal cromolyn, primarily due to its excellent safety.[3,6-10,14,48] This OTC product is labeled for use in children 2 years of age and older. Intranasal ipratropium may be considered for patients 5 years of age or older and may benefit unresponsive rhinorrhea.[48]

▶ *Pregnant Women*

Women who have AR may suffer an exacerbation of symptoms during pregnancy. However, only minor changes in the routine approach to therapy are necessary because of the pregnancy. Nasal saline irrigations are safe, effective, and improve the response to most other modes of therapy. They can be the foundation of AR therapy for pregnant patients.[28,49] Physical exercise increases vasoconstriction of the nasal mucosa, decreasing congestion and rhinorrhea. External adhesive strips can be used to help keep the nares open, especially during sleep. Second-generation antihistamines are generally considered safe, based on an increasing number of studies and experience; however, clinicians should review specific pregnancy data for specific agents. Data are somewhat lacking regarding fetal harm regarding various INCSs.[49] Data on cromolyn demonstrate no perinatal mortality or prematurity in nearly 300 infants when it was used in asthmatic mothers, thus may be a relatively safe option to consider.[49] The disadvantages are frequent administration and less efficacy than antihistamines and INCSs. Montelukast has also not demonstrated increased risk of adverse perinatal outcomes, but some recommend it primarily in those with concurrent asthma or who have demonstrated a good response prior to pregnancy.[49] Ipratropium may be useful for troublesome rhinorrhea.[9] Oral decongestants are best avoided, especially in the first trimester. If nasal congestion is severe enough to warrant a decongestant, the intranasal route of administration is preferable, due to decreased systemic exposure. If use is absolutely needed, clinicians should recommend that the maximum duration of use to maximum of 2 to 3 days.[49]

Patient Encounter 2, Part 2

Mr. J returns months later after having taken your advice. He is now noticing an increase in symptoms since taking up golfing as a hobby. He was prescribed a combination nasal corticosteroid and antihistamine by his primary care physician, but it does not seem to be helping much with his symptoms. He does saline nasal rinses several times a week with limited relief. He has missed work several times in the last few months due to unbearable congestion and sinus headaches, in addition to his nasal and ocular itching. One of his friends tells him about "allergy treatments" that helped his "bad allergies" that were once a "shot" but heard there now noninjectable options. Mr. J asks you, "would this be something I can do? Would it help me with my allergies?"

What is your explanation to Mr. J about his inquiry, and what is your recommendation at this time?

▶ *Breast-Feeding Women*

There is available information about the relative safety of AR medication use in breast-feeding women.[49] Budesonide is probably the safest INCS, and loratadine is probably the safest antihistamine if treatment is needed. Intranasal cromolyn is also considered relatively safe. Nasal saline irrigation could also be considered as a safe initial choice in treatment in breast-feeding women.

▶ *Elderly*

AR in elderly patients is treated generally as it is in younger adults; however, consideration of increased risk for certain side effects (eg, antimuscarinic) should weigh into therapy choices.[50] Therefore, first-line agents are primarily INCSs and second-generation oral or possibly intranasal antihistamines. Older patients may also have a component of atrophy of nasal tissues that can result in more nasal congestion. Most will benefit from regular nasal saline irrigation. The elderly patients are more sensitive to the sedative and antimuscarinic effects of (especially first-generation) antihistamines and to the cardiovascular and CNS stimulant effects of decongestants. These drugs should be used cautiously, if at all. An increase in cholinergic activity may result in more rhinorrhea, which may respond well to ipratropium.

Ocular Symptoms

Several products are available for instillation directly into the eyes for those patients with predominant or unresponsive ocular manifestations. They may be appropriate for occasional moderate–severe flares or episodic AR when other modes of therapy are not optimally effective. The combination (antihistamine and mast cell stabilizing) agents may be the most effective, and they have the advantages of rapid onset of action and (usually) only twice-daily administration.[3] Ketotifen is in this category and because it is available OTC, it can be an appropriate initial agent. See Table 65–9 for these products.

Patient Encounter 2, Part 3

It is now several years later, and Mr. J accompanies his wife, Mrs. J, to the clinic—they are expecting their first child. Mrs. J states, my allergies are definitely a problem, but not nearly as bad as my husband's. Mrs. J states, "I have not taken anything before for my allergies but for some reason my symptoms are really bad this season. I was not sure what to do since I am about 16 weeks along in my pregnancy, so I have not started anything yet." She reports sneezing, nasal and ocular itching, and rhinorrhea, nearly every day. She has no other comorbidities or known medication allergies.

What do you recommend and why?

Summary of Treatment

Once an agent appropriate for initial therapy is chosen, ongoing management requires repeated checks to ascertain response and freedom from intolerable or adherence limiting side effects. Either "step-up" or "step-down" therapy may be appropriate, depending on individual response. Duration of therapy can depend on type and severity of AR. For example, those with SAR may only need treatment during certain times of year, for example, spring or summer, versus those with PAR may require chronic treatment, year-round. If a given patient is well-controlled for a sustained period (eg, weeks to months) and/or allergen exposure decreases, stepping down therapy may be considered. In stepping down therapy, symptoms frequency and severity should be monitored for possible need to step up therapy. See Table 65–10 for a summary of the approach to treatment of AR. Table 65–11 attempts to rank the relative effectiveness of the classes of agents for treatment of AR by specific symptoms.

Table 65–9

Intraocular Medications

Category	Generic (Brand) Name	Formulation	Frequency	Age
Decongestant/vasoconstrictor	Naphazoline[a] (Naphcon, Privine, others)	0.012% + 0.025%	Four times daily	Adult
Decongestant/vasoconstrictor + antihistamine	Naphazoline + pheniramine[a] (Visine A)	0.025%/0.3%	Four times daily	6 yo or more
Antihistamine	Emedastine (Emadine)	0.05%	Four times daily	3 yo or more
	Alcaftadine (Lastacaft)	0.25%	Once daily	2 yo or more
Mast cell stabilizer	Cromolyn (generic)	4%	Every 4–6 hours	4 yo or more
	Lodoxamide (Alomide)	0.1%	Four times daily	2 yo or more
	Nedocromil (Alocril)	2%	Twice daily	3 yo or more
	Pemirolast (Alamast)	0.1%	Four times daily	3 yo or more
Antihistamine + mast cell stabilizer	Azelastine (Optivar)	0.05%	Twice daily	3 yo or more
	Epinastine (Elestat)	0.05%	Twice daily	2 yo or more
	Ketotifen[a] (Zaditor, Alaway, Claritin,	0.025%	Every 8–12 hours	3 yo or more
	Zyrtec, generic)	0.1%/0.2%	Twice daily/once daily	3 yo or more
	Olopatadine (Patanol/Pataday)	1.5%	Twice daily	2 yo or more
	Bepotastine (Bepreve)			
NSAIDs	Ketorolac (Acular)	0.5%	Four times daily	3 yo or more
Corticosteroid	Loteprednol (Alrex)	0.2%	Four times daily	Adult

[a] Available OTC.

Also, see Chapter 62, Glaucoma, for more details.

NSAID, nonsteroidal anti-inflammatory drug; yo, years old.

Data from Lexi-Comp OnlineTM, Pediatric & Neonatal Lexi-Drugs OnlineTM, Hudson, Ohio: Lexi-Comp, Inc.; December 31, 2020, includes any off-label dosing.

Table 65–10

Routine Approach to Therapy of AR[3,6-10,14]

All patients should practice avoidance of identified allergens

Mild Intermittent

First line:
Oral antihistamine (OTC, initially; preferably second generation)
Adjunctive/secondary (may use more than one; no specific order intended):

- Add nasal saline (eg, as irrigation)
- Consider intranasal cromolyn, especially preexposure for episodic AR
- Consider OTC INCS for refractory symptoms
- Consider intraocular medications, as needed for ocular symptoms (see Table 63–9)
- Consider OTC oral decongestant for nasal congestion
- Consider OTC intranasal decongestant for refractory nasal congestion (not more than 3 days)
- Consider prescription therapy for inadequate response (see below)

Possibly consider referral for immunotherapy

Persistent or Moderate–Severe

First line:
Intranasal corticosteroid
Add oral antihistamine (preferably second generation) for possible additional benefit if necessary

Adjunctive/secondary (may use more than one):

- Add nasal saline (eg, as irrigation)
- Consider intranasal antihistamine
- Consider combination intranasal antihistamine with corticosteroid
- Consider intraocular medications, as needed for ocular symptoms (see Table 63–9)
- Consider OTC oral decongestant for nasal congestion
- Consider short-term intranasal decongestant for refractory nasal congestion
- Consider montelukast
- Consider intranasal ipratropium for inadequately controlled rhinorrhea

Consider referral for immunotherapy

Episodic (no order of preference intended)
Oral antihistamine (OTC, initially; preferably second generation)
Consider addition of or replacement with intranasal cromolyn (OTC) or intranasal antihistamine or intranasal corticosteroid

Special Situations (children, pregnant women, elderly, ocular symptoms)
See Special Populations section of text

Table 65–11

Relative Efficacy (Semiquantitative) by Classes of Agents for Specific Symptoms of Allergic Rhinitis[6-9,13,14]

Drug Class	Nasal Congestion	Sneezing	Rhinorrhea	Nasal Itch	Ocular Symptoms
Intranasal corticosteroids[a]	+++	+++	+++	+++	+
Oral antihistamines[a]	+	++	++	++	++
Intranasal antihistamines	++	++	++	++	+
Oral decongestants[a]	++	0	0	0	0
Intranasal decongestants[a,b]	+++	0	0	0	0
Oral leukotriene antagonist	++	+	++	+	++
Intranasal mast cell stabilizer[a]	++	++	++	++	++
Intranasal antimuscarinic	0	0	++	0	0

[a] Some products in these classes are available OTC.

[b] Intranasal decongestants are best used for severe, unresponsive nasal congestion, or to facilitate mucosal contact of other intranasal medications, but in either case, they should usually be limited to no more than 3 days.

Note: There are different opinions about some of the rankings, partly due to inadequate study. Individual variation may create different relative efficacy in some patients. +++, greatest relative efficacy; 0, no relative efficacy.

Patient Care Process

Collect Information:

- Collect information from the history of present illness (HPI), past medical history (PMHx), and physical assessment. HPI includes location, onset, quality, quantity, setting, associated symptoms, and modifying factors (see Clinical Presentation and Diagnosis of Allergic Rhinitis). PMHx should include conditions associated with AR and its complications (see Epidemiology section). Physical assessment includes observation of patient and examination of nasal mucosa (see Clinical Presentation and Diagnosis of Allergic Rhinitis and Table 65–1).
- Identify therapies attempted and their efficacy.
- Determine additional considerations in treatment (eg, pregnancy, lactation, child or elderly; see Selected Populations section).

Assess the Information:

- Rule out nonallergic type of rhinitis (see Table 65–2).
- Determine extent and severity of patient's assessing frequency and severity of AR symptoms (see Clinical Presentation and Diagnosis of Allergic Rhinitis and Table 65–3).
- Determine the patient's understanding of AR.
- Assess response to past and current AR treatment. If clinical response is inadequate, assess adherence and technique. See Table 65–6. If nonadherence and poor technique do not explain suboptimal response, consider alternative treatments or specialist referral. See Table 65–10.

Develop a Care Plan:

- Advise allergen avoidance. See Table 65–4.
- Review optimal administration technique and adherence.
- Base therapy recommendations on symptoms and response to current and past treatment.

Implement the Care Plan:

- For mild AR where OTC agents can be used, provide patient with recommended therapy including drug name, dose, and dosing frequency. Educate on appropriate administration, expected outcomes, and possible side effects.
- For moderate-to-severe AR where physician management is likely needed, communicate recommendations to primary care provider and assist with follow-up if needed by monitoring patient symptoms control and treatment of side effects.

Follow up: Monitor and Evaluate:

- Follow up weekly at first, especially during worse times/seasons for change in symptoms and possible side effects.
- When optimal control is approached, increase duration between follow-up visits (eg, monthly, every 2–3 months, or less frequently).

OUTCOME EVALUATION

- Confirm the patient's understanding of the disorder (see Clinical Presentation and Diagnosis of Allergic Rhinitis).
- Confirm the patient's understanding about allergen avoidance measures (see Table 65–4).
- Assess the patient's symptom response, tolerance, and adherence.
- Assess the patient's administration technique with intranasal products.
- Recommend second-generation oral antihistamine therapy for most patients with mild or intermittent symptoms (see Clinical Presentation and Diagnosis of Allergic Rhinitis and Tables 65–8 and 65–10).
- Recommend INCS therapy for moderate–severe or persistent symptoms. Suggest additional therapy for those with incomplete control (see Clinical Presentation and Diagnosis of Allergic Rhinitis and Tables 65–6 and 65–9).
- Consider step-up therapy for exacerbations or incomplete response.
- Consider step-down therapy if symptoms are minimal or stable for several months.
- Consider referral to rule out nonallergic causes of rhinitis in nonresponding patients or those with an atypical presentation (see Clinical Presentation and Diagnosis of Allergic Rhinitis).
- Consider referral to an allergy specialist for patients who request immunotherapy.
- Consider referral to an allergy specialist for patients with comorbid conditions, especially asthma.

Abbreviations Introduced in This Chapter

AAAAI	American Academy of Allergy, Asthma, and Immunology
ACAAI	American College of Allergy, Asthma, and Immunology
ACEI	Angiotensin-converting enzyme inhibitor
AERD	Aspirin-exacerbated respiratory disease
AR	Allergic rhinitis
ARIA	Allergic rhinitis and its impact on asthma
BPH	Benign prostatic hyperplasia/hypertrophy
BTC	Behind-the-counter
CHPA	Consumer Health Protection Agency
H_1	Histamine type 1 (receptor)
HEPA	High-efficiency particulate air (filter)
HFA	Hydrofluoroalkane ("green" propellant for metered-dose INCSs)
HPA	Hypothalamic–pituitary–adrenal (axis)
HPI	History of present illness
HTN	(Essential or primary) hypertension
IAR	Intermittent allergic rhinitis (ARIA system)
IgE	Immunoglobulin E
INCS(s)	Intranasal corticosteroid(s)
LTRA	Leukotriene receptor antagonist

MDP	metered-dose pump
NARES	Nonallergic rhinitis with eosinophilia [on nasal smear] syndrome
NSAID	Nonsteroidal anti-inflammatory drug
OTC	Over-the-counter
PAR	Perennial allergic rhinitis (AAAAI/ACAAI system)
PDE-5	Phosphodiesterase (isoenzyme)-5
PER	Persistent allergic rhinitis (ARIA system)
PMHx	Past medical history
QT	Interval between the Q and T waves in an ECG
SAR	Seasonal allergic rhinitis (AAAAI/ACAAI system)
SCIT	Subcutaneous immunotherapy
SIT	Allergen-specific immunotherapy
SLIT	Sublingual immunotherapy

Acne Vulgaris

Laura A. Perry and Jenna M. Mills

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiology of acne.
2. Assess the signs and symptoms of acne in a presenting patient.
3. List the goals of treatment for patients with acne.
4. Select appropriate nonpharmacologic and pharmacologic treatment regimens for patients presenting with acne.
5. Identify adverse effects that may result from pharmacologic agents used in the treatment of acne.
6. Develop a monitoring plan that will assess the safety and efficacy of the overall disease state management of acne.
7. Create educational information for patients about acne, including appropriate self-management, available drug treatment options, and anticipated therapeutic responses.

INTRODUCTION

Acne vulgaris is an inflammatory skin disorder of the pilosebaceous units of the skin. Although most commonly seen on the face, acne can also present on the chest, back, neck, and shoulders.[1] Acne is not just a self-limiting disorder of teenagers. The clinical course of acne can be prolonged or recur, resulting in long-term physical complications, such as extensive scarring and psychological distress.[2]

EPIDEMIOLOGY AND ETIOLOGY

With an estimated 40 to 50 million people affected, acne vulgaris is the number one skin disease in the United States. Acne affects approximately 85% of adolescents and adults aged 12 to 25 years, with severity of acne correlating with pubertal maturity.[3] Additionally, acne may persist beyond puberty and has been found to affect 64% and 43% of individuals into the 20s and 30s, respectively. Acne is more likely to occur in males during adolescence and females during adulthood. Individuals with a positive family history of acne have been shown to develop more severe cases of acne at an earlier age. Prevalence of acne among ethnic groups is similar.[2,3]

The link between diet and acne has continued to be controversial, with emerging evidence suggesting a link to foods with high glycemic indexes as well as dairy products (ie, skim milk)—partially due to the hormones in the milk; however, no specific dietary changes are recommended in the management of acne.[2,4,5,] Local irritation from occlusive clothing or athletic equipment, oil-based cosmetics or beauty products, prolonged sweating or environments of high humidity, and a variety of medications may also worsen acne.[6]

PATHOPHYSIOLOGY

KEY CONCEPT The development of acne lesions results from four pathogenic factors: excess **sebum** production, **keratinization**, bacterial growth, and inflammation.[1]

The **pilosebaceous unit** of the skin consists of a hair follicle and the surrounding sebaceous glands. Sebum is released by the sebaceous glands and naturally maintains hair and skin hydration. Increased androgen levels, especially during puberty, can cause an increased size of the **sebaceous gland** and production of abnormally high levels of sebum within those glands. Keratinization, the sloughing of epithelial cells in the hair follicle, is also a natural process. In acne, however, *hyper*keratinization occurs resulting in an increased adhesiveness of the sloughed cells.

An initial acne lesion invisible to the naked eye, called a microcomedo, forms as a result of the increased cell division and cohesiveness. Subclinical microcomedo formation is a precursor for noninflammatory acne lesions called comedos. A **closed comedo** or "whitehead" appears when accumulation of epithelial cells and sebum partially obstruct the follicular opening. If the follicular opening is dilated, the keratin buildup can darken and form an **open comedo** or "blackhead."

Propionibacterium acnes, an anaerobic organism, is also found in the normal flora of the skin. This bacteria proliferates in the mixture of sebum and keratinocytes and can result in an inflammatory response producing more severe acne lesions such as **papules**, **pustules**, and **nodules**. Inflammatory lesions may result in scarring if treated inadequately.

TREATMENT

Desired Outcomes and Goals

Although traditionally thought of as a self-limiting disorder, acne can have patterns of recurrence. Because acne cannot be cured, proper treatment must involve both short-term and long-term strategies. **KEY CONCEPT** Goals of therapy are to (a) Reduce the number and severity of existing lesions, (b) Prevent the development of new lesions and recurrence, (c) Prevent long-term disfigurement and permanent scarring, and (d) Encourage treatment adherence.[4,6]

Clinical Presentation and Diagnosis of Acne

Acne lesions are most often seen on the face but can also present on the chest, back, neck, and shoulders and are described as either noninflammatory or inflammatory (Figure 66–1). Severe inflammatory lesions may lead to scarring and hyperpigmentation.

Noninflammatory Lesions

Closed comedo or "whitehead": A partially plugged follicle containing sebum, keratinocytes, and bacteria that remains beneath the surface of the skin. Closed comedos usually appear as small white bumps about 1 to 2 mm in diameter.

Open comedo or "blackhead": A partially plugged, dilated follicle containing sebum, keratinocytes, and bacteria approximately 2 to 5 mm in diameter that protrudes from the surface of the skin and appears black or brown in color. Although dark in color, blackheads do not indicate the presence of dirt, but rather, an accumulation of melanin.

Inflammatory Lesions

Papules: Solid, elevated lesion less than 0.5 cm in diameter.

Pustules: Vesicles filled with purulent fluid less than 0.5 cm in diameter.

Nodules: Warm, tender, firm lesions greater than 0.5 cm in both width and depth.

Cysts: Nodules that harden into larger, pus-filled lesions.

Scars

Inflammatory acne can result in permanent scarring that ranges from small, depressed pits to large, elevated blemishes.

Hyperpigmentation

Inflammatory acne may result in hyperpigmentation of the skin that can last for weeks to months.

Diagnosis

The diagnosis of acne vulgaris is clinical. Lesion cultures may be warranted when treatment regimens fail to rule out Gram-negative folliculitis and other skin infections. Endocrinological laboratory evaluation is only recommended for patients who have acne and additional signs of androgen excess.[4]

Assessment

No standard acne grading scale has been identified. While several grading scales exist,[4,7] most clinicians describe acne as mild (non-inflammatory lesions), moderate (many inflammatory lesions), or severe (numerous severe inflammatory lesions and evidence of scarring).

Acne can cause psychological symptoms of stress, anxiety, frustration, embarrassment, and even depression.[1,2,4] Evaluating both physical and psychological aspects of acne is imperative.

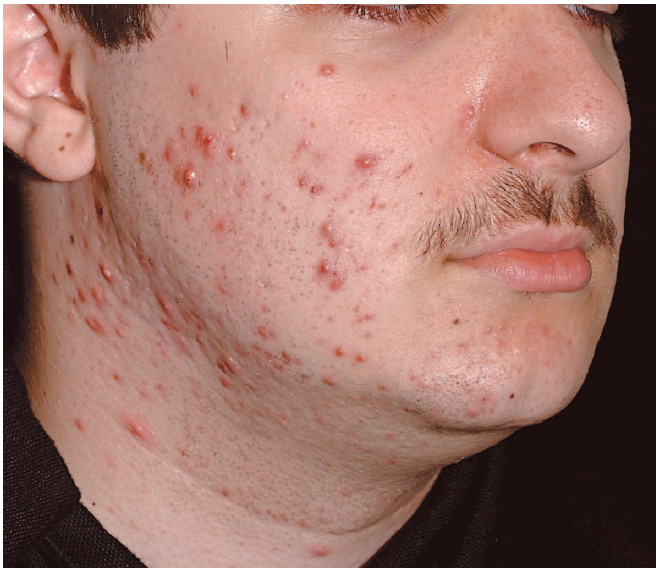

FIGURE 66–1. 20-year-old male. In this case of papulopustular acne, some inflammatory papules become nodular and thus represent early stages of nodulocystic acne. (From Wolff K, Johnson RA. Disorders of sebaceous and apocrine glands. Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology, 8th ed. New York, NY: McGraw-Hill; c2017 [cited 2020 Sept 20]. Available from https://accessmedicine-mhmedical-com.ezproxy.findlay.edu/content.aspx?bookid=2043&sectionid=154896913.)

General Approach to Treatment

KEY CONCEPT Acne treatment regimens should be based on acne severity and type of acne lesion. Other factors such as response to previous treatment, patient preference, cost, and adherence should also be considered. Topical therapy is considered first-line for mild acne with oral therapies added to topical therapy in

Patient Encounter, Part 1: Assessment

OH, a 26-year-old female, presents with facial acne. She has experienced acne since she was a teenager, which she describes as "small white bumps that appeared sporadically and weren't anything that a little makeup couldn't cover up." Her facial acne has since worsened, as the lesions have increased in number and now manifest as "red, irritated, and yellow fluid–filled bumps accompanied by larger and firmer bumps that cannot be popped." Visual examination reveals numerous noninflammatory lesions, a few papules and pustules around her nose and on her chin, and two nodules on her forehead above her right eyebrow. She states, "I thought acne was a teenager issue…it should be going away as I progress into adulthood, not getting worse!" OH washes her face twice daily with a cleansing oil and applies a deep moisturizing cream to her entire face before bed. She is a personal trainer and very physically active, especially during the summer months when she spends "as much time as possible" outdoors partaking in activities.

What reported symptoms support the diagnosis of acne?

How would you classify the patient's acne?

What factors could be contributing to the patient's acne?

moderate-to-severe acne. Using multiple topical agents that target different aspects of acne pathogenesis is more effective, reduces adverse effects, and minimizes treatment resistance.[4,7] Topical therapies should be applied to the entire area affected by acne to prevent new lesions from developing.[8]

Optimal management includes aggressive induction treatment and maintenance therapy to prevent recurrence. Improvement of symptoms following induction therapy occurs gradually, sometimes taking 6 to 8 weeks for results to be physically apparent. Patients need to be educated on continual treatment compliance during this time and should not get discouraged if acne lesions appear to worsen before getting better. Maintenance therapy should begin after 12 weeks of induction therapy and is continued for 3 to 4 months in most clinical trials. Due to frequent acne recurrences, clinical experience indicates that a longer duration of maintenance therapy may be beneficial for most patients.[4,7,8]

Nonpharmacologic Therapy

There is significant variance in the clinical benefit of many nonpharmacologic interventions for acne vulgaris. Patients should be counseled to avoid aggressive skin washing and to use a mild, noncomedogenic facial soap twice daily. Excessive washing or use of harsh or abrasive cleansers can disrupt the skin barrier and promote comedones and bacterial colonization. Manipulating or squeezing lesions should also be avoided to minimize scarring. The use of an oil-free, noncomedogenic moisturizer daily may improve the tolerability of topical drug therapy.[6,8,9]

Pharmacologic Therapy

▶ *Topical Agents*

Retinoids Topical retinoids are the foundation of first-line therapy for induction and maintenance regimens in all forms of acne. Although success is seen with monotherapy in comedonal acne, using topical retinoids in combination with benzoyl peroxide, topical antibacterial agents, or oral antibacterial agents is preferred for inflammatory acne lesions.[4,7]

Retinoids normalize epithelial cell turnover, which in turn promotes clearing of obstructed follicles and prevents microcomedo formation. Retinoids also exhibit anti-inflammatory properties through the inhibition of neutrophil and monocyte chemotaxis.[10]

Available topical retinoids include tretinoin, adapalene, tazarotene, and trifarotene. Adapalene, available by prescription and over the counter, is considered the drug of first choice because it has similar efficacy and a lower incidence of adverse effects.[4,6,7,10] Microsphere gel (Retin-A Micro) or a polyolprepolymer-2 gel or cream (Avita) gradually release the active ingredient over time and may also cause less initial skin discomfort. Topical retinoid products with a foam vehicle have a more favorable tolerability profile than comparable gel formulations.[10] Table 66–1 describes available products and adverse effects of topical retinoids.

Topical retinoids should be applied once daily at bedtime, beginning with a low-potency formulation. Increased strengths are then initiated according to treatment results and tolerance.[8] Patients should be advised that a worsening of acne symptoms generally occurs in the first few weeks of therapy, with lesion improvement occurring in 3 to 4 months.[8,11] The safety and efficacy of topical retinoids in children younger than 12 years of age and in pregnant women is not well established.[9]

Benzoyl Peroxide Benzoyl peroxide is easy to use and is recommended as an alternative to, or in combination with, topical retinoids, topical antibacterial agents, or oral antibacterial agents in the treatment of acne of all severities.[47] Benzoyl peroxide has a comedolytic effect that increases the rate of epithelial cell turnover and helps to unclog blocked pores. It also has antibacterial activity against *P. acnes*, which appears to be the main reason for its effectiveness.[12,13]

Benzoyl peroxide is available with or without a prescription and remains the most commonly purchased over-the-counter topical treatment for acne.[6,14] Some data suggests that lower strengths offer similar efficacy to higher strengths. Beginning benzoyl peroxide treatment regimen with the lowest strength and titrating to higher effective strengths over several weeks, if needed, will reduce the incidence of localized adverse effects. Newer formulations of benzoyl peroxide are combined with moisturizers to help decrease skin redness and irritation.[9,12,14]

A typical regimen for benzoyl peroxide is to apply the product to clean, dry skin no more than two times a day. The strength and dosage form selected may vary from patient to patient depending on acne severity and the sensitivity of the patient's skin. Gel preparations are the most potent dosage form. Patients with dry or overly sensitive skin should try a cream, lotion, or facial wash first.[4,8] If severe irritation or an allergic reaction develops, benzoyl peroxide should be discontinued. Patients should avoid contact with hair and dyed fabric, which may be bleached by benzoyl peroxide products.[6] Table 66–1 describes available products and adverse effects.

Antibacterials Topical antibacterials directly suppress *P. acnes* and are first-line agents used in combination with benzoyl peroxide for the treatment of mild-to-moderate inflammatory acne. To reduce the likelihood of bacterial resistance, topical antibiotics should be combined with benzoyl peroxide and never be used as monotherapy or as long-term maintenance therapy.[4,7]

Clindamycin is currently the preferred topical antibiotic for acne therapy due to increased bacterial resistance to erythromycin preparations.[4] Topical minocycline was recently approved, but long-term safety and efficacy studies are needed to determine place in therapy.[15] Applied once or twice daily for 3 months, these agents are available in various formulations and combinations with benzoyl peroxide and topical retinoids.[4,7] Table 66–1 describes the strengths, formulations and adverse effects of the available antimicrobial agents.

Azelaic Acid With antibacterial and anti-inflammatory properties, and the ability to stabilize keratinization, azelaic acid is an effective alternative in the treatment of mild-to-moderate acne in patients who cannot tolerate benzoyl peroxide or topical retinoids.[4,7,11] It can also even out skin tone and may prove effective in patients who are prone to postinflammatory hyperpigmentation resulting from acne.[4,11,16] Azelaic acid 20% cream should be applied twice daily, with improvement of symptoms seen within 4 weeks.[11]

Dapsone Dapsone gel, a sulfone drug, has antimicrobial and anti-inflammatory properties.[17] Dapsone gel may be used as an alternative agent for inflammatory acne as monotherapy or in combination with topical or oral agents. Topical dapsone gel has been shown to be more effective in adult females than in males or adolescents.[4]

Dapsone 5% is a gritty gel that should be applied in a thin layer to the affected areas twice daily.[17,18] When administered concomitantly with benzoyl peroxide, topical dapsone may become oxidized, causing orange-brown coloration of the skin which can be brushed or washed off. If no improvement is seen after 12 weeks, treatment should be reevaluated.[4,18]

Clascoterone Clascoterone cream, an androgen receptor inhibitor, decreases sebum production and inflammation that in turn

Table 66–1

Topical Agents Used in the Treatment of Acne

Drug	Brand	Dosage Form	Adverse Reactions	Comments
Retinoids				
Tretinoin	Altreno Atralin Avita Retin-A Retin-A Micro Retin-A Micro Pump	0.05% lotion 0.05% gel 0.025% cream, gel 0.025%, 0.05%, 0.1% cream; 0.01%, 0.025% gel 0.04%, 0.1% gel 0.04%, 0.06%, 0.08% gel	Erythema, dryness, scaling, stinging/burning, pruritus, initially may worsen acne Possibly teratogenic Photosensitivity	Local adverse reactions most likely occur in first 2–4 weeks of use and will usually lessen with continued use Should not be used in pregnancy; potential teratogenicity Minimize exposure to sunlight and sun lamps. Sunscreen use and protective clothing recommended
Tazarotene	Arazlo Fabior Tazorac	0.045% lotion 0.1% foam 0.1% cream, gel	Erythema, dryness, scaling, stinging/burning, pruritus, initially may worsen acne Teratogenic Photosensitivity	Local adverse reactions most likely occur in first 2 to 4 weeks of use and will usually lessen with continued use Should not be used in pregnancy; potential teratogenicity Minimize exposure to sunlight and sun lamps. Sunscreen use and protective clothing recommended
Adapalene	Differin Differin Gel (over the counter) Epiduo and Epiduo Forte	0.1% cream 0.1%, 0.3% gel 0.1% lotion 0.1% gel 0.1–2.5% and 0.3–2.5% benzoyl peroxide combination gel	Erythema, dryness, scaling, stinging/burning, pruritus, initially may worsen acne Photosensitivity	Local adverse reactions most likely occur in first 2–4 weeks of use and will usually lessen with continued use Less irritation compared to other retinoids Should not be used in pregnancy; potential teratogenicity Minimize exposure to sunlight and sun lamps. Sunscreen use and protective clothing recommended
Trifarotene	Aklief	0.005% cream	Erythema, scaling, dryness, stinging/burning, pruritus Photosensitivity	Local adverse reactions most likely occur and worsen within the first 4 weeks of treatment; often decreases with continued use Should not be used in pregnancy; potential teratogenicity Minimize exposure to sunlight and sun lamps. Sunscreen use and protective clothing recommended
Other Topical Agents				
Benzoyl Peroxide	2.5%–10%, Various over-the-counter and prescription products	Cream, foam, foaming cloths, gel, liquid wash, lotion, pad	Excessive drying, peeling, erythema, allergic contact sensitization/dermatitis Bleaching of hair and colored fabric Body odor on clothes/bedding Photosensitivity	Local reactions are dose dependent. Gradually increase dose as tolerance develops Minimize exposure to sunlight and sun lamps. Sunscreen use and protective clothing recommended Preferred topical agent in pregnancy; limited data
Azelaic Acid	Azelex	20% cream	Erythema, skin irritation	Alternative to benzoyl peroxide Possible alternative in pregnancy; limited data
Clindamycin	Cleocin-T Clindagel ClindaMax Evoclin Acanya, BenzaClin, Neuac, Onexton Veltin, Ziana	1% solution, lotion, gel, swab 1% gel 1% gel, lotion 1% foam 1.2%/2.5%, 1%/5%, 1.2%/5%, 1.2%/3.75% benzoyl peroxide combination gel 1.2%/0.025% tretinoin combination gel	Burning, itching, dryness, erythema, peeling Diarrhea, colitis (pseudomembranous colitis)	Rare cases of colitis have been observed with topical use. Discontinue immediately and seek medical attention if diarrhea occurs Should be combined with benzoyl peroxide May be considered with benzoyl peroxide during pregnancy

(Continued)

Table 66–1

Topical Agents Used in the Treatment of Acne (*Continued*)

Drug	Brand	Dosage Form	Adverse Reactions	Comments
Erythromycin	ERYGEL Ery Benzamycin	2% gel 2% pad 3%/5% benzoyl peroxide combination gel	Burning, peeling, dryness, pruritus, erythema	Should be combined with benzoyl peroxide Combination with benzoyl peroxide has not been evaluated in animal reproduction studies
Dapsone	Aczone	5%, 7.5% gel	dryness, erythema, oiliness, and peeling	Does not have a risk of phototoxicity Not a preferred agent in pregnancy; limited data
Minocycline	Amzeeq	4% foam	Redness, hyperpigmentation, headache Photosensitivity Potential risk of systemic side effects (see oral minocycline)	Avoid use in children 8 years and younger Avoid during pregnancy Avoid or minimize exposure to natural or artificial sunlight. Skin protection and loose-fitting clothing recommended
Clascoterone	Winlevi	1% cream	Redness, exfoliation of skin, xeroderma, atrophic striae	Approved for children ≥ 12 years of age Avoid during pregnancy; limited data

Data from 1) Lexicomp [Internet]. Hudson (OH): Wolters Kluwer Clinical Drug Information, Inc.1978-2020 [cited 2020 May 31]. Available from: http://online.lexi.com/lco/action/home/switch

2) IBM Micromedex [Internet]. IBM Corporation.2020 [cited 2020 May 31]. Available from: https://www.micromedexsolutions.com/home/dispatch

reduces follicular plugging.[19] This novel mechanism is the first antiandrogen therapy that can be used in both males and females. Clascoterone has demonstrated efficacy and a favorable safety profile in males and nonpregnant females with moderate-severe facial acne.[20] Long-term safety and efficacy data and comparator studies are needed to determine the benefit of clascoterone over other first-line topical agents.

Keratolytics Sulfur, resorcinol, and salicylic acid have limited evidence available to support efficacy but can be used as second-line therapies in the treatment of mild-to-moderate acne.[4,6]

Although these agents may cause less skin irritation than benzoyl peroxide or the topical retinoids, several disadvantages exist. Sulfur preparations produce an unpleasant odor when applied to the skin, whereas resorcinol may cause brown scaling. And although rare, the possibility of salicylism exists with continual salicylic acid use.[6,11,14]

▶ *Oral Agents*

Antibacterials Oral antibiotics are indicated for use in patients with moderate-to-severe acne and forms of inflammatory acne that are resistant to topical therapy. When used, oral antibiotics should be combined with a topical retinoid and/or benzoyl peroxide.[2,4,7] Because of the ability to decrease *P. acnes* colonization, oral antibiotics can prevent acne lesions from developing. The use of oral antibiotics should be limited to short periods of time, ideally 3 to 4 months, or less.[4] Assessment of response to oral antibiotics after 6 to 8 weeks of therapy is recommended. After inflammatory lesions have stopped emerging, oral antibiotics should be discontinued and replaced with topical retinoid or benzoyl peroxide containing maintenance regimens.[4,9] As with topical antibiotics, oral antibiotics should never be used as monotherapy or as long-term maintenance therapy. Additionally, the use of topical antibiotics in combination with oral antibiotics should be avoided due to increased risk of bacterial resistance.[24,7]

Tetracycline, doxycycline, and minocycline are the most commonly prescribed oral antibiotics for acne. Doxycycline and minocycline are more effective than tetracycline, but neither is superior to each other.[4] Sarecycline, a recently approved tetracycline, displays a more narrow spectrum of activity designed to target skin bacterium with the potential for fewer gastrointestinal adverse effects. Long-term safety and efficacy data are needed to clarify the benefit of using sarecycline over minocycline or doxycycline as a first-line agent.[21] Erythromycin, azithromycin, and trimethoprim (± sulfamethoxazole) are appropriate second-line agents for use when patients cannot tolerate or have developed resistance to tetracycline or its derivatives. Although effectiveness is similar to the tetracyclines, erythromycin use is often limited due to potential adverse outcomes and increased bacterial resistance.[4,22] (See Table 66–2 for antibiotic dosing guidelines and adverse effects.)

Isotretinoin Isotretinoin works on the four pathogenic factors that contribute to acne development and can produce acne remission rates of up to several years. Oral isotretinoin is Food and Drug Administration (FDA) approved for patients with severe recalcitrant nodular acne unresponsive to other topical and oral treatment regimens.[4,7] Additional evidence suggests that oral isotretinoin may be useful in treatment-resistant moderate acne or acne that is producing physical scarring or psychosocial distress.[2,4,7] Some expert clinicians suggest that oral isotretinoin therapy may be used as first-line therapy in patients with severe nodular acne due to clinical effectiveness, prevention of scarring, and quick improvements in patient quality of life.[7,8]

Adverse effects with the use of isotretinoin are frequent and generally dose-related. Table 66–2 lists common isotretinoin adverse effects and management strategies for those symptoms.

Because isotretinoin is teratogenic and is contraindicated in pregnancy, the FDA mandates an online registry program called iPLEDGE to ensure that females do not become pregnant while taking isotretinoin. Wholesalers, pharmacies, doctors, and patients must be registered in the iPLEDGE computer-based system in

Table 66–2

Oral Agents Used in the Treatment of Acne

Drug	Dosage Form (mg)	Dosing Regimen	Adverse Reactions	Comments
Oral Antibiotics				
Tetracycline	250, 500 capsule	250–500 mg twice daily	GI upset, diarrhea, headache, blurry vision, vaginal candidiasis, tooth discoloration in children Vaginal candidiasis Photosensitivity Administer 1–2 hours prior to or 4 hours after dairy products, multivitamins, iron, or antacids	Avoid use in children < 8 years Avoid use in pregnancy; possible teratogenicity Minimize exposure to sunlight and sun lamps. Sunscreen use and protective clothing recommended Take 1 hour before or 2 hours after dairy products, antacids, vitamins, or iron supplements
Doxycycline	50, 75, 100 Tablets and capsules	100 mg twice daily on day 1, then 100 mg once daily	GI upset, diarrhea, headache, blurry vision, tooth discoloration in children Vaginal candidiasis Photosensitivity Administer 1 to 2 hours prior to or 4 hours after dairy products, multivitamins, iron, or antacids	Avoid use in children < 8 years Avoid use in pregnancy; possible teratogenicity Minimize exposure to sunlight and sun lamps. Sunscreen use and protective clothing recommended Take 1 hour before or 2 hours after dairy products, antacids, vitamins, or iron supplements
Minocycline	50, 75, 100 immediate-release tablets 45, 55, 65, 80, 90, 105, 115, 135 extended-release tablets 50, 75, 100 immediate-release capsules	Immediate release: 50–100 mg twice daily Extended release: 1 mg/kg daily for 12 weeks.	GI upset, diarrhea, headache, blurry vision, lupus-like syndrome, hepatitis, exfoliative dermatitis, tooth discoloration in children Vaginal candidiasis Photosensitivity Administer 1–2 hours prior to or 4 hours after dairy products, multivitamins, iron or antacids	Avoid use in children < 8 years Avoid use in pregnancy; possible teratogenicity Minimize exposure to sunlight and sun lamps. Sunscreen use and protective clothing recommended Take 1 hour before or 2 hours after dairy products, antacids, vitamins, or iron supplements
Sarecycline	60, 100, 150 tablet	Weight-based; 33–54 kg: 60 mg once daily 55–84 kg: 100 mg once daily 85–136 kg: 150 mg once daily	GI upset, diarrhea, tooth discoloration in children Photosensitivity Administer 1 to 2 hours prior to or 4 hours after dairy products, multivitamins, iron or antacids	Avoid use in children < 8 years Avoid use in pregnancy; possible teratogenicity Minimize exposure to sunlight and sun lamps. Sunscreen use and protective clothing recommended Take 1 hour before or 2 hours after dairy products, antacids, vitamins, or iron supplements
Erythromycin	250, 500 tablets	250–500 mg twice daily	GI upset, diarrhea, rash, hearing loss, hypersensitivity reactions Vaginal candidiasis	Highest incidence of GI intolerance and increasing bacterial resistance Possible drug interactions: CYP3A4 substrate and p-glycoprotein inhibitor Alternative to tetracyclines Oral antibiotic option for pregnant women and children < 8 years
Azithromycin	500 tablet	Dosing regimens used in clinical trials have varied greatly, using pulse dose regimens (eg 500 mg once daily for 4 consecutive days per month for 3 consecutive months)	GI upset, diarrhea, rash, headache, drowsiness	Alternative if other antibiotics cannot be used Oral antibiotic option for pregnant women and children < 8 years

(*Continued*)

Table 66–2

Oral Agents Used in the Treatment of Acne (*Continued*)

Drug	Dosage Form (mg)	Dosing Regimen	Adverse Reactions	Comments
Trimethoprim	100-mg tablet	100 mg three times daily or 300 mg twice daily	GI upset, diarrhea, allergic rash, Stevens-Johnson syndrome Photosensitivity	Alternative if other antibiotics cannot be used Not preferred in pregnancy; may affect folic acid metabolism Minimize exposure to sunlight and sun lamps. Sunscreen use and protective clothing recommended
Sulfamethoxazole + trimethoprim	400/80, 800/160 tablet	400-800/80–160 mg One to two times daily	GI upset, diarrhea, allergic rash, urticaria, Stevens-Johnson syndrome Photosensitivity	Alternative if other antibiotics cannot be used Not preferred in pregnancy; may affect folic acid metabolism and possible teratogenicity Minimize exposure to sunlight and sun lamps. Sunscreen use and protective clothing recommended
Hormonal Agents				
Oral Contraceptives	Norgestimate/ethinyl estradiol (Tri-Estarylla, Tri-Previfem, Tri-Sprintec) Norethindrone acetate/ethinyl estradiol (Estrostep Fe, Tilia Fe, Tri-Legest Fe)	One tablet daily	Nausea, headache, weight gain, breast tenderness, break through bleeding, venous thromboembolism	Not for treatment of acne in men Use only in females ≥ 15 years of age Contraindicated in pregnant women
Spironolactone	25,50, 100 tablet	50–200 mg daily	Menstrual irregularities, breast tenderness, nausea, dizziness, headache, transient diuretic effect, hyperkalemia	Not recommended for treatment of acne in men Monitor serum creatinine and potassium Not recommended in pregnancy; limited data
Oral Retinoid				
Isotretinoin	10, 20, 30, 40 tablets	0.5–1 mg/kg/day in two divided doses with food	Cheilitis, dryness of the nose, eyes, and mouth, peeling, pruritus, and drying of the face and skin, alopecia, acne flare up at start of therapy Teratogenicity Depression/suicidality Musculoskeletal pain Increased serum cholesterol, triglycerides, creatine phosphokinase, and blood glucose Photosensitivity	Nasal sprays, lip moisturizers, and hard candy may help to reduce drying of mucous membranes Apply oil-free moisturizers to face to relieve drying of skin Contraindicated in pregnancy (US Boxed Warning) Monitor patient closely for changes in mood May use nonsteroidal anti-inflammatory drugs to relieve pain Monitor lipid panel, liver function tests, and blood glucose Minimize exposure to sunlight and sun lamps. Sunscreen use and protective clothing recommended

order to control the distribution, prescribing, and dispensing of isotretinoin. Two negative pregnancy tests prior to initiating therapy and one negative pregnancy test each month thereafter must be obtained and confirmed in the system before a prescription can be dispensed to female patients of childbearing potential. These patients must also commit to using two effective forms of birth control 1 month prior, during, and at least 1 month after discontinuation of isotretinoin therapy. Contact the program at their website: *https://www.ipledgeprogram.com/* for further details.

The initial dose for treatment of severe acne is typically 0.5 mg/kg daily in two divided doses, then increasing to 1 mg/kg daily, as tolerated, with goal cumulative doses of 120 to 150 mg/kg. Increasing the total daily dose to 1 mg/kg daily resulted in a significantly lower relapse and retreatment rate.[4,9,7] For patients with treatment-resistant moderate acne, low-dose isotretinoin (0.25–0.4 mg/kg/day) has comparable efficacy to conventional dosing with decreased adverse effects and improved tolerability. Intermittent dosing of isotretinoin is not recommended due to the lack of efficacy and increased relapse rates.[4] Treatment with oral isotretinoin should be continued for 4 to 6 months but may be extended for patients with an insufficient response.[4,7]

Hormonal Agents Oral contraceptives and antiandrogens are valuable second-line treatment options for moderate-to-severe inflammatory acne in female patients.[4,7] Hormonal agents primarily work by decreasing androgen production resulting in reduced sebum formation. Because sebum production occurs early in the pathogenesis of acne, it takes several months to see the full effect of hormonal agents.[4]

Although many contraceptives are effective,[23] agents containing ethinyl estradiol/norgestimate, ethinyl estradiol/norethindrone acetate/ferrous fumarate, and ethinyl estradiol/drospirenone have been FDA approved for the treatment of acne.[4] While not FDA approved, spironolactone, at higher doses, is effective for acne through antiandrogenic properties.[4,7] (See Table 66–2 for hormonal agent dosing guidelines and adverse effects).

Other Agents Although use is infrequent, several other agents are available as second- or third-line treatment options for acne when first-line therapies fail:[2,4,7]

- Corticosteroids
- Chemical peels
- Surgical extraction
- Phototherapy/photodynamic therapy
- Laser treatments

Figure 66–2 shows useful algorithms for the effective treatment of the various stages of acne.

Patient Encounter, Part 2: Plan

OH has never seen a dermatologist and has not previously tried any medication for her acne. She has friends who are being treated for acne and knows their treatment regimens consist of multiple products and repeated applications daily. She expresses, "I am ultimately looking for the simplest option available because I don't anticipate I will keep up with multiple products every day. With how much time I spend at the gym and outside, that just isn't realistic for me." She asks if Differin Gel would be a good option to "make her acne go away," since a client recommended it to her after seeing it is available over the counter. The patient appears to be in good physical health and has no known drug allergies.

Describe your treatment goals for this patient.

What nonpharmacologic treatment options and lifestyle modifications would you suggest to this patient?

Consider a pharmacologic treatment plan for this patient:

Do you recommend Differin Gel for this patient? Why or why not?

What pharmacologic treatment options are available for this patient?

List 1–2 pros and 1–2 cons for each potential treatment option. Please take patient-specific considerations into account.

Given the information presented, develop a patient-specific therapeutic plan.

	Mild	Moderate	Severe
1st Line Treatment	Benzoyl Peroxide (BP) or Topical Retinoid -or- Topical Combination Therapy** BP + Antibiotic or Retinoid + BP or Retinoid + BP + Antibiotic	Topical Combination Therapy** BP + Antibiotic or Retinoid + BP or Retinoid + BP + Antibiotic -or- Oral Antibiotic + Topical Retinoid + BP -or- Oral Antibiotic + Topical Retinoid + BP + Topical Antibiotic	Oral Antibiotic + Topical Combination Therapy** BP + Antibiotic or Retinoid + BP or Retinoid + BP + Antibiotic -or- Oral Isotretinoin
Alternative Treatment	Add Topical Retinoid or BP (if not on already) -or- Consider Alternate Retinoid -or- Consider Topical Dapsone	Consider Alternate Combination Therapy -or- Consider Change in Oral Antibiotic -or- Add Combined Oral Contraceptive or Oral Spironolactone (Females) -or- Consider Oral Isotretinoin	Consider Change in Oral Antibiotic -or- Add Combined Oral Contraceptive or Oral Spironolactone (Females) -or- Consider Oral Isotretinoin

FIGURE 66–2. Algorithms for acne treatment. (From Zaenglein AL, Pathy AL, Schlosser BJ, et al. Guidelines of care for the management of acne vulgaris. J Am Acad Dermatol. 2016;74:945–973.)

Patient Care Process: Acne

Collect Information:

- Perform dermatologic exam and note the number and type of acne lesions: open and closed comedos, papules, pustules, nodules, cysts.
- Obtain age of onset and family history of acne, including severity.
- Determine patient's current skin care routine, including use of cosmetics, facial washes, moisturizers, and other possible exacerbating factors.
- Review patient preferences and beliefs, health goals, and socioeconomic factors.
- Conduct a medication history (nonprescription, prescription, and herbal medications). Identify previous acne treatment regimens.
- Note allergies to medications or other substances.

Assess the Information:

- Assess patient symptoms and acne lesions to determine acne severity: mild, moderate, or severe.
- Determine if any medications or behaviors may be exacerbating acne.
- If patient is already receiving pharmacotherapy, assess whether active and/or previously tried therapies were effective, safe, and used as directed.

Develop a Care Plan:

- If acne not well controlled, determine appropriate pharmacotherapy options for the patient's acne severity (Figure 66–2).
- Determine whether patient has prescription medication coverage to identify possible recommendations included in the plan formulary.
- Select nondrug and drug therapy likely to be effective and safe and determine drug, dose, route, and frequency of administration/application. Use combination products as appropriate to improve adherence and reduce adverse effects (Tables 66–1 and 66–2).
- Choose appropriate changes to lifestyle.

Implement the Care Plan:

- Provide patient education on acne:
  - What is acne and how does it develop?
  - Physical and psychological complications that can result from acne.
- Educate patient on proper use, adverse effects, and expectations of acne drug therapy.
  - Inform the patient of recommended changes, deletions, and additions to acne drug regimen.
  - Review drug, dose, route/proper administration technique, and duration of therapy. Topical acne therapy should be applied to entire acne prone area and existing lesions.
  - Review possible side effects of drug therapy.
  - Inform patient of possible initial worsening of acne and/or delay of therapeutic effectiveness of acne drug therapy.
- Emphasize medication compliance and adherence to lifestyle modifications for treating existing acne lesions and preventing recurrence.
- Address any patient concerns.

Follow-up: Monitor and Evaluate:

- Follow-up every 1 to 2 months to assess effectiveness and safety of nondrug and drug therapy (Tables 66–1 and 66–2).
- If acne lesions do not respond after 3 months of drug therapy, consider an alternative acne regimen (Figure 66–2).
- If the patient experiences resolution of acne symptoms, transition to maintenance drug therapy.

OUTCOME EVALUATION

Depending on severity, complete resolution of acne lesions may take weeks to months. Monitor patients every 4 to 8 weeks during pharmacologic therapy to assess for efficacy.[4,9]

- Decreased number of lesions
- Decreased severity of lesions
- Relief of pain/irritation
- Presence of scarring or pigmentation
- Psychological effects
- Medication adherence

If no improvement is reported after 6 weeks of drug therapy or if symptoms have worsened, patients should be reevaluated and a change to an alternative drug regimen may be necessary (Figure 66–2).

Educate patients on potential adverse effects of drug therapy (Tables 66–1 and 66–2). Consider changing therapy if a patient experiences effects that are not tolerated or are a compromise to their health.

Patient Encounter, Part 3: Monitoring and Follow-Up

After implementing a therapeutic plan, OH asks, "what's the next step? Should I follow up after a certain amount of time, or am I good to go?"

Formulate a monitoring plan to assess the efficacy and safety of OH's therapeutic plan. Include timeframes and specific monitoring parameters.

Dermatitis

Lori Ernsthausen and Jenna M. Mills

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the pathophysiology of dermatitis.
2. Assess the signs and symptoms of dermatitis in a presenting patient.
3. List the goals of treatment for patients with dermatitis.
4. Select appropriate nonpharmacologic and pharmacologic treatment regimens for patients presenting with dermatitis.
5. Identify adverse effects that may result from pharmacologic agents used in the treatment of dermatitis.
6. Develop a monitoring plan that will assess the safety and efficacy of the overall disease state management of dermatitis.
7. Create educational information for patients about dermatitis, including appropriate self-management, available drug treatment options, and anticipated therapeutic responses.

INTRODUCTION

Several thousand skin disorders are currently documented, and many patients seek the assistance of a health care provider when a complication with their skin develops. Others will utilize self-care to effectively treat their symptoms.

This chapter discusses contact dermatitis (irritant and allergic), atopic dermatitis, and diaper dermatitis; other common skin and soft tissue infections, and superficial fungal infections are discussed in Chapters 76 and 85, respectively. Providing patients with appropriate therapy options, as well as patient education on treatment and prevention, will assist the successful management of many common skin disorders.

CONTACT DERMATITIS

Contact dermatitis is a condition in which exposure to an offending substance produces inflammation, erythema, and pruritus of the skin.[1,2] More specifically, contact dermatitis can be divided into either irritant or allergic forms.[3] **KEY CONCEPT** Irritant contact dermatitis (ICD) results from first-time exposure to irritating substances, such as soaps, plants, cleaning solutions, or solvents. Allergic contact dermatitis (ACD) is a delayed hypersensitivity reaction that occurs after an initial exposure to an allergen results in sensitization. With additional exposure, activation of the immune system results in dermatitis. Allergens that commonly cause ACD include poison ivy, latex, and certain types of metal (Figures 67–1 and 67–2). Table 67–1 lists agents commonly responsible for irritant and ACD. Although generally occurring on the exposed skin, such as the hands and face, contact dermatitis can appear anywhere on the body.[4,5]

Epidemiology and Etiology

Contact dermatitis is the most common occupational related skin disease.[6] Although most often seen in adults, contact dermatitis can affect all age-groups, with females at slightly greater risk than males due to increased risk of exposure.[5]

Pathophysiology

ICD is not the result of an immunologic process but rather occurs from direct injury to the skin. An irritating agent comes into contact with the skin, damages the protective layers of the epidermis, and can cause erythema, the formation of vesicles, and pruritus.[1,6] Symptoms occur within minutes to hours of exposure and begin to heal soon after the removal of the offending substance.

ACD is a type IV hypersensitivity reaction.[4] Upon initial exposure, a substance penetrates the skin, is processed by antigen-presenting cells, and activates allergen-specific T cells. Subsequent exposures to that substance will elicit a response by circulating memory T cells, resulting in an allergic reaction.[1,4,6] Symptoms of ACD are similar to those of the irritant type but may take several hours to several days to develop following reexposure.[4]

Treatment

▶ *Desired Outcomes and Goals*

KEY CONCEPT Identifying the causative substance and eliminating its exposure is the initial treatment goal for contact dermatitis. Although physical symptoms can develop almost immediately after contact, removal of the offending agent will improve existing symptoms and prevent further complications.[2] Removing the offending agent includes washing the skin and any clothing or objects that may have come into contact with the agent to prevent reexposure. *The second treatment goal is symptom relief.* Since inflammation and pruritus, as well as lesion formation, are likely to result from contact dermatitis, appropriate selection of nonpharmacologic and pharmacologic agents for these symptoms is necessary.[3]

Clinical Presentation and Diagnosis of Contact Dermatitis

Contact dermatitis is generally confined to the area of contact, but, in a highly sensitive person, a widespread or even generalized eruption may occur. Contact dermatitis is divided into two forms—irritant and allergic. Both forms may include but are not limited to:

- Erythema
- Pruritus
- Vesicles
- Papules
- Crusts
- Burning
- Pain

Irritant Form

The irritant form usually presents within hours of exposure and the rash is often localized. Irritant contact dermatitis may also result in fissuring and scaling.

Allergic Form

The allergic form can take several days to present and the condition may extend beyond the borders of the region exposed. Allergic contact dermatitis may cause intense itching and include oozing pustules and skin erosion.

Diagnosis

Contact dermatitis may be suspected based on clinical presentation, especially if the causative agent is known; however, patch testing may be necessary to confirm the diagnosis.[7]

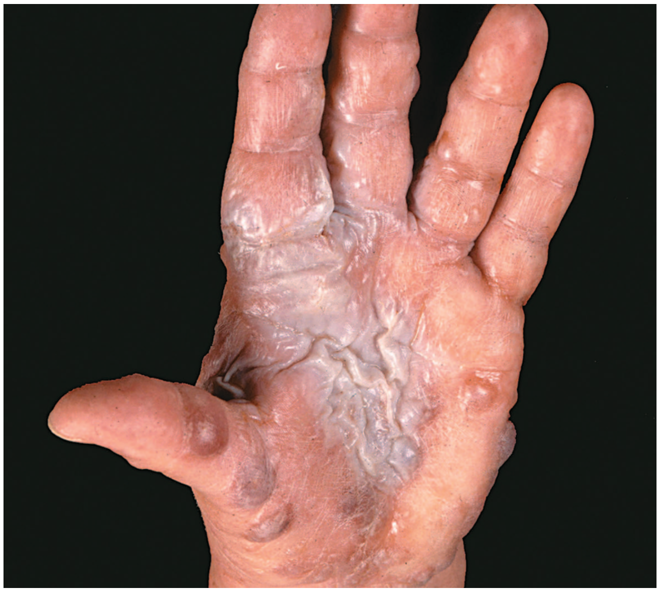

FIGURE 67–1. Acute irritant contact dermatitis on the hand due to an industrial solvent. There is massive blistering on the palm. (From Wolff K, Johnson RA, Saavedra AP, Roh EK. Eczema/dermatitis. Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology, 8th ed. New York, NY: McGraw-Hill; 2017:5.)

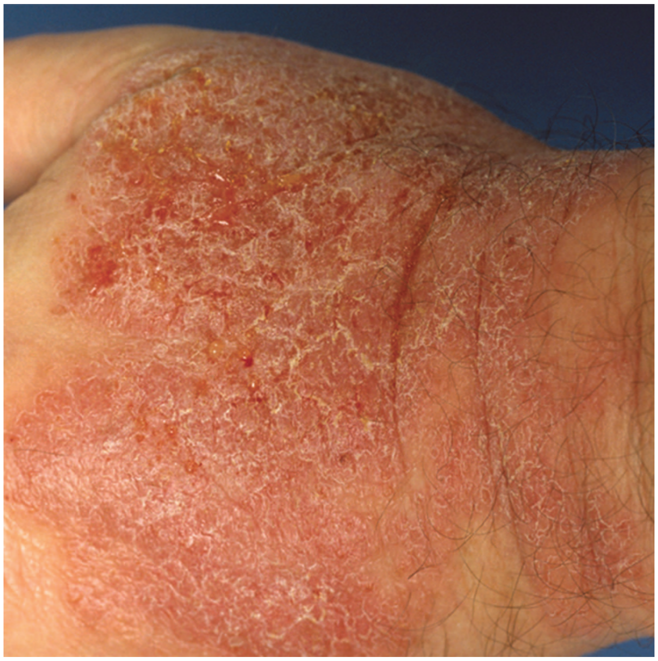

FIGURE 67–2. Allergic contact dermatitis of the hand: chromates. Confluent papules, vesicles, erosions, and crusts on the dorsum of the left hand in a construction worker who was allergic to chromates. (From Wolff K, Johnson RA, Saavedra AP, Roh EK. Eczema/dermatitis. Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology, 8th ed. New York, NY: McGraw-Hill; 2017:13–14.)

▶ *Nonpharmacologic Therapy*

In many cases, contact dermatitis may not require medical treatment. Nondrug therapy for contact dermatitis is aimed at relieving pruritus and maintaining skin hydration.[4] Effective agents used for this include the following[1,7]:

- Colloidal oatmeal baths
- Cool or tepid soapless showers
- Cool, moist compresses applied to the area for 20 to 30 minutes as often as needed
- Emollients applied to the area after bathing

Preventative measures to prevent additional exposure should be considered including gloves, protective clothing, barrier creams, and skin conditioning products.

Table 67–1

Common Agents Causing Contact Dermatitis

Irritant Contact Dermatitis
Soaps
Detergents
Cosmetics
Solvents
Acid, mild or strong
Alkali, mild or strong

Allergic Contact Dermatitis
Plant resins, poison ivy, poison oak, sumac
Metals (nickel or gold in jewelry)
Latex and rubber
Cigarette smoke
Local anesthetics (lidocaine, benzocaine)

▸ *Pharmacologic Therapy*

Topical Steroids Erythema, inflammation, pain, and itching caused by ACD can be effectively treated with topically applied corticosteroids. The use of topical corticosteroids for the management of ICD is controversial, as patients with ACD generally respond better to therapy than those with ICD.[8] With such a wide range of products and potencies, appropriate steroid selection is based on severity and location of lesions (see Table 67–2 for a list of topical steroids and potencies.) Higher potency preparations are used in areas where penetration is poor, such as the elbows and knees. Lower potency products should be reserved for areas of higher penetration, such as the face, axillae, and groin.

Table 67–2

Topical Steroids and Potencies

Potency Rating	Topical Dosage Forms
Group 1: Super-high potency	Betamethasone dipropionate 0.05% gel, lotion, ointment (Diprolene ointment)
	Clobetasol propionate 0.05% lotion/spray/shampoo (Clobex lotion/spray/shampoo, OLUX foam)
	Clobetasol propionate 0.05% cream and ointment (Cormax, Temovate)
	Fluocinonide 0.1% cream (Vanos)
	Halobetasol propionate 0.05% cream, lotion, ointment (Ultravate)
	Flurandrenolide tape 4 mcg/cm^2 (Cordran)
Group 2: High potency	Amcinonide 0.1% ointment (Cyclocort ointment)
	Betamethasone dipropionate 0.05% cream/gel (Diprolene cream, gel, and Diprosone cream)
	Clobetasol propionate 0.025% cream (Impoyz)
	Desoximetasone 0.25% cream, ointment (Topicort)
	Desoximetasone 0.25% spray (Topicort)
	Diflorasone diacetate 0.05% (ApexiCon, Florone, Psorcon)
	Fluocinonide 0.05% cream, gel, ointment, solution (Lidex)
	Halcinonide 0.1% cream (Halog)
	Halobetasol propionate 0.01% lotion (Bryhali)
Group 3: Upper mid-strength	Amcinonide 0.1% cream, lotion (Cyclocort, Amcort)
	Betamethasone dipropionate 0.1% cream, hydrophilic emollient (Diprosone)
	Betamethasone dipropionate 0.12% foam (Luxiq)
	Betamethasone valerate 0.1% ointment (Valisone ointment)
	Desoximetasone 0.05% cream (Topicort LP)
	Diflorasone diacetate 0.05% cream (Florone cream)
	Fluocinonide 0.05% cream aqueous emollient (Lidex-E)
	Fluticasone propionate 0.005% ointment (Cutivate ointment)
	Mometasone furoate 0.1% ointment (Elocon ointment)
	Triamcinolone acetonide 0.5% cream and ointment (Aristocort)
Group 4: Medium potency	Betamethasone dipropionate 0.05% spray (Sernivo)
	Clocortolone pivalate 0.1% cream (Cloderm)
	Fluocinolone acetonide 0.025% ointment (Synalar ointment)
	Flurandrenolide 0.05% ointment (Cordran)
	Hydrocortisone valerate 0.2% ointment (Westcort ointment)
	Mometasone furoate 0.1% cream, lotion, ointment, solution (Elocon)
	Triamcinolone acetonide 0.05%–0.1% ointment, cream, aerosol spray, dental paste (Kenalog, Trianex, Oralone)
Group 5: Lower mid-potency	Betamethasone dipropionate 0.05% lotion (Diprosone lotion)
	Betamethasone valerate 0.1% cream and lotion (Betnovate/Valisone cream and lotion)
	Desonide 0.05% ointment, lotion (DesOwen, Desonate, Tridesilon)
	Fluocinolone acetonide 0.025%, 0.03% cream (Synalar cream)
	Flurandrenolide 0.05% cream and lotion (Cordran)
	Fluticasone propionate 0.05% cream and lotion (Cutivate cream and lotion)
	Hydrocortisone butyrate 0.1% cream (Locoid)
	Hydrocortisone valerate 0.2% cream (Westcort cream)
	Prednicarbate 0.1% cream (Dermatop)
	Triamcinolone acetonide 0.1% cream and lotion (Kenalog cream and lotion)
Group 6: Low potency	Alclometasone dipropionate 0.05% cream and ointment (Aclovate)
	Betamethasone valerate 0.05% lotion (Beta-Val, Valisone)
	Desonide 0.05% cream, ointment, gel (DesOwen, Desonate, Tridesilon)
	Desonide 0.05% foam (Verdeso)
	Fluocinonide acetonide 0.01% cream and solution (Synalar)
	Fluocinonide acetonide 0.01% FS oil (Derma-Smoothe)
	Fluocinolone acetonide 0.01% shampoo (Capex shampoo)
	Triamcinolone acetonide 0.25% cream and lotion (Kenalog, Aristocort)
Class 7: Least Potent	Hydrocortisone 0.5%, 1%, 2%, 2.5% cream, lotion, spray, and ointment (various brands)

Data from Lexicomp [Internet]. Comparison of Representative Topical Corticosteroid Preparations (Classified According to US System). Hudson, OH: Wolters Kluwer Clinical Drug Information, Inc. 1978-2020 [cited 2020 Oct 17]. Available from: http://online.lexi.com.ezproxy.findlay.edu:2048/lco/action/doc/retrieve/docid/patch_f/3674386?cesid=6ESWxn7qMvl&searchUrl=%2Flco%2Faction%2Fsearch%3Fq%3Dtopical%252520corticosteroid%26t%3Dname%26va%3Dtopical%252520corticosteroid.

Low-potency steroids are also recommended for the treatment of infants and children.[9,10,11] The use of topical corticosteroids for prolonged periods of time should be avoided.

Adverse effects from topical steroids are usually related to the potency of the steroid, frequency of application, duration of therapy, and the site of application. Skin atrophy, hypopigmentation, striae, and steroid-induced acne are all possible side effects associated with long-term use.[12] Ointments, because of their occlusive properties, should be avoided on weeping lesions.[1,11]

Topical steroids are typically applied two to four times daily. As improvement begins, maintenance therapy should be limited to the lowest strength steroid that continues to control the condition. Once symptoms are completely resolved, use should be discontinued and should not exceed 1 to 2 weeks.[11]

Antihistamines Whether due to their antihistaminic activity or their sedative side effects, pruritus caused by contact dermatitis can be relieved with the use of sedating oral antihistamines, such as diphenhydramine or hydroxyzine. Topical antihistamines are available, but their use is limited due to their high-sensitizing potential.[1,13] In addition to sedation, many oral antihistamines can cause hypotension, dizziness, blurred vision, and confusion.

Astringents The drying effect of astringents will decrease oozing from lesions and relieve itching.[4,11] Due to their ability to cause blood vessel constriction, astringents can also decrease inflammation. Aluminum acetate (Burow's solution), aluminum sulfate/calcium acetate solution (Domeboro), calamine lotion, colloidal oatmeal baths/soaks, and witch hazel are safe and effective.[1] Aluminum acetate or aluminum sulfate/calcium acetate may be applied as a compress for 30 minutes at least four times daily as needed. Colloidal oatmeal baths or soaks may be applied for 15 to 20 minutes at least twice daily.

Adverse effects reported with these agents are minimal and include drying and tightening of the skin.

T-Cell Selective Inhibitors Topical T-cell selective inhibitors, such as tacrolimus and pimecrolimus, are approved for the treatment of atopic dermatitis but may also be effective in the treatment of ACD.[10,11]

Outcome Evaluation

With adequate treatment, most cases of contact dermatitis should improve within 7 days. Complete resolution of symptoms may take up to 3 weeks.[1] If patients experience severe symptoms associated with fever or difficulty breathing, they should be instructed to seek medical attention immediately. Furthermore, patients should return to their health care provider if any of the following occur:

- Rash has not improved (increased in size or spread to other locations) after several days of treatment.
- Patient is experiencing adverse effects from the treatment regimen.

Patient Care Process: Contact Dermatitis

Collect Information:

- Assess symptoms.
- Obtain a thorough patient history. Can the agent/exposure be identified? Has there been prior exposure to that agent? If so, what treatment regimens were used to alleviate symptoms?
- Obtain patient's allergy status.

Assess the Information:

- Determine whether the patient has ICD or ACD.
- Discuss testing needed to suggest or confirm the etiologic agent (patch testing).

Develop a Care Plan:

- Develop a treatment plan for ICD or ACD. In most cases, nondrug and nonprescription treatment options are most appropriate. If case is severe or if the patient has ACD, the plan may also include prescription therapy.

Implement the Care Plan:

- Provide patient education on ICD or ACD and treatment:
  - Possible adverse effects of drug therapy
  - Symptoms that warrant physician referral?
  - Importance of treatment compliance.
  - Educate on the recognition of agents that may cause contact dermatitis.

Follow-up: Monitor and Evaluate:

- Symptoms should improve within 2 to 3 days. If no improvement, the patient should be advised to follow up with the provider.

Patient Encounter 1

A 55-year-old woman presents to your pharmacy with complaints of intense itching and shows you a red, raised rash with papules on her arms. The patient tells you that she spent the weekend gardening around her home and yard. She tells you that she wore work gloves but had on a short-sleeved shirt. She doesn't recall seeing any poison ivy, but she indicates the rash is similar to a past exposure to poison oak several years ago. The patient states she tried some kind of soap that said it would help treat poison ivy but hasn't tried anything else to manage her symptoms, which are worsening. From the information he has presented, you conclude that she did likely come in contact with an agent while camping and that exposure caused an allergic contact dermatitis to develop.

What information supports the possibility of exposure to an allergic agent?

Describe the symptoms that support this diagnosis.

Determine what the patient has tried to relieve his symptoms.

Describe the differences between allergic and irritant contact dermatitis.

What are your treatment goals for this patient?

What nonpharmacologic and pharmacologic treatment options are available for this diagnosis?

Given the information presented, develop a treatment regimen for this patient that includes the following:

a. A statement of the problem

b. A patient-specific therapeutic plan

c. Monitoring parameters to assess efficacy and safety

ATOPIC DERMATITIS

Introduction

Atopic dermatitis, commonly referred to as eczema, is a chronic inflammatory skin disorder characterized by dry and itchy skin.[14] Atopic dermatitis has been considered to signify the first step of the "**atopic march**", which describes the development of allergic diseases, and be followed by the development of other allergic disorders, such as allergic rhinitis and asthma[14,15,16]; this progression does not happen in all individuals, however, as the association of atopic dermatitis with other atopic conditions is multifactorial and complex.[14,15] The simultaneous occurrence of atopic dermatitis, allergic rhinitis, and asthma is referred to as the atopic triad.[17] While an estimated 70% of individuals with atopic dermatitis during childhood experience remission before adolescence,[16] atopic dermatitis may persist into adulthood and lead to quality-of-life impairments, such as sleep disruption and low self-esteem.[18]

Epidemiology and Etiology

Affecting up to 25% of children and 2% to 3% of adults,[15] the incidence of atopic dermatitis has increased by two- to threefold in the past several decades in industrialized countries.[16] The lifetime prevalence of atopic dermatitis is approximately 10%.[19] Onset of atopic dermatitis most commonly occurs between 3 and 6 months of age[15]; approximately 60% and 90% of individuals experience symptoms by 1 and 5 years of age, respectively.[15] Prevalence of atopic dermatitis among males and females is similar.[14,15,20] Black race and urban living have been found to be associated with a higher prevalence of atopic dermatitis.[20] Studies regarding the effect of socioeconomic status on risk of atopic dermatitis are conflicting.[15] While atopic dermatitis is commonly associated with food allergies, no specific dietary changes are recommended for prevention.[15]

Family history of **atopy** and filaggrin gene mutations are two risk factors strongly associated with the development of atopic dermatitis.[15] Individuals with atopy may be genetically predisposed to predominantly demonstrate T-helper type 2 (Th_2) cells, which may ultimately lead to increased immunoglobulin E (IgE) production, blood eosinophilia, and increased mast cell development as a result of the cytokines produced.[14] The filaggrin gene ultimately plays a key role in maintaining epidermal hydration and barrier function[14,15]; abnormalities in the epidermal barrier may lead to increased absorption of allergens.[14] Triggers that may exacerbate atopic dermatitis are individualized; common triggers include environmental allergens (such as dust mites and pollen), infections, soaps and detergents, fragrances, clothing that is abrasive or occlusive, sweat, hot temperatures (increases sweating), cold temperatures (increases skin dryness), and psychosocial stress.[14,21,22]

Pathophysiology

KEY CONCEPT Epidermal barrier dysfunction and increased Th2 cell activity, leading to increased IgE production, are characteristic pathophysiologic features of atopic dermatitis.[14]

Under normal circumstances, corneocytes and lipids tightly bind together to form a barrier, which prevents water from leaving the skin and allergens and microbes from entering the skin.[22] However, filaggrin mutations, decreased skin barrier proteins, lipids, and ceramides, increased peptidase activity, and lack of protease inhibitors may compromise the skin barrier.[14,17,22,23] Allergens may penetrate an abnormal skin barrier and subsequently come into contact with **dendritic cells**.[14] A predominantly Th2 cell response in the skin ensues, resulting in the release of proinflammatory cytokines, such as interleukin (IL)-4, IL-5, and IL-13.[14,18,23] IgE production increases in response and results in itchy, inflamed skin.[14,23] Atopic dermatitis has been considered to be a biphasic T-cell-mediated disease, with Th2 cell response driving acute disease, and T-helper type 1 (Th1) cell response driving chronic disease.[18,23]

Clinical Presentation and Diagnosis of Atopic Dermatitis

KEY CONCEPT Atopic dermatitis is commonly described as the "itch that rashes" since pruritus is the hallmark symptom.[17,18,21,22] Sleep can be disrupted by itchy atopic skin. Rubbing or scratching atopic skin can lead to further skin irritation and inflammation, leading to additional pruritus.[14]

Atopic dermatitis may manifest as periods of exacerbations (flare-ups) followed by periods of remission[14,17] and result in erythema, edema, xerosis, crusty or scaly skin, and **lichenification**.[15] The clinical presentation of atopic dermatitis can vary based on age and lesion chronicity (see **Figure 67–3**).[15]

Age[21,23] (Figure 67-4):

Infants: Face (cheeks, chin, forehead), scalp, neck, trunk, and extensor surfaces of extremities commonly affected

Childhood: Flexural surfaces of extremities, neck, wrists, and ankles commonly affected

Adolescence/Adulthood: Flexural surfaces of extremities, hands, and feet commonly affected

Lesion Chronicity[17]:

Acute: Skin is erythematous and pruritic with papules (small, solid, elevated lesions) or vesicles (filled with fluid or air). **Excoriation** and secretions are common.

Subacute: presence of erythematous and excoriated papules and scaly plaques (large, flat, slightly elevated lesions)

Chronic: presence of thickened plaques

Skin Infections:

Secondary skin infections may present as yellow crusting over eczematous lesions, pustules (lesions filled with purulent fluid), or vesicles filled with purulent fluid, exudate, or pus.[17]

Diagnosis:

The diagnosis of atopic dermatitis is clinical.[15] No specific confirmatory laboratory test has been established.[17] Occasionally, skin biopsy, serum IgE, potassium hydroxide preparation, patch testing, or genetic testing may be performed to rule out other skin conditions.[15]

Assessment:

No standard atopic dermatitis disease severity grading scale has been identified.[16] While three validated grading scales exist,[15,17,24,25] atopic dermatitis is generally described as mild, moderate, or severe. In addition, scales assessing quality of life, disease impact, and other psychological outcomes have been developed.[15]

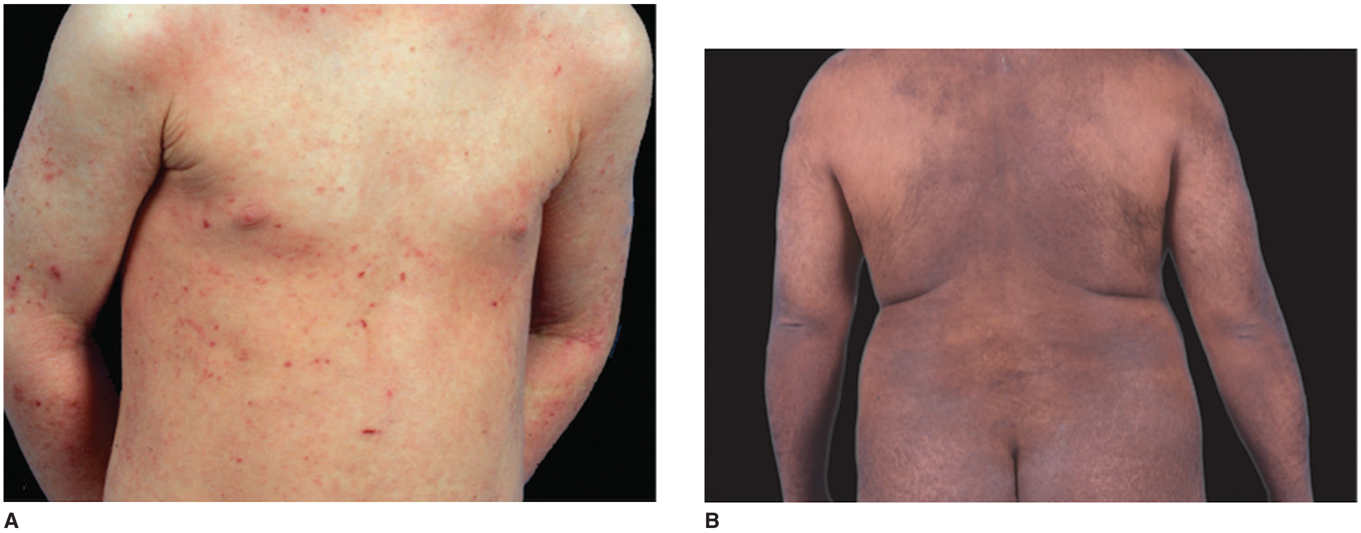

FIGURE 67–3. A: Childhood atopic dermatitis. Generalized eruption consisting of confluent, inflammatory papules that are erosive, excoriated, and crusted. **B:** Adult atopic dermatitis. Generalized eruption of follicular papules that are more heavily pigmented than normal skin in a 53-year-old woman of African extraction. There is extensive lichenification. (From Wolff K, Johnson RA, Saavedra AP, Roh EK. Eczema/dermatitis. Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology, 8th ed. New York, NY: McGraw-Hill; 2017:28.)

Individuals with atopic dermatitis are more susceptible to secondary skin infections due to the presence of a weakened skin barrier, reduced antimicrobial peptides in atopic skin, resulting in a decreased antimicrobial barrier, and pathogenic colonization.[14,22] *Staphylococcus aureus* colonizes approximately 90% of individuals with atopic dermatitis.[23] Infection by *Streptococcus pyogenes*, molluscum contagiosum, and herpes simplex virus should also be considered.[22]

Treatment

▸ *Desired Outcomes and Goals*

The successful management of atopic dermatitis includes (a) controlling pruritus, (b) healing skin lesions, (c) maintaining skin integrity, (d) identifying and removing triggers, and (e) preventing flare-ups. Ultimately, the desired goal of treatment is to

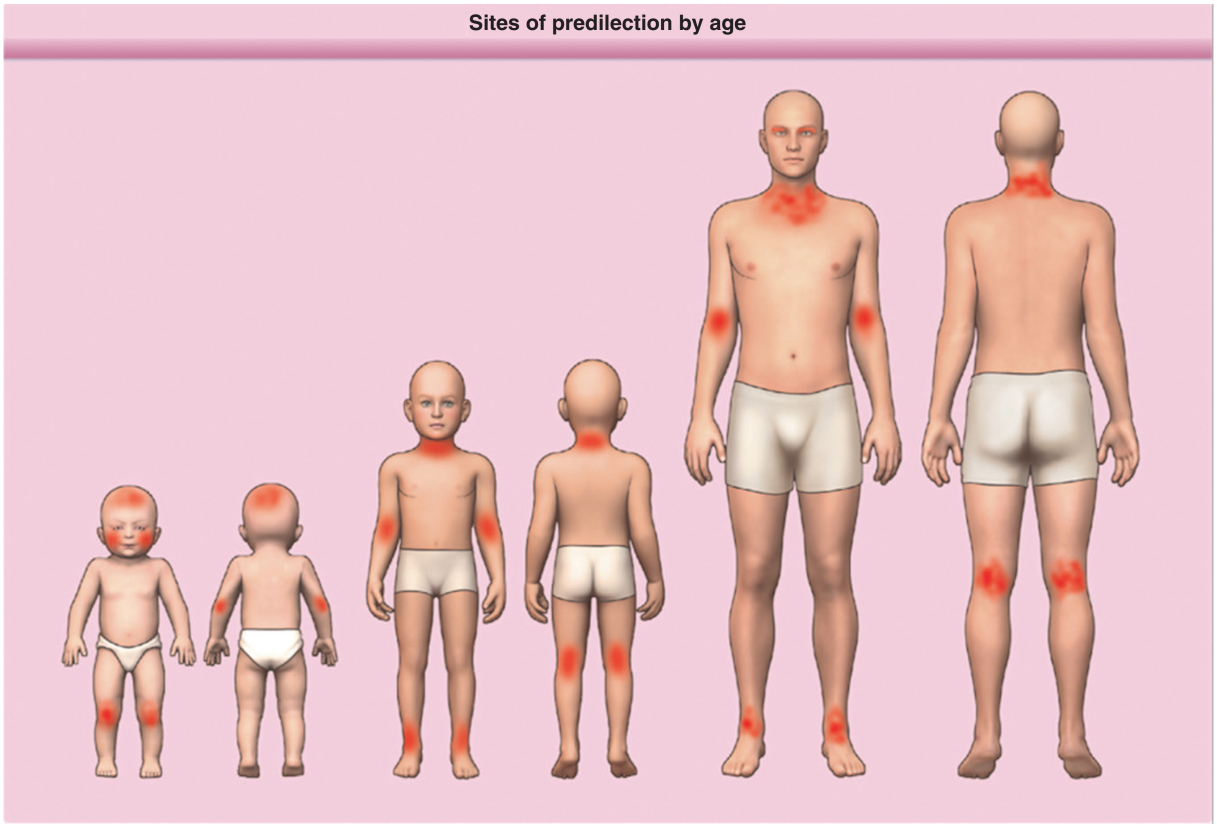

FIGURE 67–4. Atopic dermatitis progression and distribution: infancy, older childhood, and adulthood. (From Kang S, Amagai M, Bruckner AL, et al. Atopic dermatitis. Fitzpatrick's Dermatology, 9th ed. New York, NY: McGraw-Hill; 2019:4.)

prevent future exacerbations and limit the impact on the patient's quality of life. KEY CONCEPT Management of atopic dermatitis generally includes both prescription and nonprescription therapies.

▶ *Nonpharmacologic Treatment*

Nonpharmacologic treatment involves skin care maintenance to repair skin damage and maintain a functional skin barrier. In addition, by identifying and minimizing triggers or allergens, symptoms may be avoided or lessened. Application of moisturizer, especially after bathing, is important to keep skin hydrated. Reapplication may be advised; however, an optimal frequency or amount has not been defined. The use of mild soaps without fragrance may be used to cleanse skin without exacerbating symptoms and it is suggested that bathing daily, followed by the application of emollients, keeps skin hydrated and removes scales or crusts from the skin along with any irritants or allergens.[26,27] Other nonpharmacologic treatments may include light therapy and wet wrap therapy in which a topical agent is applied, followed by a wet dressing and a second dry, outside layer which can be left in place for several hours. Caution should be used with higher potency steroids in wet wrap therapy due to increased absorption and risk for hypothalamic–pituitary–adrenal axis suppression.[27]

▶ *Pharmacologic Treatment*

Prescription medication is typically indicated during exacerbations and continued until the rash resolves. After the rash has cleared, prescription medication may be discontinued or applied less frequently until another flare-up occurs. Topical steroids and/or topical calcineurin inhibitors are both used to manage itching and improve redness, papules, and plaques. Dupilumab, a newer agent, is an injectable product that may be used in patients who are not responding or responding inadequately to topical therapy.

Topical Corticosteroids KEY CONCEPT Topical corticosteroids are considered first-line treatment and are the most used medications to treat atopic dermatitis. They provide relief of inflammation, pruritus, and prevent relapse.[27] Topical corticosteroids are generally considered safe but may result in adverse effects with high doses or prolonged use. Most are prescribed for once or twice a day application during flare-ups with less frequent administration, such as once or twice weekly, once symptoms improve and treatment approach switches from treatment to management. High-potency topical corticosteroids may be used to initially gain control of the skin lesions; however, long-term use should focus on the lowest potency product to minimize adverse effects.[27] Risks for long-term use of topical corticosteroids is discussed in the "Dermatitis" section of this chapter. See Table 67–2 for a list of steroid classes and potencies.

Patient Care Process: Atopic Dermatitis

Collect Information:

- Assess the patient's symptoms, including intensity of itching and quality-of-life impairments (eg, disrupted sleep).
- Note the skin's appearance and rash location(s).
- Obtain family history of atopic conditions.
- Evaluate the patient's skin care regimen, including current use of moisturizers and any products that may exacerbate atopic dermatitis.
- Review what medications the patient has tried for atopic dermatitis in the past.
- Review the patient's health-related goals and preferences.
- Gather a medication list, including prescription and nonprescription drugs and dietary supplements.
- Obtain medication allergies and reaction.
- Review patient's comorbid medical conditions.

Assess Information:

- Assess the patient's symptoms and skin's appearance to determine disease severity (mild, moderate, or severe).
- Determine if the atopic dermatitis is flaring up or in remission.
- Assess for the presence of a secondary skin infection.
- Determine if any products, behaviors, or the environmental influences may be exacerbating the patient's atopic dermatitis.
- Assess if previous therapies were used as directed.
- Determine goals of therapy.

Develop a Care Plan:

- Develop a treatment plan that is likely to be effective based on disease severity, safe, and cost-effective.
- For nondrug and drug therapies, determine frequency of application. If pharmacotherapy is warranted, determine drug, dose, and duration of therapy.
- Eliminate potential triggers and institute appropriate lifestyle measures.

Implement the Care Plan:

- Provide patient education on atopic dermatitis and treatment:
  - Clinical presentation and potential complications of atopic dermatitis.
  - Triggers that can exacerbate atopic dermatitis.
  - Signs of secondary skin infection and when to seek medical attention.
  - Review changes to atopic dermatitis drug regimen.
  - Review drug, dose, frequency of application, and duration of therapy.
  - Inform the patient of appropriate application technique.
  - Review side effects of therapy.
  - Emphasize compliance to therapy, lifestyle measures, and avoidance of triggers.

Follow-Up: Monitor and Evaluate:

- Follow-up in 2 weeks to assess the effectiveness and safety of nonpharmacologic and pharmacologic therapy (eg, relief of itching, resolution of rash, presence of adverse effects).
- Refer for medical evaluation if signs of a skin infection are observed during therapy, such as oozing, draining, pus, or formation of yellow crusts.
- If the rash has improved, continue routine application of a moisturizer.

Topical Calcineurin Inhibitors Second-line pharmacologic agents for the treatment of atopic dermatitis include the topical calcineurin inhibitors, tacrolimus, and pimecrolimus. These products are approved for short term or intermittent use in patients aged 2 years or older in whom topical corticosteroids are not providing adequate relief of symptoms and improvement of skin lesions or who cannot tolerate topical corticosteroids.[28,29] Topical calcineurin inhibitors block T-cell activation and proliferation, which prevents the production of additional proinflammatory mediators that play a role in atopic dermatitis.[27] Because topical calcineurin inhibitors do not cause skin thinning and atrophy like topical corticosteroids, they may be used on more sensitive areas of the skin and for longer term use. Topical tacrolimus has been shown to be more potent than topical pimecrolimus, though both are effective at the treatment of atopic dermatitis. Both tacrolimus and pimecrolimus have a black box warning related to an increased risk of cancer (including skin cancers and lymphoma). Patients should be advised to limit exposure to sunlight and avoid use on malignant or premalignant skin conditions.[28,29]

Biologic Therapy Dupilumab (Dupixent) is an injectable humanized monoclonal antibody targeting IL-4. It is administered subcutaneously with an initial dose of 600 mg followed by 300 mg once every other week for maintenance therapy. The adverse effects that patients taking dupilumab are at highest risk for include hypersensitivity reactions and local injection site reactions. Dupilumab is approved for use in patients 6 years of age or older in whom topical prescription therapies have failed to control symptoms or in patients in whom the use of topical therapies is not advised. Patients started on dupilumab, who are currently using topical therapies, are generally titrated off as symptoms improve.[30]

Patient Encounter 2

A 22-year-old Black, female patient presents to the outpatient clinic with a worsening rash of small red raised lesions and papules with intense itching on her forearms and hands. She shares that this rash is similar to exacerbations she has had in the past and that typically the application of moisturizer to the area several times a day helps to manage the itch until the rash goes away. The patient has a past medical history of seasonal allergies and asthma. She's concerned that a new laundry detergent she used may be causing the rash to worsen and is wondering if there is anything else she might try to relieve the itching?

What reported symptoms support the diagnosis of atopic dermatitis?

What additional information would assist you in your assessment of the patient?

What factors could be contributing to the patient's atopic dermatitis?

Describe your treatment goals for this patient.

What nonpharmacologic treatment options would you suggest for this patient?

Consider a pharmacologic treatment plan for this patient.

Given the information presented, develop a patient-specific therapeutic plan.

Formulate a monitoring plan to assess the efficacy and safety of the patient's therapy.

Outcome Evaluation

Treatment with prescription skin medications should improve rash and itching within 2 weeks. Once rash has improved, continue application of moisturizers daily to the face and body. The presence of oozing, drainage, pus, or yellow crusts may indicate a skin infection. Patients should alert their medical provider if these symptoms develop.

DIAPER DERMATITIS

Epidemiology and Etiology

Diaper dermatitis, more commonly known as diaper rash, is a form of ICD that affects the buttocks, upper thighs, lower abdomen, and genitalia of an estimated 7% to 35% of all infants.[31,32] Onset of occurrence is usually between 3 weeks and 2 years of age, with the most cases reported between 9 and 12 months of age.[32] The use of diapers for incontinence in adults also increases the risk of developing diaper dermatitis.[32]

Pathophysiology

KEY CONCEPT Although many factors contribute to diaper rash, it is most likely the result of prolonged contact of the skin with urine and feces in the diaper. If a diaper is not changed soon after urination or defecation, the excessive hydration, friction of the diaper, and enzymes in the feces lead to breakdown in the protective layer of the skin making the area more susceptible to irritation and infection.[33,34,35,36] Although most mild cases of diaper rash present as erythema, moderate-to-severe cases can result in the formation of papules, vesicles, and even ulceration. If these cases are not effectively treated, the likelihood of secondary fungal or bacterial infections developing is greatly increased.[33]

Treatment

▶ *Desired Outcomes and Goals*

KEY CONCEPT The primary goal in the treatment of diaper rash is prevention and is most often accomplished through frequent diaper changes. **KEY CONCEPT** When a diaper rash is already present, repairing the damaged skin, relieving discomfort, and preventing secondary infections from occurring are important factors to consider when developing an effective treatment regimen.[34]

▶ *Nonpharmacologic Therapy*

Most mild cases of diaper rash can be resolved with the use of nonpharmacologic therapies. Keeping the diaper area clean and dry by changing diapers as soon as practically possible (at least every 2 hours or more frequently) is highly effective for treatment and prevention.[34,35,36] Other nondrug options include[34,36,37,38]:

- Gently wash the area with lukewarm water and mild soap and allow to completely dry before applying a new diaper
- Use water and a cotton cloth or commercial "baby wipes" without coloring, fragrances or other additives
- Keeping diapers loose and well ventilated. If financially feasible, use super-absorbent disposable diapers
- Avoiding plastic pants over diapers
- Allowing infants to take naps on an open diaper or absorbent pad to promote drying and healing

▶ *Pharmacologic Therapy*

Protectants Protectants form an occlusive barrier between the skin and moisture from the diaper. Cream and ointment preparations are effective in providing a sufficient barrier in mild, irritant,

Clinical Presentation and Diagnosis of Diaper Dermatitis

Typical Symptoms

- Erythema is the most common symptom presented with a diaper rash. The rash may begin as light-to-medium pink with poorly defined edges but may become dark red and raised lesions with distinct edges.
- Rashes generally appear in the folds of the skin around the diaper area, thighs, genitals, and buttocks.
- Other typical symptoms include irritation and pruritus.

Atypical Symptoms

Patients presenting with the following symptoms may indicate the need for more aggressive antibiotic or antifungal therapy and should be referred to a physician for further evaluation:

- Rashes not responding to typical creams and concurrent nonpharmacologic treatment
- Rashes extending beyond the diaper region (upper abdomen, back)
- Formation of papules, bullae, ulceration
- Excessive oozing
- Presence of genital discharge
- Concurrent fever
- Rashes appearing when diapers have not been used or rashes that fail to improve upon discontinuing diaper usage for extended periods of time (several days or more)
- Bleeding or open skin

Diagnosis

- The diagnosis of diaper dermatitis is clinical. The presence of *Candida albicans* can be determined by KOH testing or culture but is generally not necessary.

and noninfected diaper rashes. For more severe cases, a paste is the topical agent of choice. Pastes are thicker and often contain additional ingredients (petrolatum, moisturizers) to decrease discomfort and promote healing.[34] Zinc oxide is one of the most used topical protectants. In addition to forming an effective barrier against moisture, it has astringent and antiseptic properties that provide added symptom relief.[34]

Protectants are generally applied to the affected area after every diaper change and can be discontinued when the rash resolves. Other available protectants that can be used alone or in combination for the safe and effective treatment of diaper rash include white petrolatum, Vitamins A and D, lanolin, and topical cornstarch. Many agents contain a combination of occlusive and protective agents such as Triple Paste and Calmoseptine.

Topical Steroids Because of the increased permeability of their skin, infants are at risk for excessive absorption and toxicity from the use of topical steroids. Although effective in decreasing inflammation and relieving pruritus, steroid use in infants for the treatment of diaper dermatitis should be limited to only low-potency preparations.[37]

A thin layer of hydrocortisone cream (0.25% to 1%) applied twice a day for no more than 2 weeks is an appropriate regimen. The use of higher potency steroids, use in patients younger than 2 years old, or use extending beyond 2 weeks should be at the discretion of a physician only.

Antifungals Diaper rashes lasting longer than 48 to 72 hours are at increased risk for the development of fungal infections. These complications are most frequently caused by *C. albicans* and will require treatment with a topical antifungal[31,36] (Figure 67–5).

Adverse events with the use of topical antifungals are generally limited to local irritation at the site of application.

Nystatin, clotrimazole, and miconazole creams or ointments applied two to four times daily with diaper changes have all shown to be effective in the treatment of candidal diaper rash.[36,39] Although some of these products are available over the counter, parents and caregivers should be advised to initiate treatment with antifungal agents only after physician recommendation.

Antibacterials If conventional treatment fails, unresolved diaper rash can also lead to secondary bacterial infections. *S. aureus* and *Streptococcus* are the most likely pathogens responsible for these infections and require treatment with prescription topical (if mild and localized) or systemic (if more severe) antibiotics.[33,35,36,40] While topical protectants may be used as an adjunct in treatment, suspected bacterial infections should always be referred to a physician for accurate diagnosis and the selection of an appropriate antibacterial regimen.[33] Figure 67–6 shows a useful algorithm for the effective treatment of diaper dermatitis.

▶ *Outcome Evaluation*

Most diaper rashes can be effectively treated in less than 1 week. If symptoms do not resolve or begin to worsen, advise caregivers to seek medical attention to determine the presence of secondary fungal or bacterial infections. In addition, provide educational information on proper diaper hygiene techniques in order to prevent the development of future diaper rashes.

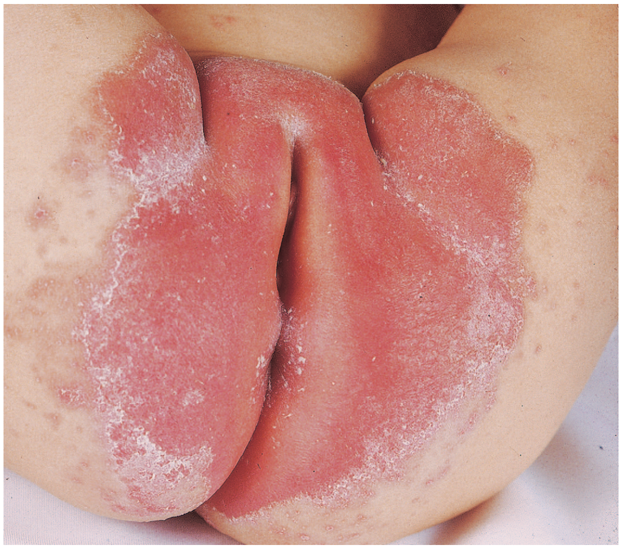

FIGURE 67–5. Candidiasis: diaper dermatitis. Confluent erosions, marginal scaling, and "satellite pustules" in the area covered by a diaper in an infant. (From Wolff K, Johnson RA, Saavedra AP, Roh EK. Fungal infections of the skin, hair, and nails. Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology, 8th ed. New York, NY: McGraw-Hill; 2017:7.)

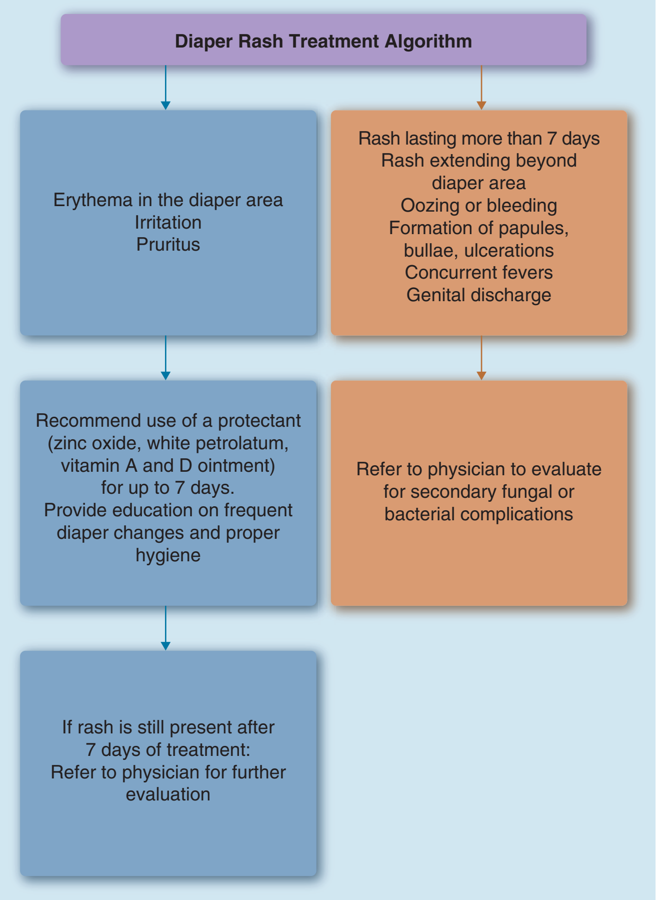

Diaper Rash Treatment Algorithm
Erythema in the diaper area Irritation Pruritus
Rash lasting more than 7 days Rash extending beyond diaper area Oozing or bleeding Formation of papules, bullae, ulcerations Concurrent fevers Genital discharge
Recommend use of a protectant (zinc oxide, white petrolatum, vitamin A and D ointment) for up to 7 days. Provide education on frequent diaper changes and proper hygiene
Refer to physician to evaluate for secondary fungal or bacterial complications
If rash is still present after 7 days of treatment: Refer to physician for further evaluation

FIGURE 67–6. Diaper dermatitis treatment algorithm. (From Krinsky DL, Ferreri SP, Hemstreet B, et al. Diaper dermatitis and prickly heat. Handbook of Nonprescription Drugs, 19th ed. Washington, DC: American Pharmacists Association; 2017:10–11.)

Patient Encounter 3

A woman presents to the front counter of a community pharmacy with a tube of diaper rash ointment. She asks if this is the best product to purchase for her 11-month-old daughter, who she suspects has developed diaper rash. The woman states her daughter woke up fussy and in a wet and dirty diaper this morning, and upon changing the diaper, found the skin to be light pink. She explains using baby wipes with each diaper changing but is concerned about how sensitive the diaper area appears to be compared to normal.

What reported symptoms support the diagnosis of diaper dermatitis?

What additional information would assist in your assessment of the patient?

What factors could be contributing to the patient's diaper dermatitis?

Describe your treatment goals for this patient.

What nonpharmacologic treatment options would you suggest to this patient?

Consider a pharmacologic treatment plan for this patient:

a. Do you recommend a protectant for this patient? Why or why not?

b. What other pharmacologic treatment options for available for the treatment of diaper dermatitis?

Given the information presented, develop a patient-specific therapeutic plan.

Formulate a monitoring plan to assess the efficacy and safety of the patient's therapy.

Patient Care Process: Diaper Dermatitis

Collect Information:

- Gather information related to rash symptoms, characteristics, location, and onset.
- Inquire about the patient's history, including similar rashes in the past, and any previous treatment.
- Obtain patient allergy status.

Assess the Information:

- Determine the level of severity—is there a possibility of a secondary fungal or bacterial infection?
- Identify any signs and symptoms that require immediate physician referral.
- Determine what treatment options, if any, have been tried and if they were successful.
- Discuss labs that may be necessary if a secondary infection is suspected (cultures, biopsies).

Develop a Care Plan:

- Discuss available barrier treatment options with the caregiver.
- Identify appropriate preventative and treatment measures.

Implement the Care Plan:

- Provide caregiver education that includes proper usage instructions and potential side effects.
- Educate the caregiver on the importance of frequent diaper changes and proper hygiene.
- Emphasize importance of treatment compliance and the use of preventative measures.

Follow-up: Monitor and Evaluate:

- Discuss symptoms to report to a physician (blistering, oozing, bleeding, changes in rash, or no improvement in symptoms within 2 to 3 days).

List of Abbreviations

ACD	Allergic contact dermatitis
ICD	Irritant contact dermatitis

Psoriasis

Amy K. Kennedy

LEARNING OBJECTIVES

Upon completion of this chapter, the reader will be able to:

1. Discuss the etiology of, and risk factors for, psoriasis.
2. Describe the pathophysiology and clinical presentations of psoriasis.
3. Delineate treatment goals for patients diagnosed with psoriasis.
4. Develop an appropriate treatment and care plan for patients diagnosed with psoriasis.
5. Recommend nonpharmacological and pharmacological treatments for psoriasis.
6. Recommend appropriate monitoring parameters for patients diagnosed with psoriasis.
7. Provide education for patients and caregivers as part of the psoriasis care plan.

INTRODUCTION

KEY CONCEPT Psoriasis is a chronic inflammatory condition that exhibits a cyclical pattern of relapse and remission. There is currently no cure for the disease and treatment is designed to manage signs and symptoms associated with the disease.[1] Remission may last years in some, whereas, in others, exacerbations may occur every few months. Patient factors known to exacerbate psoriasis are stress, environmental factors including seasonal changes, and certain medications.[2] Depression, alcohol-related problems, cardiovascular diseases, metabolic syndrome, irritable bowel disease (Crohn's and ulcerative colitis), and skin cancers are select comorbidities associated with the most severe forms of psoriasis.[1] Severity of the condition ranges from mild to severely disabling. Thus, management of psoriasis is lifelong, and treatment changes according to the illness severity at the time. Treatment should be individualized to meet patient needs. The disease may cause emotional distress requiring empathy and caring attitude, when making treatment decisions.

EPIDEMIOLOGY AND ETIOLOGY

Psoriasis is a common chronic inflammatory skin disorder with a prevalence of 2% to 3% worldwide. The prevalence in the United States is approximately 3.2%, while African, African American, and Asian populations have an estimated 0.4% to 0.7% prevalence of the disease.[3] While the overall incidence rate does not differ between men and women, the disease may present at any age, with new diagnoses peaking between ages 15 and 30 and again from 50 to 60 years.[3] Psoriasis can manifest as several different types including **plaque**, **flexural (aka inverse or intertriginous)**, **erythrodermic**, **pustular**, **guttate**, **nail**, and **psoriatic arthritis (PsA)**. Eighty to ninety percent of patients diagnosed with psoriasis present with plaque psoriasis. Plaque psoriasis presents with red-pink lesions of varying sizes covered with silvery-white scales.[2] Approximately 30% to 33% of patients with psoriasis have co-occurring PsA.[1,4] PsA is limited to joints, ligaments, and tendons and presents with pain, stiffness, swelling, and/or tenderness in the affected area. PsA progresses from mild symptoms to the destruction of joints, negatively impacting quality of life for patients.

Psoriatic patients have an increased risk of cardiovascular disease, especially myocardial infarction.[4,5] Risk is present in both mild and severe disease, with the highest risk in younger patients with severe psoriatic disease.[6] These findings persist even when corrected for other cardiovascular risk factors.[5,6,7]

Researchers have identified a mutation in the CARD14 gene that, when activated by an environmental trigger, leads to plaque psoriasis.[8] Up to 36 additional gene loci are suspected in the manifestation of psoriasis and the histocompatibility complex region of chromosome 6 (HLA-Cw*06) has been suspected in the disease.[9] KEY CONCEPT While genetic variations have a significant role, modifiable risk factors greatly impact the likelihood of developing or exacerbating existing psoriasis. These include stress, skin injury (including trauma), medications, infection, obesity, tobacco use, and cold, dry weather. First-degree relatives with psoriasis can increase risk of presentation, affecting males more than females. Women exposed to tobacco smoke have a higher risk of developing psoriasis than their male counterparts with the same exposure. Risk is also higher in urban versus rural settings. Additional factors exacerbating psoriasis include drugs such as lithium, NSAIDs, antimalarials, β-adrenergic blockers, and corticosteroid withdrawal.[10]

PATHOPHYSIOLOGY

Pathogenesis of psoriasis involves multiple components of the immune system. Cytokines, such as interleukins and tumor necrosis factor alpha, T cells, and keratinocytes, are central to the inflammatory process associated with psoriasis. Additionally, it has been found, when keratinocytes are disturbed, release of antimicrobial peptide LL-37 takes place, which binds with DNA and RNA. This complex leads to activation of plasmacytoid and myeloid dendritic cells that secrete interleukin IL-12 and IL-13. Production of these two interleukins eventually results in IL-17 and T helper cell type 1 differentiation.[2] The T cells then release

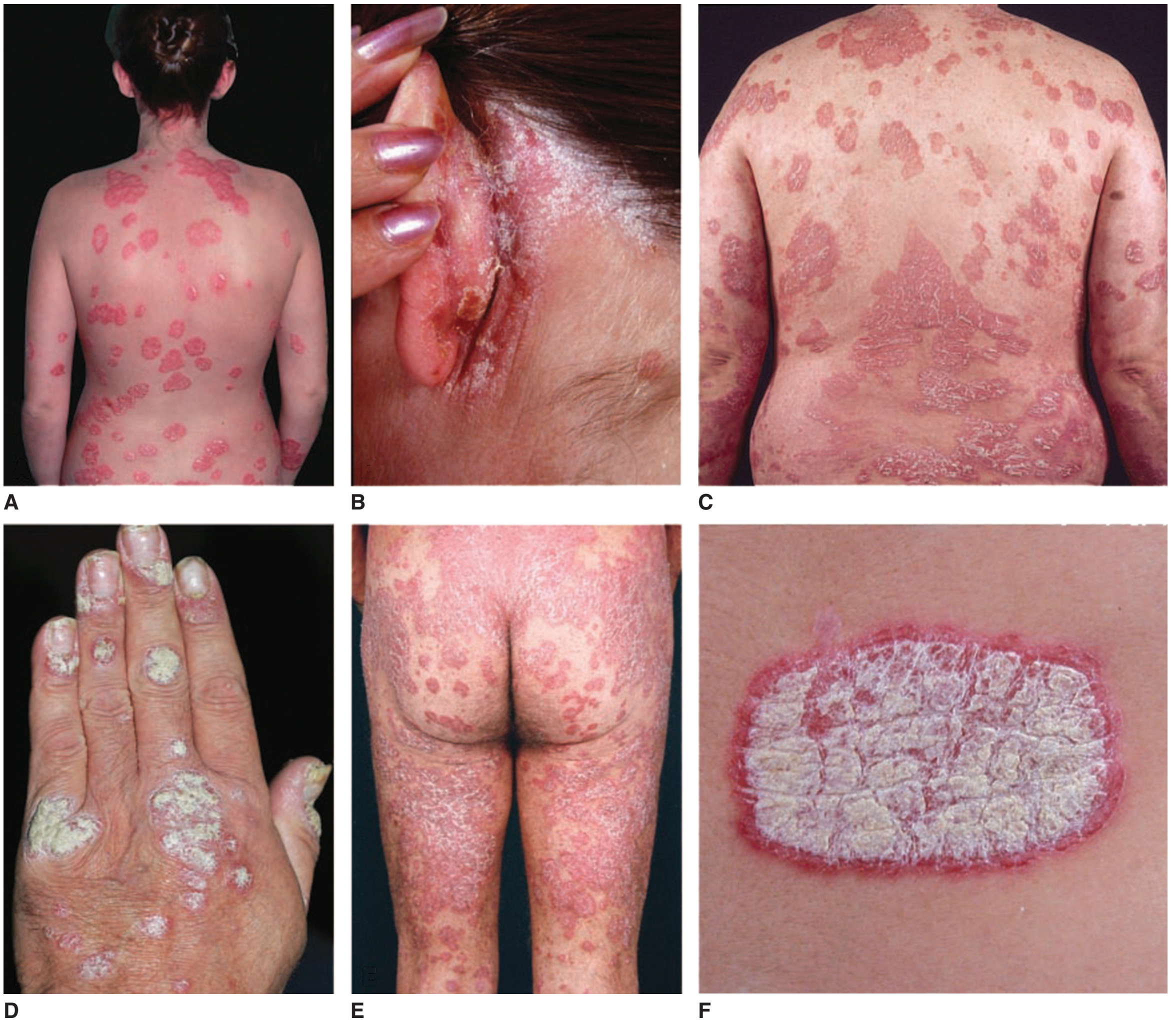

FIGURE 68–1. Chronic plaque psoriasis located at typical sites. Note marked symmetry of lesions. (From Kang S, Amagai M, Bruckner A, et al., eds. Fitzpatrick's Dermatology, 9th ed. New York, NY: McGraw-Hill; 2019. Photos used with permission from Dr. Johann Gudjonsson and Mr. Harrold Carter.)

Interleukin IL-17A, IL-17F, IL-22, and IL-23 as mediators that activate keratinocytes. This process generates a complex cascade including proinflammatory cytokines such as tumor necrosis factor (TNF alpha), interferon (IFN-alpha and IFN-gamma), and interleukin (IL-1beta, and IL-6). The entire process leads to alteration of the immune system and chronic inflammation that manifests in the skin causing vascular changes and formation of psoriatic lesions.[2] Hyperkeratosis that results from immune derangements causes the characteristic thick, scaly skin lesions. The pathologic pathway of psoriatic arthritis is the same, except the changes occurring as a result of T-cell mediators happen in the synovial fluid within joints. Osteoclast activation, osteolysis, and bone resorption produce the damage that occurs within joints.[2]

CLINICAL PRESENTATION AND DIAGNOSIS

KEY CONCEPT Diagnosis of psoriasis is usually based on recognition of characteristic plaque lesions and not on laboratory tests.

The severity of the disease is classified as mild, moderate, or severe disease based on BSA involvement. Additionally, classification may be based on assessment tools used such as the Psoriasis Area and Severity Index (PASI) which measures

Clinical Presentation and Diagnosis of Plaque Psoriasis

General characteristics	Small, discrete lesions to generalized confluent lesions over a large body surface area (BSA).
Symptoms	Severe itching (Not all patients experience)
Signs	• Raised lesions red to violet in color (commonly known as plaques). • Sharply demarcated lesion borders, except where confluent. • Lesions loosely covered with silvery-white scales, which if lifted off, show small pinpoints of bleeding (Auspitz sign). • Plaques appear on elbows, knees, scalp, umbilicus, and lumbar areas, and often extend to involve the trunk, arms, legs, face, ears, palms, soles, and nails. • Nail involvement presents as pitting, discoloration ("oil spots"), crumbling, splinter hemorrhages, growth arrest lines, or tissue buildup around the nails.

Clinical Presentation and Diagnosis of Other Types of Psoriasis

Flexural psoriasis	• Appears in intertriginous areas • Minimal scaling
Guttate psoriasis	• Sudden eruption of small, disseminated erythematosquamous papules and plaques • Often preceded by a streptococcal infection 2–3 weeks prior
Pustular psoriasis	• May be localized or generalized • May be an acute emergency requiring systemic therapy due to loss of skin integrity
Generalized pustular psoriasis	• Disseminated deep-red erythematous areas and pustules • May merge to become "lakes of pus"
Erythrodermic psoriasis	• Generalized, life-threatening condition • Erythema, desquamation, and edema • May require life support measures as well as systemic therapy

Patient Encounter, Part 1

RH is a 52-year-old man who has noticed red lesions that flake covering his back and elbows. When questioned, the patient says he has had these before, but they started spreading about 3 months ago. Since then, the lesions have become more noticeable, increasing in size. He is feeling self-conscious about what is happening and does not know what to do.

PMH: Hypertension

FH: Mother has psoriasis and rosacea. Father has hypertension. Younger brother has depression and Type 1 diabetes.

SH: RH is single with no children. He works for the city parks department and routinely forgets to wear sunscreen. He has a beer with dinner nightly and does not use tobacco.

Meds: Metoprolol ER 25 mg daily

Physical Exam

Gen: He appears distressed about the lesions.

VS: BP 134/77 mm Hg, P 78 beats/min, RR 20 breaths/min, T 37.0°C (98.6°F)

Height and Weight: Ht. 5 ft 7 in. (170 cm), Wt. 242 lb. (110 kg)

Abd: Soft, NTND; (+) Bowel sounds;

Exts: Within normal limits; no joint pains; lesions covering both elbows

Skin: Red lesions with silvery scale on elbows and back (BSA 9%)

Labs: All within normal limits, including lipids, renal function tests, and LFTs

What type of psoriasis is RH experiencing?

What risk factors does he have for psoriasis?

Table 68–1

Disease Severity Classification[4,12,14]

Mild disease	Less than 3% BSA involvement
Moderate disease	3%–10% BSA involvement OR PASI greater than or equal to 8 (higher in trials of biologics)
Severe disease	The Rule of Tens: PASI greater than or equal to 10 or DLQI greater than or equal to 10 or BSA greater than 10% (in some phototherapy trials, BSA greater than or equal to 20% is used as the lower limit) OR results in serious emotional consequences, causes intractable pruritus or occurs on the hands, feet, scalp, face, or genital area

three plaque issues: erythema, induration and scaling (overall score 0–72), Physician Global Assessment (PGA) (overall score 0–5,6), and the Dermatology Life Quality Index (DLQI) (score 0–30).[11,12]

TREATMENT

Desired Outcomes and Goals

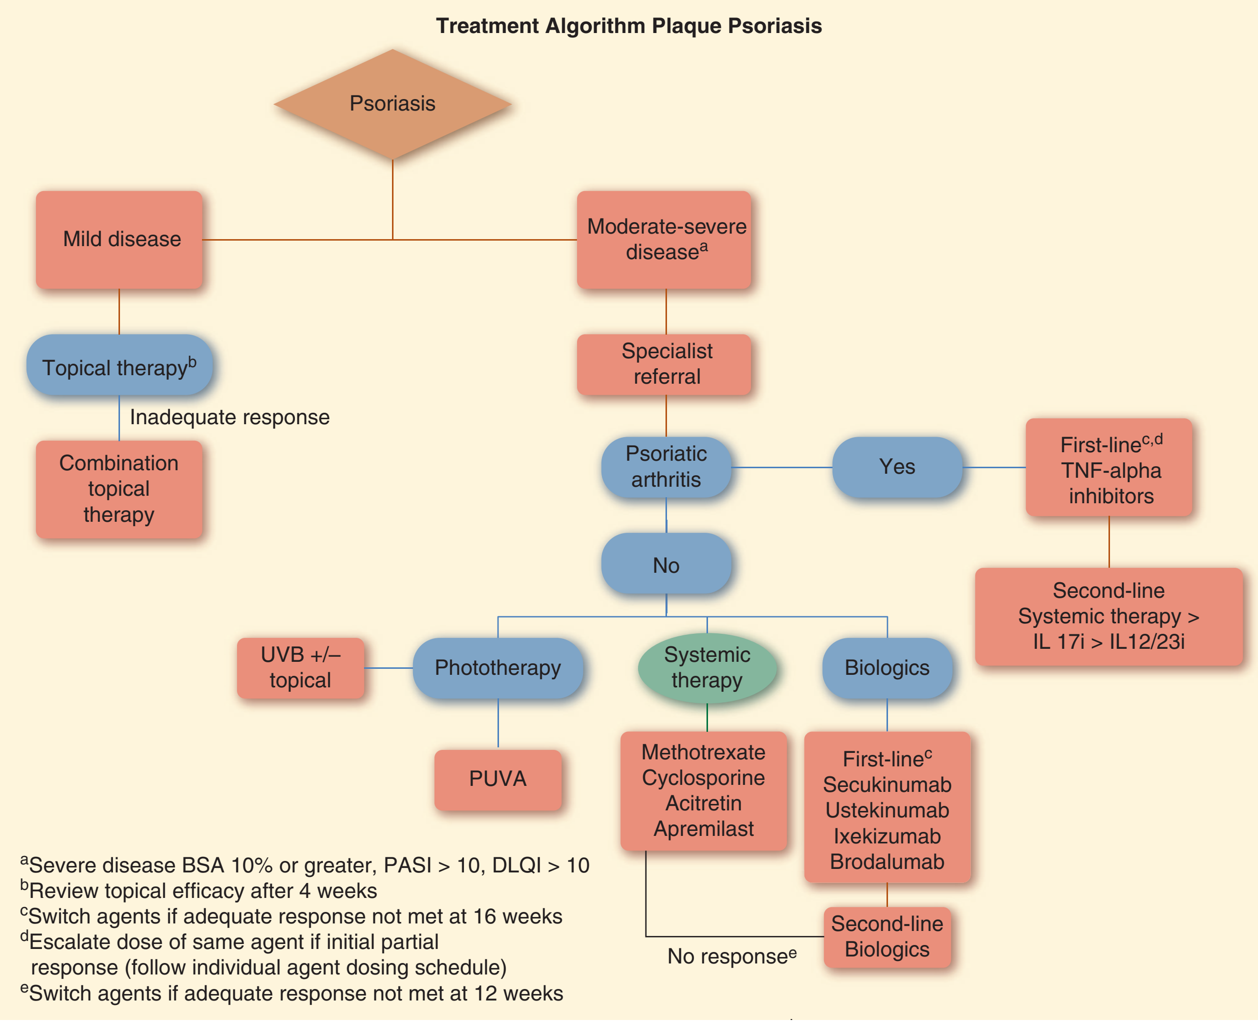
KEY CONCEPT Given its manifestations, inflammation, involvement of multiple areas of the affected skin, and the chronic nature of psoriasis, treatment goals must be individualized. Goals of treatment must be set based on clinical presentation, disease-related comorbidities, treatment-related morbidity, mortality, quality of life, staging of disease, and remission status at any given time.[4,6,7,11,12,13,14] It is imperative to remember that no cure exists for any type of psoriatic disease. However, evidence shows that current treatment options increase remission periods and reduce severity of disease.[3,14] Treatment goals should include:

- Minimize or eliminate signs of psoriasis, such as plaques and scales
- Alleviate pruritus and minimize excoriations when present
- Extend remission cycles
- Ensure appropriate management of associated comorbidities such as psoriatic arthritis, cardiovascular disorders, Crohn's disease, or clinical depression
- Avoid or minimize adverse effects from treatments
- Provide cost-effective therapy
- Provide counseling as needed (eg, stress-reduction techniques)
- Maintain or improve the patient's quality of life

General Approach to Treatment

The management of psoriasis should target the type that the patient presents with. General treatment considerations must include disease severity, location, the extent of BSA involvement, and pertinent lifestyle modifications.[11] The psychological impact of psoriasis may not correlate with the severity of the skin presentation, and it is important to continually evaluate the psychosocial effects of psoriasis on each patient.

For psoriatic arthritis (PsA), the goal of treatment is to reduce pain, reduce swelling, slow or minimize joint damage and maintain joint function.[2,3,4,6,7,11] KEY CONCEPT Effective psoriasis treatment should include both pharmacologic and nonpharmacologic approaches.[3,14]



Treatment Algorithm Plaque Psoriasis
Psoriasis
Mild disease
Moderate-severe disease[a]
Topical therapy[b]
Inadequate response
Combination topical therapy
Specialist referral
Psoriatic arthritis
Yes
First-line[c,d] TNF-alpha inhibitors
Second-line Systemic therapy > IL 17i > IL12/23i
No
UVB +/– topical
Phototherapy
Systemic therapy
Biologics
PUVA
Methotrexate Cyclosporine Acitretin Apremilast
First-line[c] Secukinumab Ustekinumab Ixekizumab Brodalumab
Second-line Biologics
No response[e]
[a]Severe disease BSA 10% or greater, PASI > 10, DLQI > 10
[b]Review topical efficacy after 4 weeks
[c]Switch agents if adequate response not met at 16 weeks
[d]Escalate dose of same agent if initial partial response (follow individual agent dosing schedule)
[e]Switch agents if adequate response not met at 12 weeks

FIGURE 68–2. Treatment algorithm for plaque psoriasis.[4,6,7,14,17,19]

Nonpharmacologic Management

KEY CONCEPT Several effective nonpharmacologic options are available to patients with psoriasis. However, considering the inflammatory nature of the disease, these treatments should be used as adjunctive treatments to therapeutic agents when appropriate.[12]

Stress reduction techniques such as psychotherapy, guided imagery, and relaxation techniques have been shown to reduce the extent and severity of psoriasis.[13,14] Oatmeal baths in tepid water may help soothe the itching associated with psoriasis. Nonmedicated moisturizers (occlusive agents, humectants, and/or emollients) help the skin retain moisture and reduce the silvery-white scaling of skin lesions. Emollients can be applied multiple times during the day to prevent skin dryness. Patients with skin sensitivities should consider the use of fragrance-free products to prevent flareups.[14] Harsh soaps, detergents, and other skin irritants should be avoided as they may worsen symptoms. Skin cleansing is appropriate; however, it should be done with lipid-free cleansers and tepid water when possible. Trauma to the skin must always be avoided as damage to skin integrity can precipitate a flare. Consequently, the use of sunscreen with sun protection factor (SPF) of 30 or greater is recommended as sunburn is one of the most common skin traumas.[15] Loose-fitting clothes are desired to help reduce skin irritation.[14]

Pharmacologic Therapy

The pathogenesis of the disease involves a complex mechanism that disturbs the immune system, causes vascular changes, and results in the development of skin lesions.[2] It is paramount that therapeutic agents opposing these processes are well represented in the treatment plan. **KEY CONCEPT** These agents are anti-inflammatory, anticytokines, and biologic therapies. They are classified into topical, phototherapy, conventional systemic therapy, and biologics.[6,14,18,19] Several factors must be taken into consideration in identifying the right therapy for a patient with psoriasis. These include the affected area of the disease, cost, availability of medication, and the preferred lifestyle of the patient. A full patient history including allergies must be collected to ensure a successful therapeutic approach. Topical agents are recommended for mild-to-moderate disease due to their affordability and fewer adverse effects. Low potency corticosteroids are used first line for mild conditions. If the condition persists, it is recommended to switch to a very high potency steroid in combination with a vitamin D analogue or topical retinoids. In general, a patient BSA should be less than 3% to qualify for topical therapy alone. A general recommendation after unsuccessful treatment with topical agents is to add phototherapy. Psoralen and ultraviolet A (PUVA) was found to be more effective than UVB in the treatment of patients with moderate-to-severe psoriasis.[16] Traditional systemic agents can be used for patients with severe disease and are often combined with topical therapy to improve effectiveness. Clinical trials indicate immunosuppressants are more effective than oral retinoids. Biological agents may be the drug of choice for severe disease depending on patient comorbidities, those intolerant to, or that fail traditional systemic agents. The choice of biologic agents depends on the patient's preference and comorbidities.[6,17] Psoriasis affecting more than 3% of BSA should be the justification for initiating systemic/biologic therapy. For patients with liver disease, kidney dysfunction, and skin cancer, it is recommended to avoid methotrexate, cyclosporine, and PUVA treatment, respectively.[6,18,19]

▶ *Topical Treatment*

These agents are first-line treatment for mild-to-moderate psoriasis. They are known for their anti-inflammatory, antiproliferative, and anti-immunologic properties. They are classified as corticosteroids, vitamin D analogues, retinoids, calcineurin inhibitors, coal tar, anthralin, and salicylic acid derivatives. Topicals can also be used as adjunct therapy to phototherapy, systemic and/or biologic agents. Different dosage forms are available such as creams, lotions, gels, foams, ointments, shampoos, oil solutions, tapes, and sprays. **KEY CONCEPT** The choice of specific dosage form or vehicle is dependent on several factors including the BSA involved, location, thickness of the lesions, and the appearance of the plaques.[14] Ointments are recommended for dry and thick lesions to enhance absorption and maintain skin moisture. Creams are indicated for acute, but moist appearing, lesions that do not require ointment-based products. Solutions/shampoos and gels are recommended for scalp lesions and foams and sprays are usually used for lesions in genital areas.[14]

Vehicle selection is an important consideration as it impacts topical efficacy. Ointments and tapes provide occlusion, enhancing drug penetration to improve efficacy. Shampoos incorporating coal tar distillates or salicylic acid with corticosteroids are useful for scalp psoriasis. Coal tar and salicylic acid are rarely used as lone agents due to tolerability issues related to staining and irritation, respectively. It is important to remember that changing vehicles may significantly alter drug potency. Ultimately, the optimal vehicle may be the one the patient is willing to use. Occlusive ointments may be too greasy and cosmetically unappealing, resulting in poor adherence. Sometimes using a cream formulation during the day and an ointment at night may be the best option.[14]

KEY CONCEPT Corticosteroids are the topical first-line treatment for mild-to-moderate psoriasis. They exert anti-inflammatory and immunosuppressive effects, resulting in reduced scaling and overall plaque size. Additionally, topical corticosteroids can be combined with other topicals or systemic/biologic agents to enhance therapy. Adverse effects include skin atrophy with prolonged use (especially if used with an occlusive agent), hypopigmentation, and striae. More than 2 to 4 weeks of continuous use should be avoided to prevent these complications.[14] Nonsteroid topicals can be used as single agents or in combination (most commonly vitamin D analogues and retinoids) with the corticosteroids to reduce exposure to corticosteroids.

▶ *Phototherapy for Psoriasis*

Phototherapy and **photochemotherapy** are generally used to manage moderate-to-severe disease, when topical treatment is not sufficient, when the patient wants to avoid systemic side effects, or as adjunct therapy to a failing regimen.[19]

Patient Encounter, Part 2

The diagnosis is the patient has plaque psoriasis.
Patient expresses to you at this time his elbows are the most bothersome, but he wants something that will take care of his psoriasis all over.

What nonpharmacologic alternatives are appropriate for this patient?

What pharmacologic agents are appropriate for this patient?

Phototherapy is commonly done using narrow band UVB (NB-UVB) radiation two to three times weekly. Once skin clears or improves, sessions can be once weekly for maintenance. UVB disrupts synthesis of proteins and nucleic acids in skin, reducing epidermal keratin proliferation. Phototherapy may be administered during pregnancy and is considered a first-line therapy for those patients as long as the patient is on adequate folate supplementation (UVB can deplete folate above a certain exposure).[19]

Photochemotherapy is the administration of phototherapy together with topical or systemic agents.[14,19] UVA has a long wavelength, and therapy with UVA is always combined with **psoralens** (eg, methoxsalen or trioxsalen), which are used as photosensitizers to increase efficacy. Use of psoralens + ultraviolet A (PUVA) for psoriasis causes two types of reactions: (a) an anoxic reaction that affects cellular deoxyribonucleic acid (DNA) that inhibits proliferation of epidermal cells and induces cell death (apoptosis), and (b) an oxygen-dependent reaction that increases formation of free radicals and reactive oxygen that may damage membranes by lipid peroxidation. PUVA applies to a group of therapies utilizing psoralens to sensitize cells to UVA light.[19]

▶ *Systemic Therapy*

Systemic therapies are used for moderate-to-severe disease. To minimize drug toxicities or increase efficacy, systemic therapies are sometimes used in conjunction with topical or phototherapy.[3,4,12,18,19,20] These agents are classified into immunosuppressants, oral retinoids, T-cell activation inhibitors, cytokine modulators, tumor necrosis factor-alpha inhibitors, and interleukin 12 and 23 blockers.[1]

Cyclosporine is an immunosuppressant that inhibits helper T cells and keratinocyte activation and proliferation. Cyclosporine is efficacious in both inducing and maintaining remission for patients with moderate-to-severe plaque psoriasis and is also effective in treating pustular, erythrodermic, and nail psoriasis.[12,18]

Methotrexate is a folic acid antagonist that interferes with purine synthesis, thus inhibiting DNA synthesis and cell replication. In addition to the antimitotic effect, it suppresses T-cell effects, and, in low doses, has anti-inflammatory and antiproliferative effects by acting on lymphoid cells. Methotrexate has a more modest effect than cyclosporine but can be used continuously for years, with persistent benefits for both psoriasis and PsA.[11] Folic acid is added to the methotrexate treatment to reduce gastrointestinal symptoms and bone marrow toxicity. Due to these side effects, extensive monitoring is required. It may take up to 4 weeks to see a clinical response after a dose increase.[11,18]

Oral apremilast is one of a class of "small molecule" systemic biologics specifically approved for PsA. It inhibits phosphodiesterase

Table 68–2

Topical Medications[2,12,14]

Actions and Effects	Selected Agents	Criteria	Approach to Therapy	Efficacy Assessment (PGA) Scores	Dosage Form/ Strength	Place in Therapy
Corticosteroids						
Corticosteroids Anti-inflammatory Vasoconstriction Immunosuppression Antiproliferative	**Very High Potency** • Betamethasone • Clobetasol • Diflorasone	Mild to moderate	Monotherapy for acute episode	41%–92% with increase in potency	Ointments Creams Lotions Gels Foams Solutions Shampoos, spray and tape	First line To avoid disease flares, taper use first every other day then twice a week then stop Lower potency should be tried on the face, intertriginous areas and areas susceptible to atrophy (e.g. forearms) Safe to use in pregnancy at low doses (60 g per week) and avoid nipple and areola area
	High Potency • Amcinoride • Betamethasone dipropionate and valerate • Desoximetasone		Monotherapy for acute episode			
	Intermediate Potency • Betamethasone • Triamcinolone		Monotherapy for acute episode			
	Low Potency • Alclometasone • Desonide • Hydrocortisone		Monotherapy for acute episode			
Vitamin D Analogues						
Not well-known Vitamin D Receptor binding is proposed Keratinocytes proliferation is attenuated	Calcipotriene	Mild to moderate	Mono- or steroid-sparing adjunctive therapy First consideration with steroid when rapid lesion eradication is desired	60%–70%	Cream Scalp solution	First line with or without steroid Can be used with methotrexate to lower doses and increase time to relapse Long-term combo with corticosteroid more effective than either alone Can be used with phototherapy but must be applied subsequently to avoid inactivation May be used during pregnancy and lactation if benefits outweigh risks
	Calcitriol			60%–70%	Ointment	
Retinoids						
Not well known. Modifies gene transcription Decrease inflammation and keratinocyte proliferation due to its retinoid acid receptors binding	Tazarotene	Mild to moderate	Mono- or adjunctive therapy with steroid. More effective with high potency steroids	63%	Gel	Second line with or without steroid Should be avoided in pregnant women (obtain pregnancy test 2 weeks prior to start of therapy)

Calcineurin Inhibitors Topical calcineurin inhibitors bind to calcineurin, blocking its phosphorylation, and thus, inhibiting T-cell activation and the synthesis of several proinflammatory cytokines that play a critical role in the pathogenesis of psoriasis	Tacrolimus	Mild to Moderate	Monotherapy for more sensitive areas of the skin such as face	65%–70%	Ointment Strengths: 0.03% and 0.1%	Third line with or without steroid Not FDA approved but often used in facial or intertriginous areas Safety in pregnancy is unknown
	Pimecrolimus	Mild to Moderate	Monotherapy for more sensitive areas of the skin such as face	56%–62%	Cream Strength: 1%	
			Other Agents			
Moisturizers Unknown	Nonmedicated Moisturizers	Mild to moderate	Commonly used throughout the day In combination with other topicals to reduce adverse effects	31%	Creams and ointments	Symptom relief/appearance of lesions Safe to use during pregnancy and lactation
Salicylates Acts as a keratolytic agent and reduces lesion scaling to improve absorption of applied medications	Salicylic acid	Mild to moderate	More effective when used as an adjunctive therapy to other topical agents (allows for more effective absorption of combination agent)	unknown	Creams Foams Ointments Shampoos Strengths 1.8%–2.5% and 3%	Adjunct therapy for scalp psoriasis used with steroids to increase efficacy (breaks down keratin)
Anthralin Inhibition of T-cell proliferation and migration of neutrophils Keratolytic agent	Anthralin	Mild to moderate	Used infrequently due to irritation	Unknown	Creams and Shampoos Strengths 1%–1.2%	Adjunct therapy often used in conjunction with steroids in a paste
Coal Tar Inhibition of cell proliferation Acts as keratoplastic Agent	Coal Tar crude Coal Tar combinations	Mild to moderate	Used infrequently due to skin irritation	Unknown	Creams, Gels Shampoo Solutions Lotions Oil Strengths 0.5% to 3%	Adjunct therapy with steroids to increase efficacy May be advisable to avoid during pregnancy

Table 68–3

Topical Medications[2,12,14]

Drug Class	Dosing and Application	Administration Guidelines	Cautions and Side Effects
Corticosteroid	• Mostly once or twice daily • Every other day or weekends only application may be suitable for long term therapy • Treatment is recommended for 2 to 3 weeks • Low and intermediate potency can be used up to 3 months	• Intermediate and low potency agents are indicated for acute and mild lesions and tapering is recommended to the lowest tolerated dose when the condition improves • Low potency agents are suitable for lesions in infants due to large BSA and elderly for the sensitive and thin layer of the skin • High and very high potency agents are indicated for chronic and severe lesions • Palms and soles of the skin require high and very high potency agents to maximize absorption and penetration due to the thickness of the skin	• Skin irritation • Dryness • Withdrawal effects
Vitamin D Analogues	Mostly once or twice daily for a maximum of 2 months for effective result	• Recommended to be used with topical steroids to speed up the healing process • Considered less toxic than topical steroids • Combination therapy with steroids has shown to be more effective than the single agent • Onset of action is slow • Avoid calcipotriene use with salicylic acid due to instability of calcipotriene	• Pruritus • Skin irritation on facial area and skin folds • Skin irritation is less with Calcitriol • Skin rashes • Burning • Changes in systemic vitamin D levels
Retinoids	Preferred as once daily at bedtime	• Best used to achieve better efficacy results with high potent steroids or UVB phototherapy • Monotherapy duration of use 8 to 12 weeks	• Skin irritation (erythema, burning) • Pruritus • Dryness • Photosensitivity • Adverse effects reduced by using cream, lower concentration or in combination
Calcineurin Inhibitors	Mostly once or twice daily depending on the product until effective result is observed	• Comparison data to other agents or in combination is lacking • Use with salicylic acid for 8 weeks showed efficacy improvement in facial lesions	• Skin irritation • Pruritus • Photosensitivity • Flushing in combination with alcohol • Black box warning-skin cancer and lymphoma (no evidence with topical use)
Other Agents • Salicylic Acid • Coal Tar • Anthralin	As directed	• Decreases the scaling of the skin lesions to allow application of other agents • Infrequent use of tars and anthralins due to irritation and staining	• Skin irritation • Potential salicylic acid toxicity manifesting as nausea and ringing in ears (can occur when treating large surface areas and in renal or hepatic impairment)

4 (PDE4) which controls part of the inflammatory actions within cells via cAMP to decrease nitric oxide synthase, TNF-alpha and interleukin [IL] 23, and increase IL-10.

Acitretin is an oral retinoid that is likely safer, but less effective, than methotrexate or cyclosporine since potentially serious adverse effects can be minimized by appropriate patient selection, careful dosing, and monitoring. Acitretin, given concurrently with phototherapy, acitretin + ultraviolet B (ReUVB) or oral retinoid + PUVA (RePUVA), has a synergistic treatment effect.[21,22] Acitretin monotherapy is usually given for 14 days before instituting UVB or PUVA.[15] ReUVB and RePUVA are well-established treatment regimens for psoriasis.[4,6,7,18,19] Pregnancy and blood donation must be avoided during treatment and for 3 years after discontinuation of therapy.[6,7,12] Acitretin can transform spontaneously or be converted by ethanol (transesterification) into etretinate, which may take up to 3 years to completely clear the body. Due to this, acitretin patients should abstain from alcoholic beverages during therapy and for at least 2 months after discontinuation.

Biologics Biologics and their biosimilars are currently recommended for consideration as first-line therapies alongside traditional systemic agents for moderate-to-severe disease.[6,18] These agents inhibit various molecular signaling steps of the immunological signaling cascade that are key determinants of the pathogenesis of psoriasis. The following agents are available for the treatment of chronic plaque psoriasis:[23,24,25]

1. Inhibitors of tumor necrosis factor, which include biologic agents such as etanercept, adalimumab, infliximab, certolizumab, and golimumab.
2. Inhibitors of interleukin, which include ustekinumab, ixekizumab, brodalumab, risankizumab, tildrakizumab, guselkumab, and secukinumab.

Their safety profile, in comparison with other systemic agents, and relatively good patient acceptability are all positive factors for use.[6] However, given immunosuppression is an adverse effect of many of these agents, clinicians should ensure appropriate vaccinations are administered and tuberculosis skin testing performed prior to initiation of therapy. Additionally, clinicians should monitor for signs/symptoms of infection throughout therapy. Primary response success with biologics is defined as 50% or greater reduction in baseline disease severity. Treatment efficacy should be assessed at 12 to 16 weeks except for infliximab which should be assessed after 8 to 10 weeks of use. Therapy should be switched if the primary response is not achieved or if the psoriasis initially responds but then loses its response. Consider a dose escalation, increase in frequency or addition of other modalities if a partial response is achieved.

All TNFα inhibitors improve the signs and symptoms of PsA, improve functional status and quality of life and inhibit progression of joint damage. Due to this, they are the preferred biologic treatment for psoriasis with concomitant PsA. Many other biologics may be used when PsA is present, but certolizumab (TNF-alpha inhibitor), guselkumab (interleukin inhibitor), and abatacept (T-cell inhibitor) can only be used for PsA and not severe psoriasis.[6,24,25]

OUTCOME EVALUATION

- Monitor for clearance of skin lesions. Depending on the agent(s) used and site of lesions, it may take 2 to 6 weeks or longer to see a response. Complete clearance may not be achieved for all patients. A BSA of 3% or less or a BSA improvement of 50% or more from baseline is considered an acceptable response.
- Beginning 3 months after the start of new therapies (Important to wait at least 90 days since it can take up to 16 weeks to effect (induction phase)):
  - A BSA of 1% or less is recommended for target therapy.
- During maintenance or remission, monitor every 6 months.
  - A BSA of 1% or less is the target response every 6 months during maintenance evaluation.
- In Europe, successful treatment is defined as a decrease in the Psoriasis Area and Severity Index (PASI) score of 75% or greater. The PASI is a scoring instrument that ranges from 0 (absence of disease) to 72 (most severe form of the disease).[17]
- Treatment failure is defined as a decrease in the PASI score of less than 50% necessitating new treatment.
- Monitor for improvement of symptoms and control of comorbid conditions. Incomplete clearance of lesions, but improvement in these metrics, can be considered at least partial treatment success. The American Academy of Dermatology/National Psoriasis Foundation (AAD-NPF) clinical guidelines on psoriasis outline other qualitative measures to be used in assessing the holistic approach to disease management.[1] It emphasizes evaluating physical, psychological, and social impact of the disease on the quality of life and daily living activities of the patients. Efficacy achievement alone may not have the overall desired effect on patients wellbeing.[1,14] Dermatology Quality of Life Scales, Dermatology Life Quality Index (DLQI), Dermatology Specific Quality of Life Instrument, and Skindex-29 are validated instruments that are used to measure these quality outcomes in patients with psoriasis by specialists.[12,18]
- Monitor for adverse effects and drug interactions, depending on agent(s) used.
- Total clearance of skin is not impossible during periods of remission; remissions may be days, months, years, and even decades in length with patients being weaned from their medications entirely or reduced to a low maintenance dose.

Patient Encounter, Part 3

The patient was started on clobetasol 0.1% ointment and phototherapy and has been doing well for several months. RH reports that his skin looks better, but he is starting to have joint pain.

Current meds: Nonmedicated moisturizer after bathing and as needed; clobetasol 0.1% ointment twice daily; phototherapy; metoprolol ER 25 mg daily

What is your main treatment goal for this patient?

What pharmacologic treatments would be appropriate for this patient at this time?

What are the monitoring parameters of your proposed treatment?

Table 68–4

Systemic Agents[3,7,11,12,18]

Drug	Mechanism of Action	Doses and Administration	Dosage Forms	Adverse Effects	Therapeutic efficacy on PASI 75	Therapeutic Application	Therapeutic Monitoring
Immunosuppressants							
Cyclosporine	An immunosuppressive agent that specifically inhibits helper T cell and keratinocyte activation and proliferation	2.5 mg/kg/day in two divided doses for at least 4 weeks This dose may be subsequently titrated and increased by 0.5 mg/kg/day every 2 weeks until there is control of plaques (max dose of 5 mg/kg /day)	Oral and IV solution	Nephrotoxicity, lowering of seizure threshold, tremor, gingival hyperplasia, hypertension, squamous cell carcinoma (cutaneous), avoid concomitant use with phototherapy due to increased photocarcinogenesis, but can be used sequentially, avoid live vaccines due to immunosuppression	~41%–71%	Recommended in severe, recalcitrant psoriasis Used in psoriasis only (children only as last line therapy)	LFTs (Baseline and routine) SCR, BUN CBC Uric acid Blood pressure Drug Interaction with cytochrome p450 substrate and inhibitors Pregnancy Therapeutic relapse after completing therapy (~3 months)
Methotrexate	Folic acid antagonist Act by interfering with purine synthesis, thus inhibiting DNA synthesis and cell replication	7.5–10 mg weekly (max of 25 mg) 2.5 mg every 12 hours times 3 doses (should be given with folate supplementation to reduce adverse effects)	Oral and injectable	Nausea, vomiting, stomatitis, fatigue, hepatotoxicity, bone marrow suppression, pulmonary fibrosis	24%–60%	First-line agent (can be used as monotherapy, but more effective in combination with TNFa agents) (can be given safely with narrow band UVB) Used in psoriasis and psoriatic arthritis (adults and children)	CBC SCR, BUN LFTs (baseline and every 3–6 months), avoid in cirrhosis and alcohol use disorders Reactivation of infections PPD test for TB Pregnancy category X
PDE 4 inhibitors							
Apremilast	Phosphodiesterase 4 (PDE4) inhibitor, with specificity for cyclic adenosine monophosphate (cAMP) that results in increased intracellular cAMP levels	Initial titration over 5 days: Day 1, 10 mg orally in AM; Day 2, 10 mg twice daily; Day 3, 10 mg in AM, 20 mg in PM; Day 4, 20 mg twice daily; Day 5, 20 mg in AM, 30 mg in PM Maintenance: Day 6 and thereafter, 30 mg orally twice daily	Oral	Diarrhea, nausea, headache, tension-type headache, weight decreased, depression, suicidal behavior, suicidal thoughts	33%	Used in psoriasis and psoriatic arthritis (adults)	Coadministration with strong CYP450 inducers (eg, rifampin, phenobarbital, carbamazepine, and phenytoin) is not recommended Reduce dose to 30 mg daily when CrCl <30 mL/min (0.5 mL/s)

Janus Kinase (JAK) Inhibitor							
Tofacitinib	Inhibits Janus kinase which are intracellular enzymes, and modulates a signaling pathway that influences the cellular processes of hemopoiesis and immune cell function	Immediate release: 5 mg twice daily Extended release: 10 mg once daily	Oral pill (immediate and extended release)	URI, headache, diarrhea, cold or flu-like symptoms	39.9%–59.2%	Used in psoriatic arthritis only (adults) (in combination with nonbioologic DMARDs) Off-label for psoriasis (can be used with methotrexate, but should not be combined with cyclosporine or biologics	Serious infection, malignancies, GI perforations, changes in CBC (reductions in lymphocytes, ANC or hemoglobin may necessitate dose changes, LFTs, or lipids, Caution with administration of live vaccines (administer zoster vaccine prior to start of therapy) When switching from IR to ER give ER tablet day after last IR dose
Oral Retinoids							
Acitretin	Stimulates differentiation and normalizes epidermal cell proliferation, not immunosuppressive	10–50 mg/day	Oral capsule	Myalgia, hair loss, hepatotoxicity, pancreatitis, hypervitaminosis A, hyperlipidemia, xerosis, epistaxis	70%–75% (dose dependent and can take 3–6 months for full treatment response)	Second line Agent (more efficacious in combination with phototherapy than monotherapy) Used in psoriasis only (adults and children)	Lipids CBC SCR, BUN (baseline and every 3 months Pregnancy category X CYP450 medications

Table 68–5

Biological Therapy[2,3,6,7,11,12,23,24,25]

Medication	Mechanism of Action	Dose and Administration	Dosage Forms	Adverse Effects	Therapeutic effects on PASI	Place in Therapy	Therapeutic Monitoring
Cytokine Modulators: Tumor Necrosis Factors							
Etanercept	Fusion protein that binds to both TNFα and TNFβ	50 mg subcutaneously twice weekly for 12 weeks then 50 mg subcutaneously weekly	Subcutaneous solution Biosimilars available: etanercept-szzs Etanercept-ykro	URI, nausea, vomiting, headaches Injection site reaction	47%–59% at weeks 12 and 24	Monotherapy for moderate–severe psoriasis (4 years and up) Monotherapy for PsA associated with any stage of psoriasis	CBC LFTs CMP hepatitis PPD (tuberculosis) Safe in pregnancy and lactation
Abatacept	Blocks T-cell activation	125 mg once weekly	Subcutaneous self-injection, IV infusion	HA, URI, cold-flu-like symptoms	Improvement of PsA symptoms	Used in psoriatic arthritis only (adults)	Signs of infection (should not be used with TNF inhibitors) Do not give live vaccines PPD prior to starting therapy (TB testing) Info lacking on use in pregnancy
Adalimumab	Human monoclonal antibody that binds TNFα inhibiting its interaction with receptors	80 mg subcutaneously, first dose then 40 mg subcutaneously on week 2, then 40 mg subcutaneously every 2 weeks	Subcutaneous solution Biosimilars available: adalimumab-adbm, adalimumab-atto adalimumab-adaz adalimumab-bwwd adalimumab-afzb adalimumab-fkjp	URI, pharyngitis, nausea, dyspepsia, fatigue, headaches Injection site reaction	53%–80% at weeks 12 and 16	First line, can be used as monotherapy for adults, monotherapy for PsA with any stage of psoriasis	CBC LFTs CMP hepatitis PPD (tuberculosis) Efficacy-limiting immunogenicity (mitigated by using with methotrexate) Safe in pregnancy and lactation
Certolizumab	Humanized antigen binding fragment of a monoclonal antibody which binds to TNFα blocking receptors	400 mg (2 injections of 200 mg each) on weeks 0,2, and 4 then every other week	Subcutaneous injection	URI Rash UTI Serious allergic reaction Lupus-like syndrome	75%–83%	Monotherapy for psoriasis and PsA	CBC LFTs CMP hepatitis Signs and symptoms of infection Safe in pregnancy and lactation
Infliximab	Chimeric monoclonal antibody that targets TNFα	5 mg/kg IV on weeks 0, 2, 6 and then 5 mg every 8 weeks (10 mg/kg dosing is reserved for IBD)	Intravenous and subcutaneous solutions Biosimilars available: infliximab-abda, infliximab-dyyb, infliximab-qbtx infliximab-qbtx infliximab-axxq	URI, pharyngitis, diarrhea, fatigue, hypersensitivity reaction, infusion-related reactions	76%–82% at weeks 10 and 24	Monotherapy PsA therapy with or without MTX associated with any stage of psoriasis	CBC CMP hepatitis PPD (tuberculosis) Efficacy-limiting immunogenicity Safe in pregnancy and lactation

Golimumab	Human monoclonal antibody that binds to both soluble and transmembrane bioactive forms of human tumor necrosis factor alfa (TNF alfa; a cytokine protein), resulting in inhibition of TNF alfa biological activity by preventing the binding of TNF alfa to its receptors	50 mg SC once monthly 2 mg/kg 30-minute IV infusion at 0, 4, then every 8 weeks	Subcutaneous and IV solution	Hypertension, rash, ALT/SGPT level raised, AST/SGOT level raised, dizziness, paresthesia, bronchitis, sinusitis, URI, new or worsening heart failure	Improvement in symptoms and inhibition of structural damage	Used in psoriatic arthritis only (adults) alone or with methotrexate	LFTs Infection Edema
Cytokine Modulators: Interleukin inhibitors							
Ustekinumab	Human monoclonal antibody that targets IL12/23 p40	45–90 mg subcutaneously on week 0 and 4, then every 12 weeks (45 mg if <100 kg vs 90 mg >100 kg)	Subcutaneous solution	Headache, URI, pharyngitis, abdominal pain	66%–78% at weeks 12 and 28 Less effective than TNF for PsA, does not have label for prevention of joint destruction	First line, can be used as monotherapy Used in psoriasis (people over 12 years old) and psoriatic arthritis (adults) Monotherapy PsA with any stage of psoriasis	CBC CMP hepatitis PPD (TB testing) Signs of serious infection (increased with methotrexate) Efficacy-limiting immunogenicity occurs: antibodies are produced resulting in lowered serum levels, and loss of efficacy Uncertain pregnancy and lactation risk
Secukinumab	Human monoclonal antibody that antagonizes IL17A	300 mg subcutaneously at weeks 0, 1, 2, 3, and 4 then 300 mg every 4 weeks	Subcutaneous solution	Nasopharyngitis, diarrhea, URI	82%–86% at week 12	First line, can be used as monotherapy Used in psoriasis and psoriatic arthritis (adults) (FDA approved) Monotherapy PsA at any psoriasis stage	CBC CMP hepatitis PPD (TB testing) Signs of serious infection (increased with methotrexate) Contraindicated in inflammatory bowel disease, Caution in patients with chronic or recurrent infection Rare antibodies (< 0.4%) and not associated with a loss of efficacy No studies in human pregnancy

(*Continued*)

Table 68–5

Biological Therapy[2,3,6,7,11,12,23,24,25] (*Continued*)

Medication	Mechanism of Action	Dose and Administration	Dosage Forms	Adverse Effects	Therapeutic effects on PASI	Place in Therapy	Therapeutic Monitoring
Ixekizumab	Human monoclonal antibody that inhibits the release of proinflammatory cytokines and chemokines by selectively binding with interleukin 17A cytokine	160 mg (two 80 mg injections) subcutaneously at week 0, followed by 80 mg subcutaneously at weeks 2, 4, 6, 8, 10, and 12, then 80 mg subcutaneously every 4 weeks	Subcutaneous solution	Injection site reaction, neutropenia, URI, hypersensitivity reaction	71%–100% at week 12 If neutralizing antibodies develop, can reduce drug concentrations resulting in a loss of efficacy	First line, can be used as monotherapy Used in psoriasis and psoriatic arthritis (adults) (FDA approved) Monotherapy for PsA associated with psoriasis	Caution in patients with chronic or recurrent infection, CBC CMP hepatitis PPD (TB testing) Signs of serious infection (increased with methotrexate) No studies in human pregnancy
Brodalumab	Human monoclonal IgG2 antibody that blocks the release of proinflammatory cytokines and chemokines by selectively binding to human interleukin-17 receptor A (IL-17RA) and inhibiting its interactions with cytokines IL-17A, IL-17F, IL-17C, and IL-17A/F heterodimer and IL-25	210 mg subcutaneously on weeks 0, 1, and 2, then every 2 weeks thereafter	Subcutaneous solution	Diarrhea, mycosis, arthralgia, headache, pain in throat, fatigue, neutropenia, cryptococcal meningitis, suicidal thoughts	67%–86% at week 12	Second line Used in psoriasis (adults) and psoriatic arthritis	PPD (tuberculosis) Caution in patients with chronic or recurrent infection Contraindicated in inflammatory bowel disease No studies in human pregnancy
Guselkumab	Human monoclonal antibody Blocks interleukin 23 (IL-23)	100 mg SC Weeks 0 and 4, then every 8 weeks	Subcutaneous solution	URI, HA, joint pain, diarrhea	70%	Used in psoriasis only (adults)	CBC CMP PPD (tuberculosis) Hepatitis Safety in pregnancy is unknown Signs of infection
Tildrakizumab	Monoclonal antibody designed to selectively block IL-23	100 mg SC Weeks 0 and 4, then every 12 weeks	Subcutaneous injection	URI, HA, joint pain, diarrhea	61%–66%	Used in psoriasis only (adults)	CBC CMP PPD (tuberculosis) Hepatitis Safety in pregnancy is unknown If antibodies develop, can lower serum concentrations and reduce efficacy
Risankizumab	Monoclonal antibody that selectively inhibits IL-23	150 mg (two 75 mg injections) administered by subcutaneous injection Week 0, 4, and every 12 weeks thereafter	Subcutaneous self-injection	URI, HA, joint pain, diarrhea	77%	Used in psoriasis only (adults)	CBC CMP PPD (tuberculosis) Hepatitis Safety in pregnancy is unknown

Patient Care Process

Collect Information:

- Perform a medication history for use of prescription and nonprescription medications and dietary supplements. Identify allergies to medications and other substances.
- Review the medical history, history of psoriasis (signs, symptoms, treatments), and physical assessment findings (eg, BMI, BSA % covered in lesions/plaques)
- Speak with patient and review records to identify lifestyle habits (note tobacco use), preferences and beliefs, health goals, and socioeconomic factors that affect medication access and other aspects of care.
- Identify sources of stress that could worsen psoriasis.
- Document pertinent family medical history (eg, heart disease, stroke, diabetes, dyslipidemia).

Assess the Information:

- Determine whether patient is taking any substance that could adversely affect psoriasis control or interact with prescribed medications.
- Based on the medical history, determine whether patient has any contraindications to therapy.
- Determine the severity and type of psoriasis.
- Identify comorbidities associated with psoriasis.
- Document location and BSA % covered by lesions/plaques.
- Assess efficacy, safety, and patient adherence of current and past pharmacotherapy.
- Identify significant adverse drug effects or interactions.

Develop a Care Plan:

- If patient is not at desired level of remission, determine pharmacologic treatment (**Figure 68–1**).
- Select lifestyle modifications likely to be effective, safe, and applicable to the patient.
- Choose optimal medications and doses for the patient (**Tables 68–2** to **68–5**). Use combination therapy when appropriate to take advantage of complementary mechanisms of action and to reduce side effects.

Implement the Care Plan:

- Educate the patient about changes in drug therapy, medication administration, potential new adverse effects, and how to manage and report adverse effects.
- Address any patient concerns about psoriasis and its management.
- Discuss importance of medication adherence and lifestyle modifications to prolong remission.
- Determine whether the patient has insurance coverage or whether recommended agents are included on the institution's formulary.
- Educate patient about the involvement of dermatologists (eg, when biologic therapy is warranted).

Follow-up: Monitor and Evaluate:

- Follow up at 6-to-12-week intervals to assess effectiveness and safety of therapy until remission is achieved.
- Review medication adherence and BSA % covered measurements, evaluating the degree of control.
- Once in remission, monitor patient twice yearly to assess control and pertinent lab monitoring. Determine whether the patient is experiencing any adverse reactions or drug interactions.

SUMMARY

Psoriasis is a chronic disease with no current cure but requires lifelong management. No two cases are identical and treatment must be tailored to the patient with the help of a dermatologist. The disease can severely impact the quality of life of the patients by affecting physical, psychological, and social well-being. AAD-NPF guidelines recommend a holistic approach, assessing all areas of life in caring for patients that live with this disease.

Abbreviations Introduced in This Chapter

BSA	Body surface area
cAMP	Cyclic 3'-5'-adenosine monophosphate
DISH	Diffuse idiopathic skeletal hyperostosis
IF-©	Interferon-*gamma*
IL-2	Interleukin-2
IL-10	Interleukin-10
IL-12/23	Interleukin-12 and interleukin-23
LFT	Liver function test
MI	Myocardial infarction
NB-UVB	Narrowband ultraviolet B
NSAIDS	Nonsteroidal anti-inflammatory drugs
PASI	Psoriasis Area and Severity Index
PGA	Physician Global Assessment
PPD	Purified protein derivative
PUVA	Psoralen ultraviolet A therapy
PsA	Psoriatic arthritis
PUVA	Psoralens + ultraviolet A
RePUVA	Oral retinoid + PUVA
ReUVB	Acitretin + ultraviolet B
RRR	Regular rate and rhythm
SCAT	Short-contact anthralin therapy
TNF	Tumor necrosis factor
UVB	Ultraviolet B

69 Anemia

Maribel A. Pereiras

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Discuss common causes of anemia.
2. Identify common signs and symptoms of anemia.
3. Describe diagnostic evaluation required to determine the etiology of anemia.
4. Develop a treatment regimen considering the underlying cause and patient-specific variables.
5. Compare and contrast oral and parenteral iron preparations.
6. Explain the optimal use of folic acid and vitamin B_{12} in patients with macrocytic anemia.
7. Evaluate the proper use of epoetin and darbepoetin in patients with anemia caused by cancer chemotherapy or chronic kidney disease.
8. Develop a plan to monitor the outcomes of pharmacotherapy for the treatment of anemia.

INTRODUCTION

KEY CONCEPT Anemia is a deficiency of erythrocytes with a corresponding reduction in the concentration of hemoglobin (Hgb) that results in reduced oxygen-carrying capacity of the blood. Some patients with anemia may be asymptomatic initially, but eventually, the lack of oxygen to tissues results in fatigue, lethargy, shortness of breath, headache, edema, and tachycardia. Common causes include acute or chronic blood loss, decreased functional red blood cell (RBC) production, and increased RBC destruction. Determination of the underlying cause of anemia is essential for successful management.

EPIDEMIOLOGY AND ETIOLOGY

Anemia is a common diagnosis with a prevalence that varies widely based on age, gender, race/ethnicity, and geographic location (Table 69–1).[1,2] As per the World Health Organization, anemia is a serious global issue affecting up to 42% of young children (< 5 years old) and 40% of pregnant women. Patients with specific comorbidities such as cancer and chronic kidney disease (CKD) also have a significantly higher rate of anemia. The incidence of anemia in cancer patients ranges from 30% to 90%. Contributing factors include the underlying malignancy and myelosuppressive antineoplastic therapy.[3] The prevalence of anemia in patients with CKD ranges from 15% to 20% in stages 1 through 3 and up to 70% in stage 5.[4]

A decrease in erythrocyte production can be multifactorial. One common cause is nutritional deficiencies (iron, vitamin B_{12}, and folic acid) that are often easily treatable and most commonly seen in up to a third of elderly patients.[5] Women of childbearing potential are also another group that is at risk of iron deficiency anemia (IDA), given poor dietary intake or iron loss through monthly menstrual cycles. Patients with cancer or CKD generally have dysregulations in iron and erythropoietin (EPO) hemostasis leading to a risk of developing anemia. Patients with chronic immune-related diseases such as rheumatoid arthritis and systemic lupus erythematosus are also at increased risk to develop anemia as a complication of their disease. Anemia related to chronic inflammatory conditions is termed anemia of chronic disease (ACD).[5]

Drug therapy is the mainstay of treatment for anemias caused by reduced RBC production and is the focus of this chapter. Anemia due to the destruction of erythrocytes, such as with blood loss, trauma, or hemolytic anemia, will not be discussed.[6]

PATHOPHYSIOLOGY

Erythropoiesis

Erythropoiesis begins with a pluripotent stem cell in the bone marrow undergoing differentiation and ends with the appearance of RBCs in peripheral blood. The production of RBCs is stimulated by EPO, a hormone secreted by the kidney in response to cellular hypoxia. EPO stimulates RBC production by inducing differentiation of RBC precursors in the bone marrow to become **reticulocytes** (Figure 69–1). Reticulocytes become erythrocytes after 1 to 2 days in the bloodstream.[7] This process is also dependent upon a steady supply of important ingredients, iron, folic acid, and vitamin B_{12}.

Decreased Production Anemias

▶ *Nutritional Deficiencies*

Diets poor in nutritional supplements may contribute to a decrease in erythrocyte production. Socioeconomics, religious choices, or geographical location may determine dietary lifestyle choices. Diets that are low or absent in meat consumption may increase the risk of IDA, while diets that lack animal products (such as dairy or eggs) may lead to B_{12} deficiency anemia. Those with dietary restrictions should be counseled on maintaining a balanced diet and to be inclusive of foods that are rich in

Table 69–1

Prevalence of Anemia[1,2]

Children (1–5 years)	43%
Males (17–84 years)	29%
Males (85+ years)	26%
Females (15–49 years, pregnant)	38%
Females (15–49 years, nonpregnant)	29%
Females (85+ years)	20%

supplementation. If the dietary restrictions are severe, the use of supplemental products may be necessary.

Deficiencies in folic acid and vitamin B_{12} may hinder the process of erythrocyte maturation. Folic acid and vitamin B_{12} are required for the formation of DNA. Significant decreases in the amount of either folic acid or B_{12} inhibit DNA synthesis and consequently RBC production.[7,8] Poor diet can contribute to folic acid and vitamin B_{12} deficiencies. Pernicious anemia is a specific severe vitamin B_{12} anemia caused by the malabsorption of vitamin B_{12}. Normal B_{12} absorption and transport is depicted in Figure 69–2. In pernicious anemia, there is an absence of intrinsic factor, a glycoprotein produced by gastric parietal cells, which binds to vitamin B_{12} and facilitates its absorption in the ileum. This condition results in B_{12} deficiency despite adequate dietary B_{12} intake.[9] Aside from the vital role vitamin B_{12} plays in red cell and DNA production, it also serves a critical role in neurological function. Therefore, severe vitamin B_{12} anemias may also manifest neurological dysfunction.

Iron is also essential for RBC production. It is required in the nucleus formation of the iron-porphyrin heme ring, along with globin chains, which creates hemoglobin. Lack of iron leads to a decrease in Hgb synthesis and decreased RBC production. Normal homeostasis of iron transport and metabolism is depicted in Figure 69–3.[10] Approximately 1 to 2 mg of iron is absorbed through the duodenum daily, and the same amount is lost via blood loss, desquamation of mucosal cells, or menstruation. Daily iron requirements also increase during growth and pregnancy.

IDA typically occurs because of inadequate absorption of iron or excessive blood loss. Inadequate absorption may occur in patients who have congenital or acquired intestinal conditions, such as inflammatory bowel disease, celiac disease, or bowel resection. Achlorhydria and diets poor in iron may also contribute to iron-deficient states. Iron deficiency may also occur following excessive iron loss. Common etiologies include excessive menstruation, ulcers, neoplastic lesions, and excessive bleeding following surgery or trauma.[10,11]

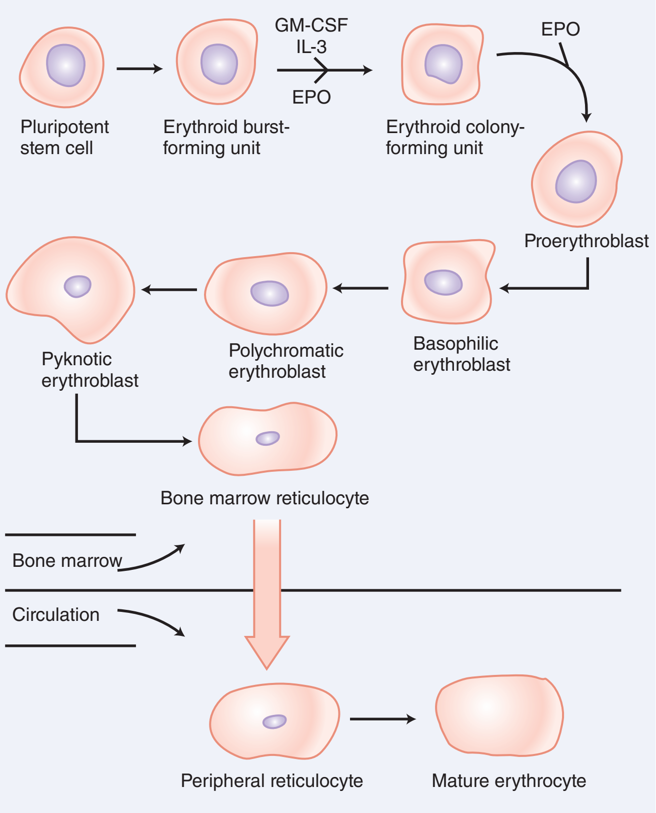

FIGURE 69–1. The process of erythropoiesis.

▶ *Dysregulation of Iron Homeostasis and Impaired Marrow Production*

Chronic diseases associated with ACD include infection, autoimmune disease, CKD, and cancer. A major contributing factor for the development of ACD is disturbance of iron homeostasis related to the activation of the immune system. Hepcidin is an acute-phase protein expressed in response to the upregulation of inflammatory cytokines. Increased expression of hepcidin causes decreased iron absorption from the gastrointestinal (GI) tract and inhibition of iron release from macrophages. In addition, immune activation can cause upregulation of cytokines that impair the proliferation and differentiation of erythroid precursors. Decreased production and blunted responsiveness to EPO can also contribute to ACD; this is best documented in patients with CKD. Finally, disruption of erythropoiesis secondary to infiltration of the bone marrow by cancer can lead to anemia.[3,5,10-12]

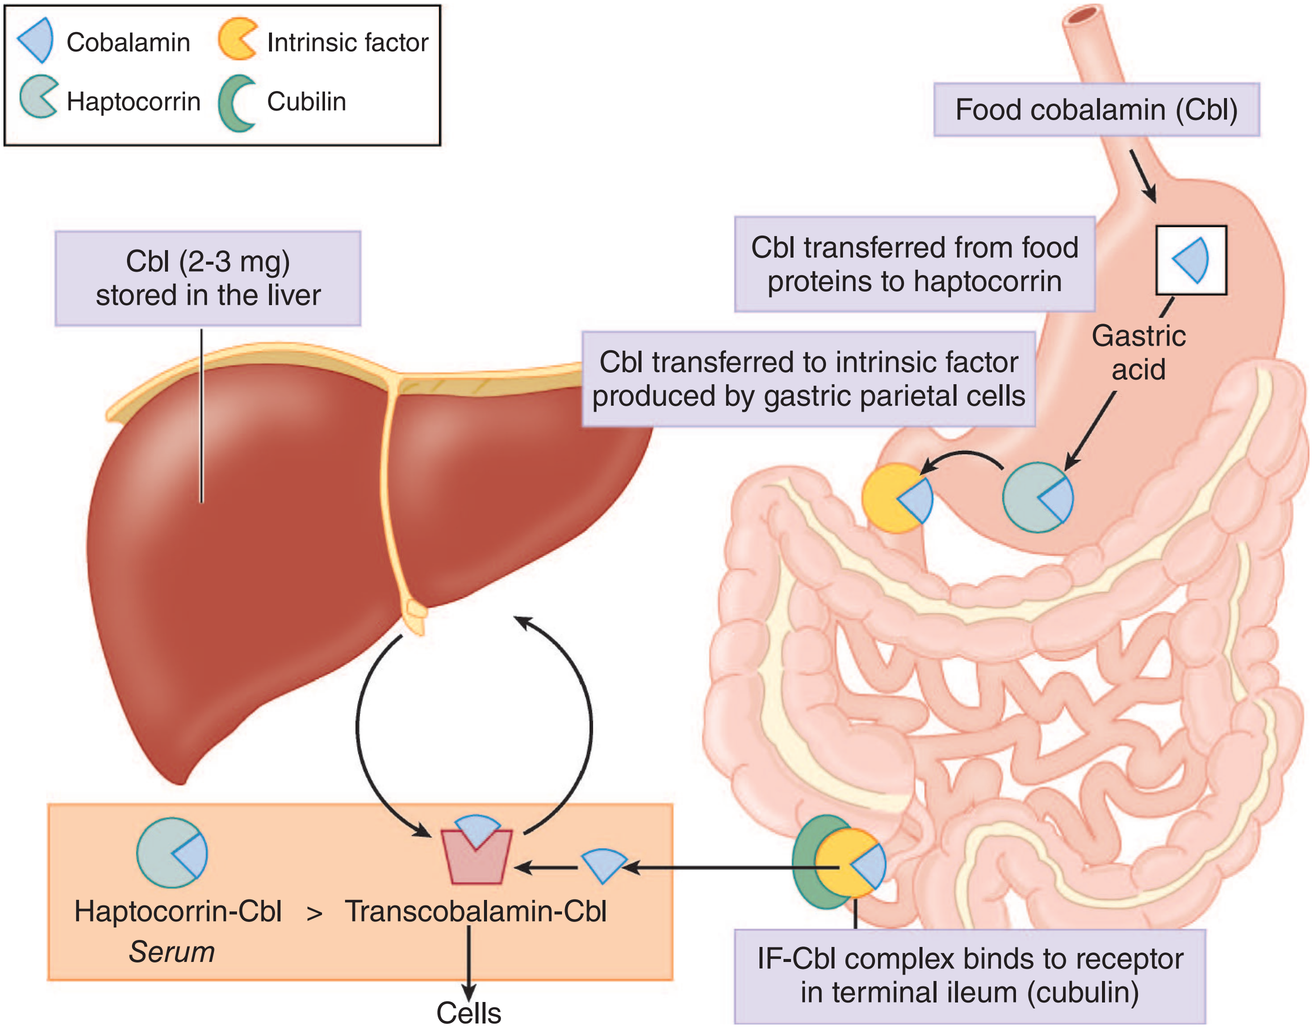
TREATMENT

Desired Outcomes

KEY CONCEPT The goal of anemia therapy is to increase Hgb to levels that improve red cell oxygen-carrying capacity, alleviate symptoms, and prevent complications from anemia. Normal Hgb values are 14.0 to 17.5 g/dL (140–175 g/L or 8.69–10.9 mmol/L) for males and 12.3 to 15.3 g/dL (123–153 g/L or 7.63–9.50 mmol/L) for females. It is important to note that continuation of therapy should be assessed primarily by the resolution of clinical symptoms. Patients who experience a resolution in their symptoms (eg, shortness of breath, tachycardia, fatigue, dizziness) may not require aggressive therapy to maintain their Hgb values within normal limits. Hypoxia and cardiovascular sequelae due to anemia can be avoided if Hgb levels are greater than 7.0 g/dL (70 g/L or 4.34 mmol/L).[11] In patients with acute coronary syndrome, consideration for transfusions can be given when Hgb levels are 8 g/dL (80 g/L or 4.96 mmol/L) or less.[44]

General Approach to the Anemic Patient

KEY CONCEPT The underlying cause of anemia must be determined and used to guide therapy. A complete blood count (CBC) is the laboratory evaluation that provides objective RBC characteristics useful in determining etiology and appropriate treatment. The mean corpuscular volume and determination of iron, ferritin, folate, and vitamin B_{12} levels are required to correctly diagnose a patient's anemia. Figure 69–4 and Table 69–2 illustrate how laboratory test results determine the correct diagnosis.



Cobalamin
Intrinsic factor
Haptocorrin
Cubilin
Food cobalamin (Cbl)
Cbl (2-3 mg) stored in the liver
Cbl transferred from food proteins to haptocorrin
Gastric acid
Cbl transferred to intrinsic factor produced by gastric parietal cells
Haptocorrin-Cbl > Transcobalamin-Cbl
Serum
Cells
IF-Cbl complex binds to receptor in terminal ileum (cubulin)

Clinical Presentation and Diagnosis of Anemia

Signs and Symptoms

Generally, the signs and symptoms of anemia are nonspecific and may include the following:

- Fatigue, lethargy, dizziness
- Shortness of breath
- Headache
- Edema
- Tachycardia

Other findings that may be present in some patients include the following:

- Dry skin, chapped lips
- Nail brittleness or spoon-shaped nails
- Hunger for ice, starch, or clay (termed **pica**)
- Cognitive impairment, gait abnormalities, irritability, peripheral neuropathy (vitamin B_{12} anemia)

Medical History

Inquire about the following conditions:

- History of blood loss, such as hemorrhoids, melena, or menorrhagia (IDA)
- Dietary habits (vegan/vegetarian), malnourishment, or recent weight loss (vitamin B_{12} or folate deficiency)
- Recent GI surgeries (gastric bypass) (vitamin B_{12} or folate deficiency)
- Alcoholism (folate deficiency)
- Cancer or CKD

(*Continued*)

Clinical Presentation and Diagnosis of Anemia (Continued)

- Chronic autoimmune disorders or infections, such as HIV infection or rheumatoid arthritis (anemia of chronic disease)

Physical Examination

These findings aid the clinician in determining the severity of the anemia:

- Orthostatic hypotension and tachycardia secondary to volume depletion
- Cutaneous changes such as pallor, jaundice, and nail brittleness

Laboratory Evaluation

Table 69–2 describes common tests used to determine the etiology of anemia. A diagnostic and treatment algorithm for anemia is outlined in Figure 69–4.

1. A CBC is a necessary first step in evaluating a patient with anemia. If the Hgb and Hct are less than the normal range, the patient is anemic. Subsequent evaluations of RBC indices and the peripheral smear often are necessary to determine the etiology (and ultimately, the treatment) of the anemia.
2. Evaluating the mean corpuscular volume (MCV) is the next step in an anemia workup. It is classified as microcytic, normocytic, or macrocytic if the MCV is below, within, or above the normal range of 80 to 96 fL/cell, respectively.

Microcytic Anemia and Iron Evaluation

Iron studies (see Table 69–2) should be evaluated in the setting of a low MCV. These include the following:

- Serum iron
- Serum **ferritin**—the best indirect determinant of body iron stores. It is commonly decreased in patients with IDA
- Total iron-binding capacity (TIBC)—quantifies the iron-binding capacity of transferrin and is increased in IDA
- **Transferrin saturation** (serum iron/TIBC)—indicates the amount of transferrin that is bound with iron; it is lower in IDA

Macrocytic Anemia

- Evaluate folic acid and vitamin B_{12} levels in the setting of an elevated MCV
- Further investigation such as administering radiolabeled B_{12} (ie, Schilling test) to determine if there is a lack of intrinsic factor or use of intrinsic factor antibodies

Normocytic Anemia

- Evaluate reticulocytes and CBC
- High reticulocyte counts may indicate RBC loss via acute blood loss, hemolysis, or splenic sequestration
- Low serum iron with normal to increased ferritin consistent with ACD

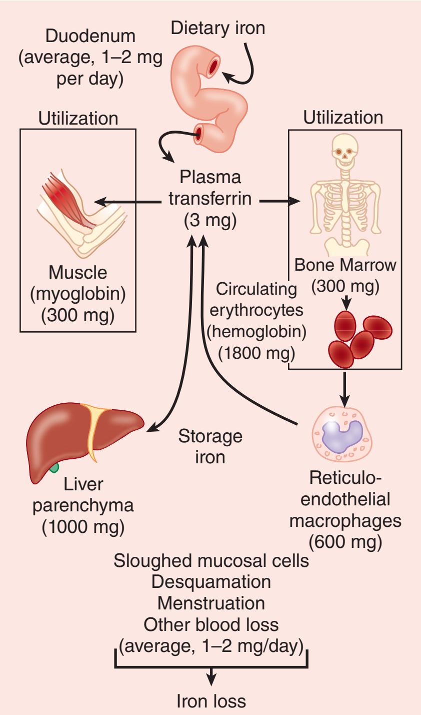

FIGURE 69–3. The distribution of iron use in adults. (From Andrews N. Disorders of iron metabolism. N Engl J Med. 1999;341(26): 1986–1995.)

Nonpharmacologic Therapy

The primary nonpharmacologic treatment of anemia is transfusion of RBCs. Safety concerns, cost, and the limited availability of this therapy support efforts to establish the "optimum" threshold for administering RBC transfusions. A Cochrane review concluded it is appropriate to use "restrictive transfusion triggers in patients free of serious cardiac disease." The authors concluded a reasonable "trigger for transfusion" for patients without significant cardiovascular disease is 7.0 g/dL (70 g/L or 4.34 mmol/L).[13] The Transfusion Requirements In Critical Care trial reported no significant differences in hospital mortality between patients randomly assigned to maintain Hgb levels of 7.0 to 9.0 g/dL (70–90 g/L or 4.34–5.59 mmol/L) and 10.0 to 12.0 g/dL (100–120 g/L or 6.21–7.45 mmol/L).[14] Typically, only patients with acute symptoms (ie, dyspnea, chest pain) and Hgb concentrations in the range of 7.0 to 9.0 g/dL (70–90 g/L or 4.34–5.59 mmol/L) require blood transfusions.

Anemia can be attributed to diets poor in iron, folic acid, or vitamin B_{12}. However, in the United States, nutrient-poor diets rarely cause anemia. Therefore, ingesting a diet that is rich in iron, folic acid, or vitamin B_{12} should be encouraged but is rarely the sole modality of treatment. Food sources of iron, folic acid, and vitamin B_{12} are listed in Table 69–3.

Pharmacologic Therapy

▶ *Iron Deficiency Anemia*

KEY CONCEPT The gold standard treatment of IDA is oral iron therapy that provides 150 to 200 mg of elemental iron daily in

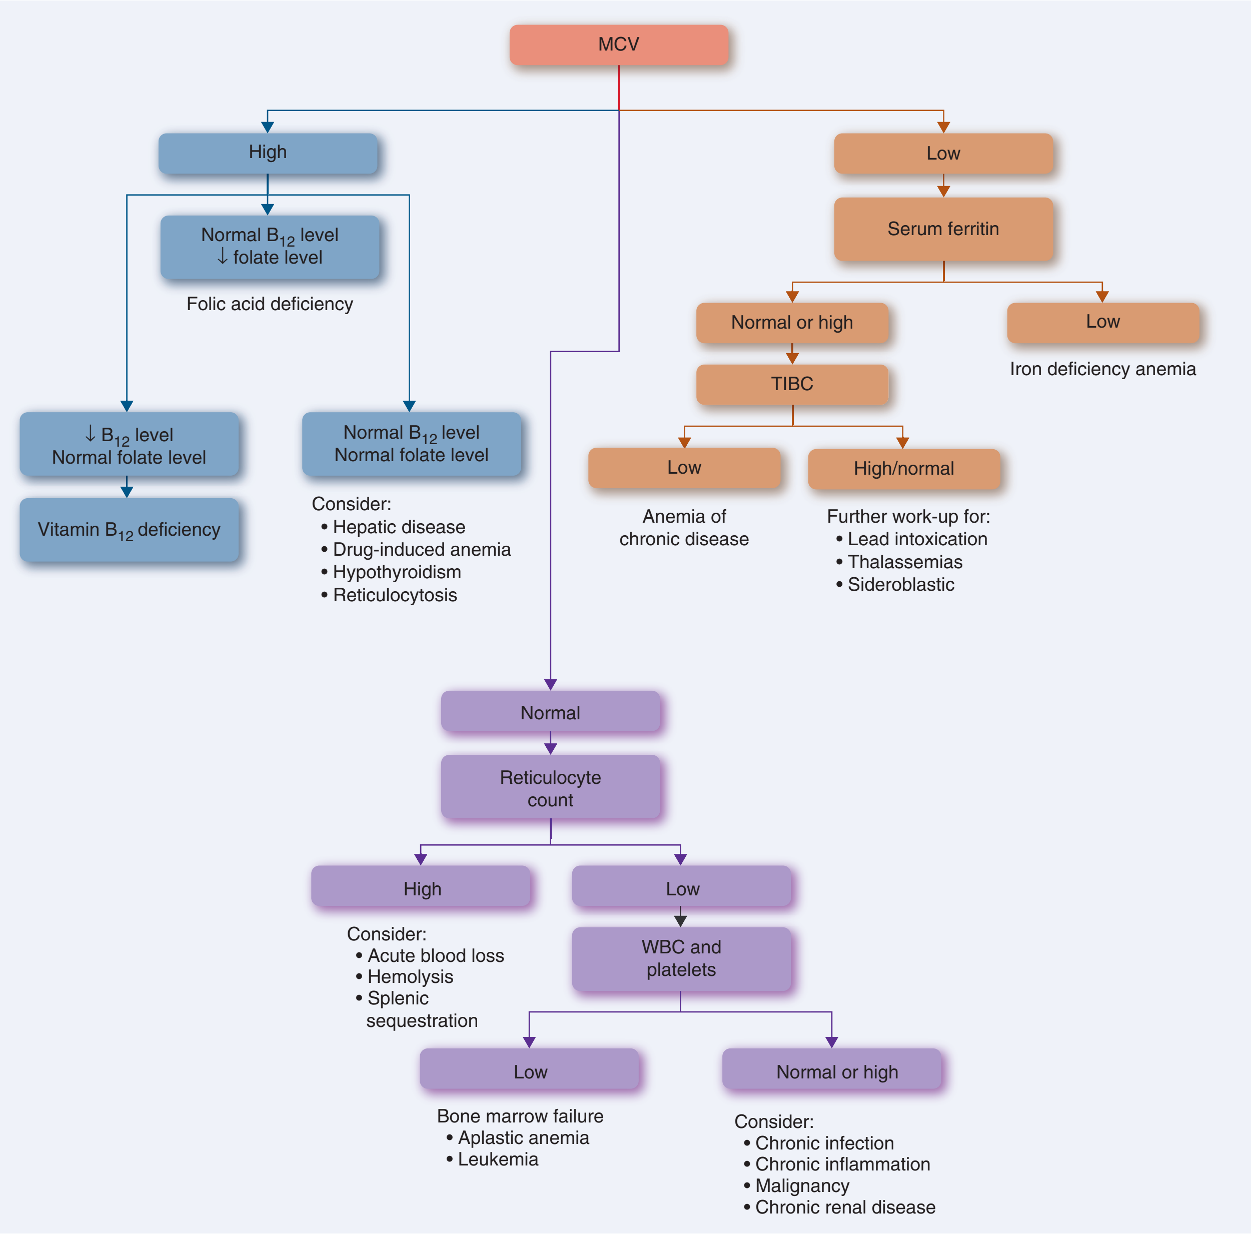
Patient Encounter 1, Part 1

A 58-year-old man was admitted to the emergency department. His wife found him at home passed out on the floor with several beer cans around him. According to his wife, he had been suffering from depression for being laid off from work during the COVID pandemic and had taken up drinking. For the last 2 months, she estimates he drank anywhere from 3 to 5 cans of beer a day with more on the weekends. She reported him as moody and even on his "good days" noted him to be weak, tired, and stumbling about as he walked. He has a medical history of hypertension, diabetes, and he is on several medications. Surgical history includes gastric bypass surgery, 6 years ago. Upon physical exam, he appears pale and is found to be tachycardic and dyspneic.

What aspects of this patient's history suggest he may be anemic?

What laboratory assessments are needed to make a diagnosis and therapeutic plan?

How would the requested laboratory parameter(s) aid your decision-making?



MCV

Table 69–2

Pertinent Laboratory Tests in the Evaluation of Anemia

Test Name	Normal Range	Description/Significance
CBC		
Hgb	Males: 14.0–17.5 g/dL (140–175 g/L or 8.69–10.9 mmol/L) Females: 12.3–15.3 g/dL (123–153 g/L or 7.63–9.50 mmol/L)	Amount of Hgb in the blood; signifies oxygen-carrying capacity of the blood and determines whether a patient is anemic
Hct	Males: 40.7%–50.3% (0.407–0.503) Females: 36.1%–44.3% (0.361–0.44.3)	The percent of blood that the erythrocytes encompass; also indicates anemia; the Hgb is measured, and the Hct is calculated
RBC	Males: $4.5–5.9 \times 10^6$ cells/μL ($4.5–5.9 \times 10^{12}$ cells/L) Females: $4.1–5.1 \times 10^6$ cells/μL ($4.1–5.1 \times 10^{12}$ cells/L)	The number of erythrocytes in a volume of blood; also indicates anemia, but seldom used
RBC Indices		
MCV	80–97.6 μm^3/cell (80–97.6 fL/cell)	A widely used laboratory value to measure RBC "size"; higher values indicate **macrocytosis** and lower values indicate **microcytosis**
MCH	27–33 pg/cell	Amount of Hgb per RBC; may be decreased in IDA
MCHC	32–36 g/dL (320–360 g/L)	Hgb divided by the Hct; also low in IDA
Iron Studies		
Serum iron		
Males	45–160 mcg/dL (8.1–28.6 μmol/L)	Measures amount of iron bound to transferrin; low in IDA
Females	30–160 mcg/dL (5.4–28.6 μmol/L)	
Serum ferritin		
Males	20–250 ng/mL (20–250 mcg/L; 45–562 pmol/L)	Ferritin is the protein–iron complex found in macrophages used for iron storage; low in IDA
Females	10–150 ng/mL (10–150 mcg/L; 22–337 pmol/L)	
TIBC	220–420 mcg/dL (39.4–75.2 μmol/L)	Measures the capacity of transferrin to bind iron; high in IDA
TSAT	15%–50% (0.15–0.50)	TSAT (%) = (serum iron/TIBC) × 100; a saturation of less than 15% (0.15) is common in IDA
Other Tests		
RBC distribution width (RDW)	11.5%–14.5% (0.115–0.145)	A higher value means the presence of many different sizes of RBCs; the MCV is therefore less reliable when RDW is larger
Reticulocyte count (erythrocyte precursors)		Should be elevated in patients who are responding to treatment
Males	0.5%–1.5% of RBCs (0.005–0.015)	
Females	0.5%–2.5% of RBCs (0.005–0.025)	
Folic acid (plasma)	3.1–12.4 ng/mL or mcg/L (7.0–28.1 nmol/L)	Used to determine folic acid deficiency
Folic acid (RBC)	125–600 ng/mL (283–1360 nmol/L)	Used to determine folic acid deficiency
Vitamin B_{12}	180–1000 pg/mL (133–738 pmol/L)	Used to determine vitamin B_{12} deficiency
EPO level	2–25 mIU/mL (2–25 IU/L)	Patients may benefit from EPO therapy if they are anemic, and EPO levels are normal or mildly elevated

EPO, erythropoietin; Hct, hematocrit; Hgb, hemoglobin; IDA, iron deficiency anemia; MCH, mean cell hemoglobin; MCHC, mean cell hemoglobin concentration; MCV, mean cell volume; RDW, RBC distribution width; TIBC, total iron-binding capacity; TSAT, transferrin saturation.

Table 69–3

Food Sources of Iron, Vitamin B_{12}, or Folic Acid[41-43]

Nutrient	Food Sources
Iron	Red meat, organ meats, seafood, wheat germ, egg yolks, white beans, lentils, kidney beans, nuts and dried fruit, fortified cereals/breads
Vitamin B_{12}	Eggs, milk, yogurt, fish/seafood, poultry, meat, fortified cereals
Folic acid	Dark green vegetables (spinach, asparagus, brussels sprouts, broccoli), liver, peanuts, beans (kidney beans), fruits, fortified cereals, chickpeas, enriched pasta/breads/rice

divided doses. Many different iron products and salt forms are available. Typically, iron sulfate is the most commonly used formulation. Table 69–4 lists commonly prescribed oral iron products and the amount of elemental iron provided by each.

Iron supplementation resolves anemia by replenishing iron stores to levels necessary for RBC production and maturation. After absorption, iron binds to transferrin in the plasma and is transported to the muscles (for myoglobin), liver (for storage), or bone marrow (for red cell production). Reticulocytosis should occur in 7 to 10 days, and Hgb values should rise by about 1.0 g/dL (10 g/L or 0.62 mmol/L) per week. Patients should be reassessed if Hgb does not increase by 2.0 g/dL (20 g/L or 1.24 mmol/L) in 3 weeks.[15]

The preferred regimen for oral iron is 50 to 65 mg of elemental iron, two to three doses daily on an empty stomach.

Table 69–4

Oral Iron Products and Elemental Iron Content[37-40]

Salt Form	Brand Name(s)	Percent of Elemental Iron	Formulation Types
Ferrous sulfate	FeroSul Fer-In-Sol Slow Fe	~20	Elixir, liquid, solution Tablet—slow and extended release
Ferrous sulfate, anhydrous	N/A	~30	Tablet
Ferrous gluconate	Ferate	~12	Tablets
Ferrous fumarate	Ferretts Ferrimin Hemocyte	33	Tablets
Polysaccharide–iron complex	Niferex Ferrex NovaFerrum	Dose expressed as elemental iron	Liquid Capsule

Patient Encounter 1, Part 2

Laboratory parameters are ordered, and the following is reported

CBC

- WBC: 8.70×10^3/μL (8.70×10^9/L)
- Hgb: 8.3 g/dL (83 g/L; 5.15 mmol/L)
- Hct: 24.8% (0.248)
- Plt: 135×10^3/μL (135×10^9/L)

Red Blood Cell Indices

- MCV: 120.4 μm^3 (120.4 fL)
- MCH: 28.4 pg/cell
- MCHC: 35.3 g/dL (353 g/L; 21.9 mmol/L)

Others

- RBC count: 3.9×10^6/μL (3.9×10^{12}/L)
- RDW: 22% (0.22)

Iron Studies

- Serum iron: 100 mcg/dL (17.9 μmol/L)
- Serum ferritin: 123 ng/L (123 mcg/L; 276 pmol/L)
- TIBC: 300 mcg/dL (53.7 μmol/L)
- Transferrin saturation: 36% (0.36)

B$_{12}$ and Folate

- Serum folate: 4.3 ng/mL (9.77 nmol/L)
- Serum B$_{12}$: 106 pg/mL (78.201 pmol/L)

Is this a macrocytic or microcytic anemia?

Specifically, what is the etiology of the anemia?

Recommend the most appropriate drug regimen (drug, dosage form, and schedule).

Administration on an empty stomach (1 hour before or 2 hours after a meal) is preferred for maximal absorption. If patients develop intolerable GI side effects (ie, heartburn, nausea, bloating) after taking iron on an empty stomach, they should be advised to take it with meals. Enteric coated iron supplements are also available that may help with tolerability. However, the use of food intake or enteric coated products does decrease absorption. Some data suggests that coadministration of vitamin C may improve oral absorption although there is little evidence to support this.[27] New data is emerging regarding the optimal dosing schema for iron supplementation based on additional information regarding iron absorption and the effect on hepcidin. A study by Motretti and colleagues suggests that lower doses and less frequent dosing may improve the amount of iron absorbed. This data requires further evaluation but may offer a more convenient dosing schedule while minimizing side effects.[17,18] Common toxicities associated with oral iron include abdominal pain, nausea, heartburn, constipation, and dark stools.[16]

Potentially clinically significant drug–drug interactions involving iron products include fluoroquinolones, tetracyclines, eltrombopag, and mycophenolate mofetil. Iron decreases the absorption of these drugs. The absorption of iron is influenced by gastric acidity. Limited data supports drugs that decrease gastric acidity (antacids, proton pump inhibitors, and H2-receptor antagonists) may impair the absorption of iron. If concurrent administration cannot be avoided, to minimize this interaction, oral iron should be administered at least several hours before or after the affected drug. The absorption can also be affected by certain disease states that may limit the absorption, such as celiac disease, inflammatory bowel disease, or patients who have had gastric surgeries.[11]

Parenteral iron therapy is indicated when patients cannot tolerate oral formulations, have decreased intestinal absorption, or are noncompliant. Five parenteral iron formulations are available in the United States.[19-24] Table 69–5[20-24] provides details pertinent to the use of these products. Iron dextran (ID) was available in two formulations, as a high- and low-molecular-weight iron product. Dexferrum (the high-molecular-weight [HMW] product) is associated with a much higher incidence of life-threatening adverse effects, typically anaphylactic-like reactions, and this formulation has been discontinued.[25] Although total dose infusion (TDI), where the total replacement dose of iron administered in one dose is not an approved method of administration in the United States, low-molecular-weight ID is approved for TDI in Europe. TDI administration achieves similar patient outcomes while lowering costs. Sodium ferric gluconate complex, iron sucrose, ferumoxytol, and ferric carboxymaltose received FDA labeling for the treatment of patients with anemia and CKD in the last decade.[19-24] Although the occurrence of life-threatening adverse events caused by parenteral iron is extremely low, the absolute rate of life-threatening events is substantially higher for HMW ID.[21]

The dose of iron dextran is calculated by the following equation: dose (mL) = 0.0442 (desired Hgb − observed Hgb) × body weight + (0.26 × body weight). The body weight that should be used is lean body weight for adults and children weighing more than 15 kg and actual body weight for children weighing 5 to 15 kg. Hemoglobin should be expressed in units of g/dL (hemoglobin expressed in g/L × 0.10, or mmol/L × 1.61). The dose in milligrams can be calculated based on a standard concentration of 50 mg of elemental iron per milliliter.[19] Prescribing information recommends administering iron dextran in 100-mg aliquots daily until the total dose is achieved. However, anecdotal evidence reports that the total calculated dose can be administered safely over 4 to 6 hours on 1 day. Because of the risk of anaphylaxis, a

Data from Auerbach M, Adamson JW. How we diagnose and treat iron deficiency anemia. Am J Hematol. 2016; 91:31–38.

test dose of iron dextran (0.5 mL over at least 30 seconds) must be administered to patients before their first dose of iron dextran. Patients should be monitored for signs of anaphylaxis for at least 1 hour before administering the remaining total dose. Other adverse effects include arthralgias, arrhythmias, hypotension, flushing, and pruritus.[19]

▸ *Vitamin B_{12} and Folic Acid Anemia*

KEY CONCEPT Anemia caused by vitamin B_{12} deficiency (also known as pernicious anemia) or folic acid deficiency is treated by replacing the missing nutrient. Both folic acid and vitamin B_{12} are essential for erythrocyte production and maturation.

Oral and parenteral vitamin B_{12} (cyanocobalamin) replacement therapies are equally effective in patients able to absorb B_{12}. Vitamin B_{12} is absorbed completely following parenteral administration, whereas oral vitamin B_{12} is absorbed poorly via the GI tract and primarily within the terminal ileum. Consequently, cyanocobalamin is commonly administered as an intramuscular injection of 1000 mcg/day for 1 week, followed by 1000 mcg/week for a month or until the Hgb normalizes. Lifelong maintenance therapy (1000 mcg/month IM) is required for patients with pernicious anemia. An alternative maintenance regimen for pernicious anemia is oral cyanocobalamin (1000–2000 mcg/day); however, level of cobalamin must be monitored frequently to ensure adequate absorption. In patients with severe neurological signs or CNS symptoms, oral therapy is not recommended. If the etiology was a dietary deficiency or reversible malabsorption syndrome, oral therapy may be utilized, and treatment can be discontinued after the underlying cause is corrected and vitamin B_{12} stores normalized. A common oral dosing regimen is from 1000 to 2000 mcg/day. If parenteral cyanocobalamin is used initially, oral vitamin B_{12} can be useful as maintenance therapy. Typically, resolution of neurologic symptoms, disappearance of megaloblastic RBCs, and increased Hgb levels occur within a week of therapy.[26] Vitamin B_{12} is well tolerated and reported adverse effects include injection-site pain, pruritus, and rash.[27]

Patient Encounter 1, Part 3

The patient is diagnosed with vitamin B_{12} deficiency anemia and is started on parenteral cyanocobalamin for 1 month followed by 1000 mcg of oral cobalamin taken daily. He is also encouraged to improve his nutritional intake, take steps to stop drinking, and recommended to a behavioral health center for more support. At his first weekly visit, he reports enrolling in the behavioral program and a new sense of "direction." A follow-up CBC a month later reveals an Hgb of 10 g/dL (100 g/L or 6.2 mmol/L), previously 8.3 g/dL (83 g/L or 5.15 mmol/L). He states he has noticed improvement in mood and has more energy. He is also making better choices in his dietary habits. Upon occasion, he will miss "a dose or two," given his other medications he also must remember to take.

What hemoglobin level would constitute a therapeutic response in this patient?

How can compliance be improved in this patient?

The effective dose of folic acid is 1 mg/day by mouth. Absorption of folic acid is rapid and complete. However, patients with malabsorption syndromes or short gut syndrome may require doses up to 5 mg/day and longer therapy durations. Reticulocytosis occurs within days of commencing therapy. Typically, a patient's Hgb will start to rise after 2 weeks of therapy and normalize after 2 to 4 months of therapy. Folic acid is well tolerated. Nonspecific adverse effects include allergic reactions, flushing, and rash.

▸ *Anemia of Chronic Disease*

KEY CONCEPT Decreased RBC transfusion requirements are a goal of therapy in patients with ACD treated with the EPO-stimulating agent (ESAs). However, in 2007, the FDA product labeling for epoetin and darbepoetin was revised to include new data documenting safety concerns. Subsequently, the Centers for Medicare and Medicaid Services (CMS) implemented more restrictive ESA coverage determination guidelines. In 2010, the FDA implemented a risk evaluation and mitigation strategy (REMS) for ESAs administered to treat patients with cancer who are undergoing chemotherapy, but in 2017, the FDA decided the REMS program was no longer needed.[28] Table 69–6 summarizes the FDA-labeled dosing regimens for patients whose anemia of

Table 69–6

ESA Products and Usual Doses for Anemia from Cancer/Chemotherapy, CKD, and Zidovudine/HIV Infection in Adult Patients[a]

	Type of ESA	Biosimilar Available	Cancer/Chemotherapy Dosing Regimens	CKD Dosing Regimens	Zidovudine/HIV Dosing Regimen[d]
Epoetin-α (Epogen, Procrit, or biosimilar)	First generation	Yes	150 U/kg SC three times per week 40,000 units SC once every week	50–100 U/kg SC or IV three times per week	100 U/kg IV or SC three times per week
Darbepoetin-α (Aranesp or biosimilar)	Second generation	No	2.25 mcg/kg SC once every week 500 mcg SC fixed dose every 3 weeks	0.45 mcg/kg SC or IV once every week[b] 0.75 mcg/kg SC or IV once every 2 weeks[b] 0.45 mcg/kg SC or IV once every 4 weeks[c]	Not recommended
Methoxy polyethylene glycol–epoetin beta (Mircera)	Third generation, continuous ESA	No	NA	Not on prior ESA therapy: 0.6 mcg/kg SC or IV every 2 weeks. One hemoglobin stable may give monthly with a dose that is double the dose given every 2 weeks[e,f]	NA

[a] Indications and dosage regimens per FDA product labeling.

[b] For patients on dialysis.

[c] For patients not on dialysis.

[d] FDA-labeled indication for Procrit (epoetin-α), not Epogen (epoetin-α) or darbepoetin.

[e] IV is preferred for those on hemodialysis.

[f] For patients on ESA therapy, there is conversion dosing based on the total weekly epoetin alfa dose, prefer to product package insert for details.

chronic disease is related to cancer chemotherapy, CKD, or zidovudine treatment.

Epoetin, a recombinant human EPO, binds to the EPO receptors on RBC precursor cells in the bone marrow and results in increased RBC production. Darbepoetin, a synthetic EPO analog, differs from epoetin in that it is a glycosylated protein and exhibits a longer half-life, allowing for a longer dosing interval. Clinical practice guidelines consider epoetin and darbepoetin to be therapeutic equivalents.[3,29] KEY CONCEPT ESAs should only be used to prevent a transfusion and should not be initiated unless the hemoglobin is less than 10.0 g/dL (100 g/L, 6.21 mmol/L), and chemotherapy is planned for a minimum of 2 additional months. Over the last few years, a biosimilar agent for the reference product of epoetin has been developed. A biosimilar is a biological product that has been approved based on data demonstrating that it is highly similar to an FDA-approved biological product, known as the reference product, and that there are no clinically meaningful differences between the biosimilar and the reference product.[47] The biosimilar, epoetin alfa-epbx, utilizes the same dosing, schedules and indications as the reference product; however, it has not been deemed interchangeable. ESA-labeled dosing regimens for treatment of patients receiving chemotherapy are summarized in Table 69–6.

Within the ESA therapeutic category, there also exists a continuous EPO receptor activator (CERA). Methoxy polyethylene glycol–epoetin beta is a novel third-generation pegylated epoetin beta (PEG–EPO) product. This product has the longest half-life of the ESAs. It is estimated to last 6 times longer than darbepoetin alfa and up to 20 times longer than epoetin. However, this medication is only indicated for use in patients with chronic kidney disease.

Anemia Due to Chemotherapy in Patients with Cancer Postmarketing outcome data documented that cancer patients administered ESAs had an increased risk of thrombotic events, shorter progression-free and overall survival.[30] ESAs increased mortality of patients while on a study (combined hazard ratio [cHR] 1.17; 95% confidence interval [CI] 1.06–1.30) and worsened overall survival (cHR 1.06; 95% CI 1.00–1.12). This corresponds to a 17% increased risk of mortality for patients treated with ESAs and a 6% increase of mortality overall. Based on these data, the FDA revised ESA product labeling, restricting their administration to patients with chemotherapy-induced anemia without curative

Patient Encounter 2, Part 1

A 34-year-old woman presents to her obstetrician for her prenatal visit. She is 16 weeks pregnant and her children at home are 2 and 4 years old. She has been fatigued for the last 2 months and feels it has been from caring for her two children and working part-time. Her food habits have been irregular, as she had severe morning sickness up until recently. She has also developed a fondness for sucking on ice chips. Her physical examination is notable for pallor and pale conjunctiva. Medical history is negative.

What aspects of this patient's history suggest she may be anemic?

What laboratory assessments are required to make an appropriate diagnosis and therapeutic plan?

Patient Encounter 2, Part 2

Laboratory results:

CBC

- WBC: 5.7 × 10^3/mm^3 (5.7 × 109/L)
- Hgb: 6.7 g/dL (67 g/L; 4.16 mmol/L)
- Hct: 20.8% (0.208)
- Plt: 210 × 103/µL (210 × 109/L)

Red Blood Cell Indices

- MCV: 71 µm^3 (71 fL)
- MCH: 23 pg/cell
- MCHC: 28.3 g/dL (283 g/L; 17.6 mmol/L)

Iron Studies

- Serum iron: 27 mcg/dL (4.8 µmol/L)
- Serum ferritin: 6.9 ng/mL (6.9 mcg/L; 16 pmol/L)
- TIBC: 459 mcg/dL (82.2 µmol/L)
- Transferrin saturation: 11% (0.11)

B$_{12}$ and Folate

- Serum B$_{12}$: 657 pg/mL (484.86 pmol/L)
- Serum folate: 10 ng/mL (22.7 nmol/L)

Is this a macrocytic or microcytic anemia?

Specifically, what is the etiology of the anemia?

Recommend the most appropriate drug regimen (drug, dosage form, and schedule).

intent. The 2019 update of the joint American Society of Clinical Oncology/American Society of Hematology clinical practice guideline on the use of ESAs in patients with cancer adopted FDA recommendations for more restrictive use of ESA in patients with cancer.[29]

In 2008, CMS published more restrictive coverage criteria for ESA treatment of chemotherapy-associated anemia. Patients should be monitored every 4 weeks. If Hgb has not increased by 1.0 g/dL (10 g/L, 0.62 mmol/L) after 4 weeks and remains less than 10.0 g/dL (100 g/L, 6.21 mmol/L), a one-time dose escalation of 25% is appropriate. If Hgb increases by more than 1.0 g/dL (10 g/L, 0.62 mmol/L), or is more than 10.0 g/dL (100 g/L, 6.21 mmol/L), the ESA should be discontinued. At 8 weeks if Hgb has increased by 1 g/dL (10 g/L, 0.62 mmol/L) but remains less than 10.0 g/dL (100 g/L, 6.21 mmol/L), continued ESA administration is covered. However, if after 8 weeks Hgb fails to increase by 1 g/dL (10 g/L, 0.62 mmol/L), CMS payment of therapy is not covered. CMS covers ESA therapy for up to 8 weeks after the completion of chemotherapy for patients achieving responses.[3,31]

Patient Encounter 2, Part 3

The patient is diagnosed with iron deficiency anemia (IDA) and is started on ferrous sulfate 325 mg po three times daily to be taken on an empty stomach. A follow-up CBC 1 month later reveals an Hgb of 7.8 g/dL (78 g/L; 4.84 mmol/L), previously 6.7 g/dL (67 g/L; 4.16 mmol/L). She reports a slight improvement in mood and more energy. She no longer craves the ice chips as intensely as before. However, she struggles to be compliant and has developed constipation.

What hemoglobin level would constitute a therapeutic response in this patient?

What recommendation(s) would you make regarding the compliance to help with constipation?

"Functional" iron deficiency exists when total iron stores are normal or increased, but disruption of iron homeostasis prevents utilization of the stored iron for erythropoiesis. "Functional" iron deficiency has been described in patients with ACD. Therefore, it is imperative that patients starting ESA therapy have laboratory studies performed to assess iron stores. If results document that a patient has suboptimal iron stores, iron replacement therapy is indicated prior to initiation of ESA therapy. In addition, a workup to assess for rationales for iron deficiency should be explored. The updated 2019 ASCO/ASH guidelines also state that iron supplementation may be used to help improve ESA response in patients with chemotherapy-associated anemia without iron deficiency.[29]

Anemia Due to CKD Anemia is common in patients with CKD. Early treatment of anemia in patients with CKD on dialysis has been associated with slower disease progression and lower risk of death. It is essential to evaluate and treat anemia in patients before they progress to stage 5 CKD (glomerular filtration rate [GFR] less than 15 mL/min/1.73 m^2 [0.14 mL/s/m^2]).[32]

Patients with CKD typically develop normocytic, normochromic anemia as a result of EPO deficiency. However, a thorough workup of anemia should be performed to rule out other etiologies.[32] The 2012 KDIGO Clinical Practice Guideline for Anemia in Chronic Kidney Disease recommends that ESA therapy be started when the hemoglobin is between 9.0 and 10.0 g/dL (90–100 g/L) in dialysis patients. For those CKD patients not on dialysis, the guidelines recommend that ESAs be started when the Hgb is less than 10.0 g/dL (10 g/L) and should also be based on patient-specific scenarios—if the rate of Hgb decline predicts the need for an RBC transfusion and if a goal of therapy is to either reduce the risk of RBC transfusion–related risks or reduce the chance of alloimmunization.[32,33] This dosing strategy was adopted to decrease the risk of serious adverse cardiovascular events. ESA-labeled dosing regimens for patients with CKD are summarized in Table 69–6.[34-36]

Although EPO deficiency is the primary cause of CKD anemia, iron deficiency may also exist. Iron stores in patients with CKD should be maintained so that transferrin saturation is greater than 20% (0.20) and serum ferritin is greater than 100 ng/mL (100 mcg/L or 225 pmol/L). If iron stores are not maintained appropriately, epoetin, darbepoetin, or methoxy polyethylene glycol–epoetin beta will not be effective. Most CKD patients will require iron supplementation.[32]

Anemia Due to Zidovudine in HIV-Infected Patients Early clinical trials evaluating the efficacy of zidovudine in patients with HIV documented that nearly 50% of patients treated with zidovudine developed anemia requiring RBC transfusions. Subsequently, results from numerous clinical trials reported that epoetin resulted in statistically significant decreases in transfusion requirements for patients with HIV who have serum EPO levels less than 500 mU/mL (500 U/L). Currently, epoetin has a labeled indication for the treatment of anemia in patients with EPO levels

Patient Care Process

Collect Information:

- Review the medical and surgical history in conjunction with any physical assessment findings
- Speak with the patient/family member to evaluate lifestyle habits, particularly dietary preferences, beliefs, health goals, and socioeconomic factors

Assess the Information:

- Based on physical examination and review of systems, determine if the patient exhibits signs or symptoms of anemia
- Review current medications and assess if they could be contributing to anemia
- Evaluate CBC, if anemia is present, assess RBC indices to determine if the anemia is microcytic, normocytic, or macrocytic
- Assess iron, folic acid, and vitamin B_{12} studies to determine etiology of anemia

Develop a Care Plan:

- Determine whether a transfusion or pharmacotherapy is indicated. If pharmacotherapy is needed, decide whether oral or intravenous therapy is indicated [41]
- When initiating ESAs, assess the patient's iron status
- Discuss the importance of medication adherence to oral therapy
- Choose oral medications and doses that are optimal for the patient
- Select lifestyle and diet modifications that are likely to be effective and safe for the patient

Implement the Care Plan:

- Educate the patient on medication administration, potential new adverse effects, and how to report adverse effects
- Review signs and symptoms of anemia with the patient and address any concerns about anemia and its management
- Determine whether the patient has insurance coverage or recommended agents are included on the institution's formulary

Follow-up: Monitor and Evaluate:

- Follow up monthly to assess efficacy and tolerance of therapy until resolution of symptoms and Hgb goal is achieved
- Monitor for resolution of symptoms such as fatigue, shortness of breath, lethargy, headache, edema, and tachycardia
- Monitor the CBC monthly
- Monitor compliance of prescribed therapy and for side effects, such as:
  - Oral iron: nausea, vomiting, abdominal pain, heartburn, constipation, and dark stools
  - Parenteral iron: anaphylaxis (test dose required for iron dextran and observe for 1 hour after), injection-site pain/irritation, arthralgias, myalgias, flushing, malaise, and fever
  - Folic acid: bad taste, nausea, rash, and allergic reactions
  - Vitamin B_{12}: pain and erythema at injection site
  - ESAs: hypertension (monitor blood pressure), thrombosis (eg, deep vein thrombosis/pulmonary embolism, myocardial infarction, cerebrovascular accident, and transient ischemic attack), arthralgias, and headache

less than 500 mU/mL (500 U/L) and administered zidovudine doses less than 4200 mg/week.[34]

OUTCOME EVALUATION

KEY CONCEPT Patients should be monitored for Hgb response, symptom resolution, and adverse effects at appropriate intervals, and treatment regimens adjusted accordingly. The goal of anemia therapy is to correct the underlying etiology of the anemia, normalize the Hgb, and alleviate associated symptoms.

- To ensure response for patients with IDA, monitor CBC with special attention to occurrence of reticulocytosis and iron studies.
- A 1.0 g/dL (10 g/L or 0.62 mmol/L) per week increase in Hgb is desirable in patients with IDA. Reevaluate patients with increases less than 2.0 g/dL (20 g/L or 1.24 mmol/L) in 3 weeks.
- For patients with folic acid deficiency, monitor Hgb periodically and reevaluate patients who fail to normalize Hgb levels after 2 months of therapy.
- For patients with vitamin B_{12} deficiency, monitor for resolution of neurologic symptoms (ie, confusion and paresthesias), if applicable, and Hgb levels weekly until the levels normalize.[42]
- For cancer patients treated with chemotherapy without curative intent, initiate ESA treatment when Hgb levels are less than 10.0 g/dL (100 g/L or 6.21 mmol/L) and monitor Hgb levels weekly. If Hgb levels exceed 1.0 g/dL (10 g/L or 0.62 mmol/L) or 10.0 g/dL (100 g/L or 6.21 mmol/L), hold therapy until the Hgb level drops below 10.0 g/dL (100 g/L or 6.21 mmol/L). Restart the ESA at the lowest dose sufficient to reduce transfusions.
- For patients with CKD on dialysis, initiate ESA treatment when Hgb levels are less than 10.0 g/dL (100 g/L or 6.21 mmol/L) and monitor Hgb levels weekly. If Hgb levels approach or exceed 11.0 g/dL (110 g/L or 6.83 mmol/L), reduce or hold further doses until the level drops below 10.0 g/dL (100 g/L or 6.21 mmol/L). Restart the ESA at the lowest dose sufficient to reduce transfusions.

- For patients with CKD not on dialysis, initiate ESA treatment when Hgb levels are less than 10.0 g/dL (100 g/L or 6.21 mmol/L) and when the following additional criteria apply:
    - The rate of hemoglobin decline indicates the likelihood of a transfusion AND
    - Reducing the risks of alloimmunization and/or RBC transfusion is a goal. Monitor Hgb levels weekly. If Hgb levels exceed 10.0 g/dL (100 g/L or 6.21 mmol/L), reduce or hold further doses until the level drops below 10.0 g/dL (100 g/L or 6.21 mmol/L). Restart the ESA at the lowest dose sufficient to reduce transfusions.

Abbreviations Introduced in This Chapter

ACD	Anemia chronic disease
CKD	Chronic kidney disease
EPO	Erythropoietin
ESA	Erythropoietin-stimulating agent
GFR	Glomerular filtration rate
Hct	Hematocrit
Hgb	Hemoglobin
IDA	Iron deficiency anemia
MCV	Mean corpuscular volume
MCH	Mean corpuscular hemoglobin
RBC	Red blood cells
TIBC	Total iron-binding capacity

Coagulation and Platelet Disorders

Anna Dushenkov and Paiboon Jungsuwadee

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe the basics of the regulation of hemostasis and thrombosis.
2. Select appropriate nonpharmacological and pharmacological therapy for a patient with hemophilia in a given clinical situation.
3. Calculate an appropriate factor-concentrate dose for a product, given the percentage correction desired based on clinical situation.
4. List possible complications from hemophilia-induced bleeding episodes.
5. Choose an appropriate treatment strategy for patients with factor VIII or IX inhibitors.
6. Devise a treatment plan for a patient with a specific variant of von Willebrand disease (vWD).
7. Describe various recessively inherited coagulation disorders (RICDs) and the role of specific factor replacement in RICD management.
8. Recommend first-and second-line treatment approaches for immune thrombocytopenia (ITP).
9. Identify basic clinical features, causes, and management of select thrombotic microangiopathies (TMAs).

INTRODUCTION

Components of Hemostatic System

Following vessel injury, the endothelium is activated, and a series of physiological responses to prevent bleeding are initiated. The endothelial response involves vasoconstriction, platelet plug formation, coagulation, and fibrinolysis regulation. Under normal circumstances, platelets circulate in the blood in an inactive form. After injury, platelets undergo activation, which consists of (a) adhesion to the subendothelium, (b) secretion of granules containing chemical mediators (eg, adenosine diphosphate, thromboxane A2, and thrombin), and (c) aggregation. The chemical factors that are released from the injured tissue and platelets activate coagulation cascade and formation of thrombin. In turn, thrombin catalyzes conversion of fibrinogen to fibrin and its subsequent incorporation into the platelet plug. In parallel with coagulation, the fibrinolytic system is activated locally. Plasminogen is converted to plasmin, which dissolves the fibrin mesh (Figure 70–1).[1]

INHERITED COAGULATION DISORDERS

HEMOPHILIA

Epidemiology and Etiology

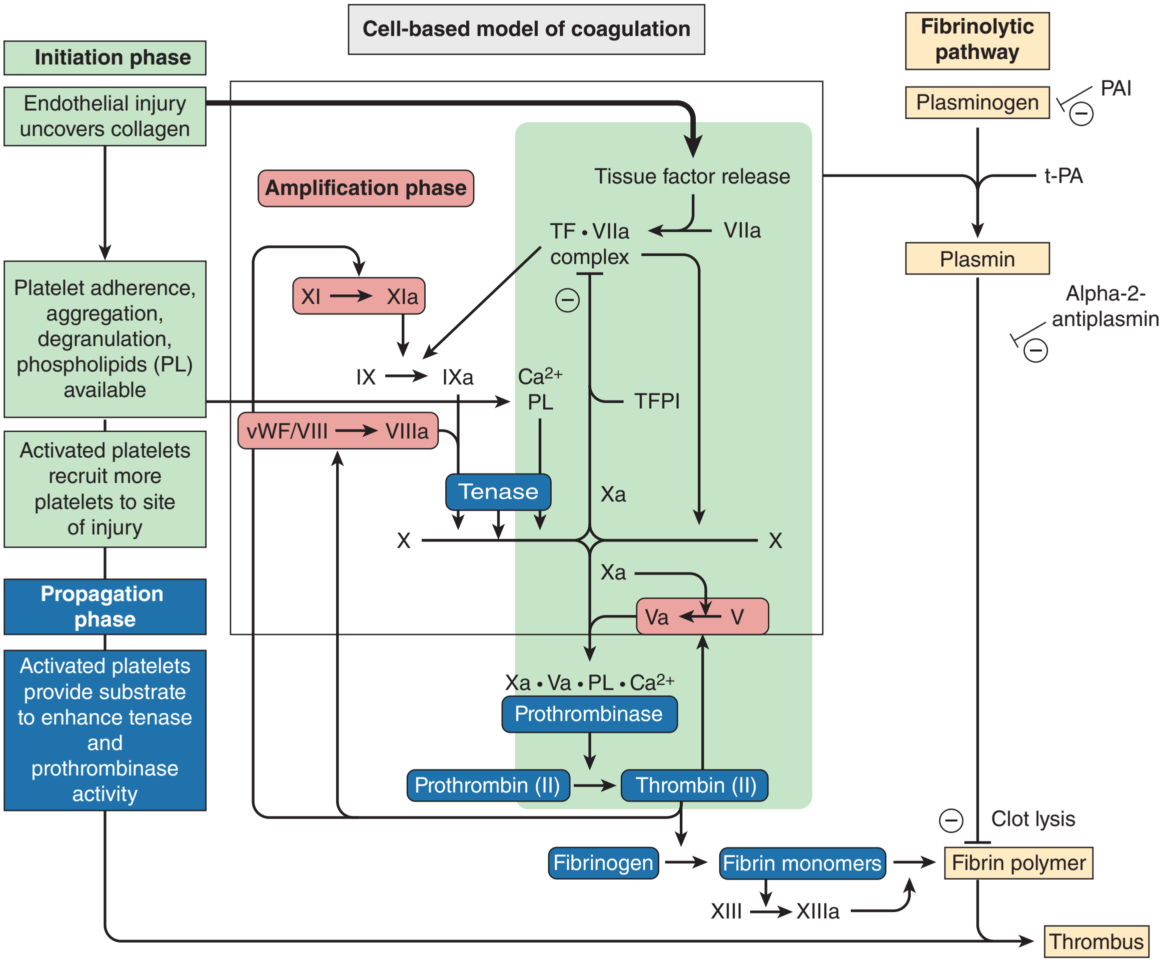
Hemophilia A (classic hemophilia) and B (Christmas disease) are coagulation disorders (RICDs) that result from defects in the genes encoding for plasma coagulation proteins, factor VIII (FVIII) and factor IX (FIX), respectively. The incidences of hemophilia A and B are estimated at 1 in 5000 and 1 in 30,000 male births. The disease manifests as mostly spontaneous bleedings that are either intra-articular, with 70%–80% of episodes that can lead to painful muscle atrophy and arthropathy in turn resulting in poor quality of life or intracranial hemorrhages (ICHs) that are much less common but potentially fatal.[2,3]

Pathophysiology

The pathophysiology of hemophilia is based on the deficiency of FVIII or FIX resulting in inadequate thrombin generation and impaired coagulation cascade (Figure 70–1). Hemophilias are X-linked recessive diseases (both factor VIII [*F8*] and IX [*F9*] genes are located on the X-chromosome). Generally, males carrying a defective allele for either *F8* or *F9* on their X-chromosome do not transmit the gene to their sons. However, their daughters are obligate carriers. More than 1000 mutations in *F8* and *F9* genes have been identified as causes of clinical hemophilia.[1] Consequently, hemophilia is not a result of a single genetic mutation. However, inversion at intron 22 of the *F8* gene accounts for 40% of severe hemophilia A cases, and this mutation is assessed during carrier and prenatal testing when there is a known intron 22 inversion in the family.[4] As for hemophilia B, the *F9* gene mutations appear to be the most common contributing factors. According to the European Association for Haemophilia and Allied Disorders (EAHAD) database (http://dbs.eahad.org), point mutations of the *F9* gene account for 71.9%.[5]

Complications of Hemophilia

The severity of bleeding associated with hemophilia correlates with the degree of FVIII or FIX deficiency as measured against the normal plasma level. Table 70–1 summarizes the age at onset and laboratory and clinical manifestations of hemophilia A and B.[6]



Cell-based model of coagulation
Initiation phase
Endothelial injury uncovers collagen
Platelet adherence, aggregation, degranulation, phospholipids (PL) available
Activated platelets recruit more platelets to site of injury
Propagation phase
Activated platelets provide substrate to enhance tenase and prothrombinase activity
Amplification phase
Tissue factor release
TF • VIIa complex
VIIa
XI → XIa
IX → IXa
Ca2+ PL
TFPI
vWF/VIII → VIIIa

FIGURE 70–1. Coagulation and thrombolytic cascade model. This model shows successive activation of coagulation factors proceeding from the top to the bottom where thrombin and fibrin are generated. (Ca^{2+}, calcium; PAI, plasminogen activator inhibitor; PL, phospholipids; TF, tissue factor [thromboplastin]; TFPI, tissue factor pathway inhibitor; t-PA, tissue plasminogen activator; vWf, von Willebrand factor. All clotting factors are shown as Roman numerals and the addition of an "a" indicates "activated.") (From Hammer GD, McPhee SJ. Blood disorders. Pathophysiology of Disease: An Introduction to Clinical Medicine, 8th ed.; 2019, Figure 6–5.)

Table 70–1

Laboratory and Clinical Manifestations of Hemophilia

	Severe (< 0.01 IU/mL [10 IU/L])	Moderate (0.01–0.05 IU/mL [10–50 IU/L])	Mild (> 0.05 IU/mL [50 IU/L])
Age at onset	1 year or less	1–2 years	2 years–adult
Neonatal symptoms			
PCB	Usual	Usual	Rare
ICH	Occasional	Uncommon	Rare
Muscle/joint hemorrhage	Spontaneous	Minor trauma	Minor trauma
CNS hemorrhage	High risk	Moderate risk	Rare
Postsurgical hemorrhage (without prophylaxis)	Frank bleeding, severe	Wound bleeding, common	Wound bleeding
Oral hemorrhage following trauma, tooth extraction	Usual	Common	Common

CNS, central nervous system; ICH, intracranial hemorrhage; PCB, postcircumcisional bleeding.

Normal range of factor VIII/IX activity level is 0.5–1.5 IU/mL (500–1500 IU/L). 1 IU/mL (1000 IU/L) corresponds to 100% of the factor found in 1 mL of normal plasma.

Treatment

▶ *Desired Outcomes*

Patients with hemophilia are cared for by interdisciplinary teams all who share the same short- and long-term management goals.[7] The short-term goals of hemophilia treatment include the following:

- Decrease the number of bleeding episodes per year or bleeding frequency
- Normalize or improve clotting factor concentrate levels

The long-term goals of hemophilia treatment include the following:

- Maintain clinical joint function
- Normalize orthopedic joint score
- Normalize radiologic joint score
- Maintain quality-of-life measurements

▶ *General Approach to Treatment*

KEY CONCEPT Intravenous factor replacement with recombinant or plasma-derived products to treat or prevent bleeding is the mainstay treatment of hemophilia. Primary prophylaxis is defined as the regular administration of factor concentrates in the absence of documented joint disease and initiated before the age of three.[8] Primary prophylaxis is recommended for individuals who have not had a bleeding episode but have severe factor deficiency (FVIII or IX activity levels < 1%) as it is efficacious in preventing bleeding and associated complications.[9] In addition, several studies have shown the benefit of prophylaxis in reducing morbidity in severe hemophilia A and B in both children and adults.[10]

▶ *Nonpharmacologic Therapy*

Supportive Care Rest, ice, compression, elevation (RICE) can be used during the bleeding episode, following with casts, splints, and crutches after the bleeding has been controlled.

Surgery Surgical arthroscopic synovectomy reduces replacement therapy–resistant disease and repetitive hemarthrosis of a single joint. This procedure removes inflamed joint tissue. Patients may have decreased range of motion after the surgery.

Orthotics Joint prostheses do not deal with the deformities directly. Orthotics in hemophilia serves as an important supportive measure before or after surgery.

▶ *Pharmacologic Therapy*

Hemophilia A

DDAVP Primary therapy is based on disease severity and type of hemorrhage.[11] Most patients with mild-to-moderate disease and minor bleeding episodes can be treated with 1-desamino-8-D-arginine vasopressin (desmopressin acetate [DDAVP]), a synthetic analogue of the antidiuretic hormone, vasopressin. DDAVP causes release of von Willebrand factor (vWF) and FVIII from the endothelial storage sites. DDAVP increases plasma FVIII levels by two- to four-fold within 60 minutes after an infusion or 90 minutes after an intranasal administration.[12] The recommended dose is 0.3 mcg/kg, IV (infused over 15–30 minutes) or subcutaneously (if < 1.5 mL) or 150 mcg (in patients weighing < 50 kg) to 300 mcg (in patients weighing 50 kg or more) intranasally via concentrated nasal spray, which may be repeated after 24 hours.[11] Desmopressin infusion may be administered daily for up to 3 days. FVIII levels should be obtained after administration. Facial flushing, hyper- or hypotension, gastrointestinal upset, and headache are the common side effects of desmopressin. Water retention and hyponatremia may occur; patients should be instructed to limit water intake while taking DDAVP. Serious side effects include seizures related to hyponatremia and myocardial infarction. Due to higher incidence of hyponatremia-related seizures in patients less than 2 years old, the use of desmopressin is not recommended in this population. Tachyphylaxis, an attenuated response with repeated administration, may occur after several doses.[13] DDAVP should not be used in severe life-threatening bleeding due to delayed response, and

Clinical Presentation and Diagnosis of Hemophilia A and B

Hemophilia A and B are clinically indistinguishable.

Symptoms

- Ecchymosis
- Hemarthrosis—bleeding into joint spaces[a] (especially knee, elbow, and ankle)
  - Joint pain, swelling, and erythema
  - Cutaneous warmth
  - Decreased range of motion
- Muscle hemorrhage
  - Swelling
  - Pain with motion of affected muscle
  - Signs of nerve compression
  - Potential life-threatening blood loss, especially with thigh bleeding
- Mouth bleeding with dental extractions or trauma
- Genitourinary bleeding
- Gastrointestinal bleeding
- Hematuria
- Intracranial hemorrhage (spontaneous or following trauma), with headache, vomiting, change in mental status, and focal neurologic signs
- Excessive bleeding with surgery

Diagnostic Parameters/Laboratory Testing

- Family history
- Normal prothrombin time (PT)
- Normal platelet count
- Prolonged activated partial thromboplastin time (aPTT)
- Low FVIII level (hemophilia A)
- Low FIX level (hemophilia B)

---

[a] Hallmark of hemophilia; inadequately managed recurrent hemarthrosis leads to deformity and chronic pain (hemophilic arthropathy).

the increase in FVIII may not be sufficient for proper clotting. DDAVP is usually used to treat mild hemophilia A.

According to the manufacturer, the use of DDAVP is contraindicated in patients with creatinine clearance less than 50 mL/min (0.83 mL/s); however, it has been used off-label in patients with impaired renal function.

Antifibrinolytic Therapy Aminocaproic acid and tranexamic acid are antifibrinolytic agents that reduce plasminogen activity leading to clot stabilization and inhibition of clot lysis. These agents are usually used as adjuncts in dental procedures or in difficult-to-control menorrhagia episodes and must be administered with appropriate factor concentrates to form a clot.[11]

Factor VIII Replacement Patients with severe hemophilia A may receive primary (before the first major bleed) or secondary (after the first major bleed) prophylaxis. Patients with hemophilia who experience a major bleed require FVIII replacement.[7] The therapy may include recombinant (produced via transfection of mammalian cells with the human *F8* gene) or plasma-derived (concentrate from pooled plasma) FVIII (Table 70–2). Newer generation plasma-derived coagulation factor concentrates are considerably safer after advancements in viral testing and inactivation technology. Recombinant factor VIII (rFVIII) products are stabilized with sucrose, trehalose, and mannitol or produced in human cell lines, eliminating the concern for viral transmission.[11]

Several strategies have been utilized to extend the half-lives of recombinant FVIII and FIX (EHL rFVIII and EHL rFIX, respectively).[14-17] Those strategies include fusion of the rFVIII or rFIX to a fragment-crystallizable region (Fc region) of immunoglobulin as in ie, Eloctate for rFVIII or Alprolix for rFIX, or to recombinant albumin as in ie, Idelvion for rFIX. Other strategies are PEGylation of the recombinant clotting factors as in ie, Adynovate, Esperoct for rFVIII or Rebinyn for rFIX, or as a single chain construct as in ie, Afstyla for rFVIII.

The severity of hemorrhage and its location are the major determinants of percentage correction to target, as well as duration of therapy (Table 70–3). The normal range of FVIII activity level is 1 IU/mL (1000 IU/L), which corresponds to 100% of the factor found in 1 mL of normal plasma. Minor bleeding may be treated with a goal of 25% to 30% (0.25–0.30 IU/mL [250–300 IU/L]) of normal activity, whereas serious or life-threatening bleeding requires greater than 80% of normal activity. FVIII is a large molecule that remains in the intravascular space, and its estimated volume of distribution is around 50 mL/kg. Generally, FVIII levels increase by 2% (0.02 IU/mL [20 IU/L]) for every 1 U/kg of FVIII concentrate infused. To calculate FVIII replacement dose, the following equation can be used:

$$\text{Dose of FVIII (U)} = \text{weight (kg)} \times (\text{desired percentage increase}) \times 0.5$$

Thus, to increase FVIII levels by 50% (eg, from 0% to 50%) in a 70-kg (154-lb) patient, an IV dose of 1750 U is required. The median half-life of FVIII ranges from 9.4 hours (in 1–6-year olds) to 10.4 hours (in 10–65-year olds).[18,19] Half the initial dose is given every half-life (every 8–12 hours) to maintain the desired FVIII level. Although intermittent bolus infusions of FVIII concentrates have been used successfully, continuous infusion protocols can be used in patients requiring prolonged treatment of acute hemorrhage to avoid dangerously low trough levels and decrease the overall cost of therapy. FVIII can be administered as a continuous infusion at 2 to 4 U/kg/hour with daily factor level monitoring to ensure appropriate rate of infusion.[20,21]

Hemophilia B

Factor IX Replacement Hemophilia B therapy may include recombinant (produced via transfection of mammalian cells with the human *F9* gene) or plasma-derived (concentrate from pooled plasma) FIX (Table 70–2). Guidelines for choosing the factor-concentrate formulation for hemophilia B are similar to the guidelines for hemophilia A. However, older generation FIX concentrates containing other vitamin K–dependent proteins, called prothrombin complex concentrates (PCCs), have been associated with thrombogenic side effects, and these products are not the first-line treatment for hemophilia B. Being a small protein, FIX molecules pass into both the intravascular and the extravascular spaces. Therefore, the volume of distribution of FIX is twice that of FVIII. Consequently, 1 U of FIX administered per kilogram of body weight yields a 1% rise in the plasma FIX level (0.01 IU/mL [10 IU/L]). To calculate the FIX replacement dose, the following equation can be used:

$$\text{Dose of FIX (U)} = \text{weight (kg)} \times (\text{desired percentage increase}) \times \text{F}$$

where for example, F for Benefix is 1.2 for adults and 1.4 for children less than 15 years old.[22] Thus, to increase FIX levels by 50% (eg, from 0% to 50%) in a 70-kg (154-lb) 14-year-old patient, the required dose of FIX is 4900 U IV. The half-life of FIX ranges from 16 to 17 hours; therefore, doses are given every 18 to 24 hours.

Administration of EHL products might overcome the need for frequent, several times per week infusions, resulting in up to estimated 50% fewer infusions per year of treatment.[23]

With the rapidly increasing use of EHL formulations, it has become evident that there is a lack of standardized treatment algorithms that would maximize patients outcomes.[24] Several population-based pharmacokinetic models eg, Web Accessible Population Pharmacokinetic Service for Hemophilia (WAPPS-Hemo, www.wapps-hemo.org), were designed to guide practitioners in EHL products' dosing and frequency of administration.

▶ Treatment of Patients With FVIII or FIX Inhibitors

FVIII and FIX inhibitors are antibodies that develop in response to replacement therapy in approximately 30% and 5% of hemophilia A and hemophilia B patients, respectively. This is the most serious complication with no difference between plasma-derived and recombinant products in their potential for inhibitor development. The antibodies bind to and neutralize the activity of infused factor concentrates. Other complications include anaphylaxis.[25] Although the inhibitors do not increase hemorrhage frequency, their existence challenges treatment of bleeding episodes. Titers of inhibitors are measured and reported in Bethesda units (BU), and this measurement is used to guide therapy (Figure 70–2). Management of acute bleeding in patients with factor inhibitors includes the administration of FVIII concentrates, PCCs, aPCC, recombinant factor VIIa (rFVIIa), and recombinant porcine FVIII.[26] Immune tolerance induction can be attempted to prevent future bleeding episodes.

FVIII concentrates can be used in patients with low inhibitor levels to control acute bleeding episodes. The dose of FVIII is determined based on clinical response (Figure 70–2).

PCCs contain vitamin K–dependent factors II, VII, IX, and X. These agents bypass FVIII, at which the antibody is directed (Figure 70–2). However, PCCs carry the risk of serious thrombotic complications. The only aPCC agent available, FEIBA (Factor Eight Inhibitor Bypassing Activity), has a higher concentration of activated factors.

Table 70–2

Selected Clotting Factor Products

Brand Name	Product Type	Viral Inactivation/Exclusion Method	Stabilizer	Half-life, h (Adult)
Factor VIII				
Alphanate	Plasma-derived FVIII/vWF	Solvent-detergent, dry heat	Human albumin	17.9 ± 9.6
Hemofil M	Plasma-derived FVIII	Solvent-detergent/Immunoaffinity chromatography	Human albumin	14.8 ± 3.0
Humate-P	Plasma-derived FVIII/vWF	Cryoprecipitate-pasteurization	NS	12.2
Koāte-DVI	Plasma-derived FVIII	Solvent-detergent, dry heat	Human albumin	16.1
Advate[III]	Recombinant FVIII	Solvent-detergent/Immunoaffinity chromatography	Trehalose, mannitol	12.0 ± 2.9[€]
Adynovate[III]	Recombinant FVIII; PEGylated	Solvent-detergent/Immunoaffinity chromatography	Trehalose, mannitol	14.7 ± 3.8
Afstyla[III]	Recombinant B-domain truncated FVIII; Single chain	NS/Immunoaffinity chromatography	Sucrose	14.2
Eloctate[IV]	Recombinant B-domain deleted FVIII; Fc fusion	Detergent and nanofiltration/Affinity chromatography	Sucrose	19.7
Esperoct[IV]	Recombinant B-domain truncated FVIII; GlycoPEGylated	Detergent and nanofiltration/Affinity chromatography	NS	21.7
Helixate FS[II]	Recombinant FVIII	Solvent-detergent/Immunoaffinity chromatography	Sucrose	13.7 ± 1.8
Jivi	Recombinant B-domain deleted FVIII	Filtration/Chromatography	Sucrose	18.6 ± 4.6
Kogenate FS[II]	Recombinant FVIII	Solvent-detergent/Immunoaffinity chromatography	Sucrose	13.7± 1.8
Kovaltry[III]	Recombinant FVIII	Detergent and nanofiltration/Affinity chromatography	Sucrose	14.3 ± 3.7
Novoeight[III]	Recombinant FVIII	Detergent and nanofiltration/Affinity chromatography	Sucrose	12.0
Nuwiq[IV]	Recombinant B-domain deleted FVIII	Solvent-detergent and nanofiltration/Chromatography	Sucrose	17.1 ± 11.2
Recombinate[I]	Recombinant FVIII	NS/Immunoaffinity chromatography	Human albumin, rvWF	14.6 ± 4.9
ReFacto[II]	Recombinant B-domain deleted FVIII	NS/Chromatography	Human albumin	13.7 ± 3.7
Xyntha[III]	Recombinant B-domain deleted FVIII	Solvent-detergent, nanofiltration/Affinity chromatography	Sucrose	11.2 ± 5.0
Factor IX				
AlphaNine SD	Plasma-derived FIX	Solvent-detergent and nanofiltration/Affinity chromatography	NS	21
Mononine	Plasma-derived FIX	Nanofiltration/Immunoaffinity chromatography	Mannitol	22.6
Profilnine	Plasma-derived Factors II, IX, X	Solvent-detergent and nanofiltration/Chromatography	NS	24.7 ± 8.3
Alprolix[IV]	Recombinant FIX; Fc fusion	Detergent and nanofiltration/NS	Sucrose, mannitol	86
BeneFIX[III]	Recombinant FIX	Nanofiltration/Chromatography	Sucrose	18.8 ± 5.4
Idelvion[III]	Recombinant FIX; rAlbumin fusion	Solvent-detergent and nanofiltration/NS	Sucrose, mannitol	118
Ixinity[III]	Recombinant FIX	Solvent-detergent and nanofiltration/Chromatography	Trehalose, mannitol	24 ± 7
Rebinyn	Recombinant FIX; PEGylated	Detergent and nanofiltration/Immunoaffinity chromatography	Sucrose, mannitol	114.9
Rixubis[III]	Recombinant FIX	Solvent-detergent and nanofiltration/Chromatography	Sucrose, mannitol	26.7 ± 3
APCC				
Feiba VH or NF	Plasma-derived Factors II, VIIa, IX, X	Nanofiltration and vapor heat	NS	NS
PCC				
Profilnine SD	Plasma-derived Factors II, IX, X	Solvent-detergent and nanofiltration/Chromatography	NS	24.7 ± 8.3
Other				
NovoSeven RT	Recombinant FVIIa	NS/Chromatography	Sucrose, mannitol	3.3 ± 0.3
Vonvendi	Recombinant vWF	Immunoaffinity purification	Trehalose, mannitol	19.1 ± 4.3
Wilate	Plasma-derived FVIII/vWF complex	Solvent-detergent and dry heat/Ion-exchange chromatography	Sucrose	10.6 ± 2.7

[€], Adolescent (12 to < 16 years)

[I], first generation; [II], second generation; [III], third generation; [IV], fourth generation of recombinant factor products; NS, not specified

APCC, activated prothrombin complex concentrate; NS, not specified; PCC, prothrombin complex concentrate; vWF, von Willebrand factor.

Table 70–3

Guidelines for Replacement Dosing With Factor VIII and Factor IX

Type of Hemorrhage	Desired Plasma FVIII Level (% of Normal)	Desired Plasma FXI Level (% of Normal)	Duration of Therapy (days)
CNS, intracranial, retropharyngeal, retroperitoneal, surgical prophylaxis	80–100	80–100	FVIII: every 8–12 hours over 10–14 days FIX: every 12 hours over 10–14 days
Mild hemarthrosis, mucosal (eg, epistaxis), superficial hematoma	30	20–30	FVIII: every 8–12 hours over 1–2 days FIX: every 12–24 hours over 1–2 days

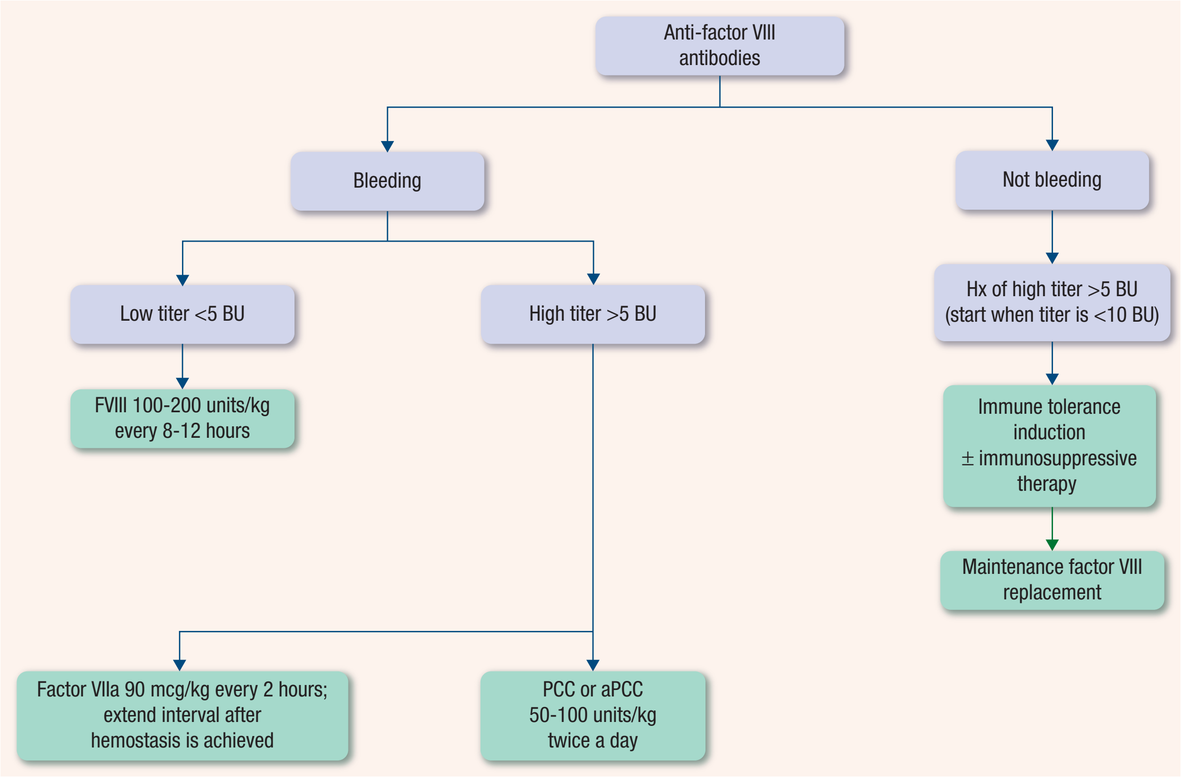
rFVIIa is a bypassing agent designed to generate thrombin only at tissue injury sites, where it binds tissue factor. Due to its local action, rFVIIa is associated with fewer systemic thrombotic events than PCC. rFVIIa is used effectively in surgeries and spontaneous bleeds.[27]

Recombinant porcine FVIII serves as a third-line agent (only after FVIIa and aPCC have failed) due to the relatively high incidence of cross-reactivity with FVIII inhibitors.

Induction of immune tolerance, which is often performed with the goal of eliminating the inhibitor, is accomplished by the administration of repetitive doses of FVIII or FIX with or without immunosuppressive therapy. It is effective in 70% of patients with hemophilia A and 30% of patients with hemophilia B.

Approval of emicizumab introduced a new era in the management of hemophilia when therapeutic agents are not the replacement factors but rather molecules that either mimic the function of the missing coagulation protein or modulate the coagulation cascade.[2,28] Emicizumab is a bispecific humanized monoclonal immunoglobulin G4 (IgG4) antibody that recognizes both FIXa and factor X (FX). Emicizumab bridges FIXa and FX, therefore, resembling the function of missing FVIIIa needed for hemostasis.[29] Emicizumab is administered subcutaneously with a varying frequency between 1 and 4 weeks injection.[30] The selection of a weight-based dosing regimen should take into consideration patient's preferences, which can drive meaningful adherence.

Gene therapy is a modality that offers a potential for hemophilia cure when after a single treatment, patient will no longer develop bleeding or other disease complications. Sustainable expression of FIX was achieved in a small number of patients with hemophilia B after an injection of adeno-associated viral vector carrying FIX variant gene coupled with the sequences optimizing expression and targeting the liver. Patients demonstrated a reduced annualized bleeding rate along with a decreased need for factor replacement. These successful results prompted extensive research in gene therapy for hemophilia A where recently similar promising outcomes have been reported.[31]



Anti-factor VIII antibodies
Bleeding
Not bleeding
Low titer <5 BU
High titer >5 BU
Hx of high titer >5 BU (start when titer is <10 BU)
FVIII 100-200 units/kg every 8-12 hours
Immune tolerance induction ± immunosuppressive therapy
Maintenance factor VIII replacement
Factor VIIa 90 mcg/kg every 2 hours; extend interval after hemostasis is achieved
PCC or aPCC 50-100 units/kg twice a day

FIGURE 70–2. Treatment algorithm for the management of patients with hemophilia A and factor VIII antibodies. (aPCC, activated prothrombin complex concentrate; BU, Bethesda unit; PCC, prothrombin complex concentrate). (From DiPiro JT, Yee GC, Posey L, Haines ST, NolinFigure TD, Ellingrod V. Coagulation disorders. Pharmacotherapy: A Pathophysiologic Approach, 11th ed.; 2020, Figure 119–1.)

▶ *Treatment of Pain Associated with Hemophilia*

Pain commonly occurs in patients with hemophilia. Acute bleeding episodes and long-term joint destruction are common sources of pain. Acetaminophen and opioid analgesics are recommended to control mild-to-moderate and severe pain, respectively. Nonsteroidal anti-inflammatory drugs (NSAIDs) and aspirin should generally be avoided because these drugs bind to platelets and increase the risk of bleeding. Selective cyclooxygenase-2 (COX-2) inhibitors can be used with caution.[32]

Outcome Evaluation

The main goal of hemophilia treatment is to prevent bleeding episodes and their long-term complications. Clinicians should evaluate patients for the following:

- Musculoskeletal status, including joint range of motion and radiologic assessment, as indicated.
- Number and type of bleeding episodes to assess adequacy of prophylactic treatment and home therapy.
- Development of inhibitors due to the use of clotting-factor concentrates, especially in patients with severe disease and those poorly responding to treatment.
- Following the age-appropriate vaccination schedules in hemophiliacs without the evidence of immunity.

VON WILLEBRAND DISEASE

Epidemiology and Etiology

Von Willebrand disease (vWD) is the most common inherited bleeding disorder caused by a deficiency or dysfunction of vWF. It is classified based on the quantitative deficiency of vWF or qualitative abnormalities of vWF. Based on population studies, the prevalence of vWD is 0.6% to 1.3%. In contrast to hemophilia, the majority of vWD cases are inherited as an autosomal dominant disorder, suggesting equal frequency in males and females.[33,34]

Pathophysiology

vWF is a large multimeric glycoprotein with two main functions in hemostasis: to aid platelet adhesion to injured blood vessel walls and to carry and stabilize factor VIII in plasma. Table 70–4 represents three main vWD phenotypes, their frequency, and genetic transmission.[35]

Patient Encounter 1, Part 1: vWD

A 15-year-old girl without significant past medical history is referred to a hematology clinic with a complaint of having heavy menstrual bleeds with normal menstrual cycle but with clots, size of about a quarter and soaking through a pad within an hour. The bleeds usually last for 10 days. Her mother reports history of spontaneous nosebleeds and easy bruising in male and female members of the family.

What are this patient's risk factors for vWD?

What additional information for developing a treatment plan do you need to collect?

Treatment

▶ *Desired Outcomes*

Unlike in hemophilia, the bleeding tendency in vWD is less frequent and generally less severe. Consequently, chronic prophylaxis is usually unwarranted. The goal of mainstay therapy in vWD is:

- To stop spontaneous bleeding as necessary
- To prevent surgical and postpartum bleeding

▶ *Nonpharmacologic Therapy*

Local measures, including pressure and ice, may be used to control superficial bleeding.

▶ *Pharmacologic Therapy*

Systemic therapy is used to prevent bleeding associated with surgery, childbirth, and dental extractions and to treat bleeding that cannot be controlled with local measures. The two systemic approaches involve using desmopressin (DDAVP), which stimulates the release of endogenous vWF, or administering products that contain vWF. The National Heart, Lung, and Blood Institute issued comprehensive evidence-based guidelines for the diagnosis and management of vWD.[34]

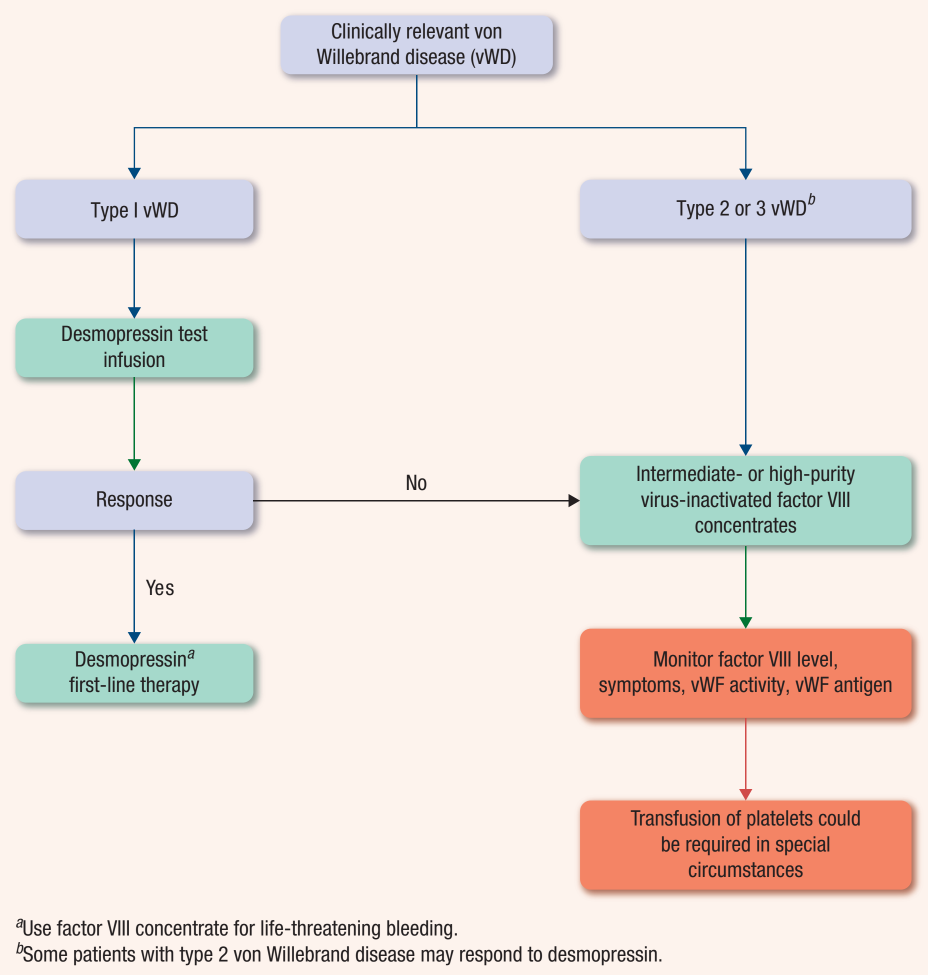
The general approach to the treatment of vWD is depicted in Figure 70–3.

DDAVP Most patients with type 1 vWD (functionally normal vWF) and minor bleeding episodes can be treated with desmopressin, which induces the release of factor VIII and vWF from the endothelial cells through interaction with vasopressin V2

Table 70–4

Classification of vWD

Phenotype	Mechanism of Disease	Percentage of Cases	Genetic Transmission
Type 1 vWD	Partial (mild-to-moderate) quantitative deficiency of vWF and FVIII	70–80	Autosomal dominant
Type 2 vWD	Qualitative abnormalities of vWF	10–30	
2A	Decreased platelet-dependent vWF function owing to the lack of larger multimers	10–20	Autosomal dominant (or recessive)
2B	Decreased vWF function due to increased affinity to platelet GPIb and resultant sequestration or loss	5	Autosomal dominant
2M	Defective platelet-dependent vWF functions not associated with multimer defects	Uncommon	Autosomal dominant (or recessive)
2N	Defective vWF binding to FVIII	Uncommon	Autosomal recessive
Type 3 vWD	Severe quantitative deficiency of vWF	Rare	Autosomal recessive



Clinically relevant von Willebrand disease (vWD)
Type I vWD
Type 2 or 3 vWD[b]
Desmopressin test infusion
Response
No
Yes
Intermediate- or high-purity virus-inactivated factor VIII concentrates
Desmopressin[a] first-line therapy
Monitor factor VIII level, symptoms, vWF activity, vWF antigen
Transfusion of platelets could be required in special circumstances

[a] Use factor VIII concentrate for life-threatening bleeding.
[b] Some patients with type 2 von Willebrand disease may respond to desmopressin.

FIGURE 70–3. General approach to treatment of vWD. (From DiPiro JT, Yee GC, Posey L, Haines ST, Nolin TD, Ellingrod V. Coagulation disorders. Pharmacotherapy: A Pathophysiologic Approach, 11th ed.; 2020, Figure 119–2.)

receptors. The recommended dose is the same as that used to treat mild FVIII deficiency (0.3 mcg/kg IV infused over 15–30 minutes or 150–300 mcg intranasally via concentrated nasal spray; may repeat after 24 hours). This therapy is generally ineffective in individuals with type 2A disease, who secrete abnormal vWF. It is recommended for individuals with type 2B disease who respond to DDAVP. The drug may increase the risk of postinfusion thrombocytopenia, in which case a concomitant platelet infusion is administered. Patient with type 3 vWD, who lack releasable stores of vWF, do not respond to DDAVP therapy.[36]

The individual responsiveness to desmopressin is inconsistent, and a test dose administered at the time of diagnosis or prior to therapy is the best predictor of response. Generally, DDAVP is more effective in individuals with vWD than in patients with hemophilia, with an average two- to five-fold increase in vWF and FVIII levels over the baseline. In patients with an adequate response, desmopressin is the first-line therapy because it allows for once-daily administration (elevates plasma levels for 8–10 hours), does not pose a threat in terms of viral transmission, and costs substantially less than the plasma-derived products.

Antifibrinolytic Therapy Fibrinolysis inhibitors and oral contraceptives are used successfully in the management of epistaxis and menorrhagia or as adjuvant treatments.[37] Fibrinolysis inhibitors include aminocaproic acid (25–60 mg/kg, orally or IV [or 4–5 g] every 4–6 hours, to a maximum dose of 24 g/day) and tranexamic acid (10 mg/kg, IV every 8 hours). Oral tranexamic acid is FDA approved for the treatment of cyclic heavy menstrual bleeding although it is not approved for the management of patients with vWD. The IV form of tranexamic acid can be given as swish and swallow or spit every 6 to 8 hours for bleeding prophylaxis in dental surgery. Both aminocaproic acid and tranexamic acid are dose adjusted for patients with renal insufficiency.

Replacement Therapy KEY CONCEPT Type 1 vWD patients unresponsive to desmopressin, patients with types 2 and 3 vWD, and patients undergoing major surgery require replacement therapy with plasma-derived, intermediate- and high-purity virus-inactivated FVIII concentrates containing vWF. Ultra-high-purity plasma-derived and recombinant FVIII concentrates should not be used for the treatment of vWD because those products do not contain vWF.

Table 70–5 provides typical dosing guidelines and target levels of replacement therapy—concentrates to control various types of hemorrhage.

Vonicog alfa is the first recombinant vWF approved for the perioperative management of bleeding and on-demand treatment and control of bleeding episodes in patient with vWD older than 18 years of age.[38]

Table 70–5

Replacement Therapy in vWD

Condition	Therapy	Recommended Dosage
Major surgery	Maintain vWF:RCo and FVIII levels at least 100 IU/dL (1000 IU/L) followed by 50 IU/dL (500 IU/L) for 7–14 days	40–60 U/kg[a] loading dose, followed by 20–40 U/kg every 12–24 hours
	To minimize risk of thrombosis: vWF:RCo levels should not exceed 200 IU/dL (2000 IU/L), and FVIII levels should not exceed 250 IU/dL (2500 IU/L)	DDAVP may be added after a few days
Minor surgery	Prophylaxis: maintain vWF:RCo and FVIII levels at least 30 IU/dL (300 IU/L) (preferably > 50 IU/dL [> 500 IU/L])	30–60 U/kg loading dose, followed by 20–40 U/kg every 12–48 hours
	Minor surgery: maintain vWF:RCo and FVIII levels at least 30 IU/dL (300 IU/L) (preferably > 50 IU/dL [> 500 IU/L]) for 3–5 days	DDAVP may be added after a few days

[a] vWF concentrates are dosed based on vWF:RCo units concentration in the preparation to achieve the desired vWF:RCo levels.

Clinical Presentation and Diagnosis of vWD

Clinical manifestations vary depending on the subtype. Patients with mild disease may be asymptomatic into adulthood.

Symptoms

- Bruising
- Mucocutaneous bleeding
- Epistaxis
- Oral cavity bleeding
- Menorrhagia
- Gastrointestinal bleeding
- Joint and deep tissue bleeding
- Postoperative bleeding

Laboratory Testing

- Low or normal vWF antigen concentration in plasma (vWF:Ag)
- Low or normal factor VIII coagulation assay (FVIII:C)[a]
- Low ristocetin cofactor activity (vWF:RCo)[b]

---

[a] FVIII coagulation assay measures the ability of vWF to bind and maintain adequate levels of FVIII.

[b] Ristocetin cofactor activity (vWF:RCo) assay measures the ability of vWF to interact with intact platelets (normal 50–200 IU/dL [500–2000 IU/L]).

Outcome Evaluation

The main goal of vWF treatment is to prevent bleeding with surgery or dental procedures. Clinicians should evaluate patients every 6 to 12 months for the following:

- Number and type of bleeding episodes to assess the need for prophylactic treatment.
- Ensure adequate levels of vWF and FVIII prior to minor and major surgical procedures and for the treatment of bleeding.
- Vaccination against hepatitis A and B is recommended in all patients with vWF deficiency with no evidence of immunity.

OTHER CLOTTING FACTOR DEFICIENCIES

Etiology and Epidemiology

RICDs refer to relatively rare deficiencies in factors II, V, VII, and X to XIII resulting in either decreased clotting factor production or production of a dysfunctional molecule with reduced activity.[39] The clinical severity of bleeding varies and generally is poorly correlated with the factor blood levels. Table 70–6 illustrates these clotting factor deficiencies and some of their characteristics.

Pathophysiology

The RICDs are rare genetic disorders. Mutations in the genes responsible for the respective clotting factors result in impaired functionality or production of the factor.

Table 70–6

Clotting Factor Deficiency Characteristics

Factor Deficient	Inheritance Pattern	Estimated Incidence	Laboratory Abnormalities	Severity and Site of Bleeding
II	Autosomal dominant or recessive	Extremely rare	Prolonged PT and aPTT	Mild-to-moderate umbilical cord, joint, and mucosal tract
V	Autosomal recessive	1:1,000,000	Prolonged PT and aPTT	Mild-to-moderate mucosal tract
VII	Autosomal recessive	1:500,000	Prolonged PT	Mild-to-severe mucosal tract and joint
X	Autosomal recessive	1:1,000,000	Prolonged PT and aPTT	Mild-to-severe umbilical cord, joint, and muscle
XI	Autosomal recessive	4% of Ashkenazi Jews: otherwise rare	Prolonged aPTT	Mild-to-moderate posttraumatic bleeding
XII	Unknown	Unknown	Prolonged aPTT	No bleeding
XIII	Autosomal recessive	< 1:2,000,000	Normal PT and aPTT	Moderate-to-severe umbilical cord, intracranial, and joint bleeding; recurrent miscarriages, impaired wound healing

aPTT, activated partial thromboplastin time; PT, prothrombin time.

Patient Encounter 1, Part 2: vWD

Medications: None

Allergies: NKA

PE/ROS:

Well-nourished, well-developed (WNWD) female, otherwise healthy. Wt 52 kg.

Labs:

Platelet count: 205 × 10^3/mm^3 (205 × 10^9/L) (normal 140–440 × 10^3/mm^3 [140–440 × 10^9/L])

aPTT: 40 seconds (normal 25–40 seconds)

PT: 14 seconds (normal 11–15 seconds)

FVIII-C: 51% (normal 50%–150%)

vWF:RCo: 25 IU/dL or 250 IU/L (normal 50–200 IU/dL or 500–2000 IU/L)

vWF-Ag: 28 IU/dL or 280 IU/L (normal 50–200 IU/dL or 500–2000 IU/L)

Given this additional information, is this patient's presentation consistent with vWD?

Define treatment goals for this patient.

Treatment

▶ *Desired Outcomes*

Therapeutic interventions for RICDs improve hemostasis via replacement of deficient blood coagulation factors while minimizing the development of immune tolerance.[40]

Hemostatic levels should be maintained for the following conditions:

- Spontaneous bleeding—until bleeding stops
- Minor surgery—for 2 to 3 days
- Major surgery—until incision site has healed

▶ *Nonpharmacologic Therapy*

Transfusional Therapies

KEY CONCEPT The primary treatment of RICDs is single-donor fresh frozen plasma (FFP) that contains all coagulation factors. Disadvantages of FFP treatment include the risk of the patient becoming volume overloaded, especially when repeated infusions are administered to improve and maintain hemostasis; risk of infections; and risk of inhibitor development. PCCs licensed for the treatment of hemophilia B also contain significant levels of vitamin K–dependent factors and may be used for treatment of RICD. Table 70–7 lists the recommended RICD treatment schedules in different clinical scenarios.

Table 70–7

Treatment of Factor Deficiencies

Factor Deficient	Major Surgery	Spontaneous Bleeding
II	1. PCC: 20–30 U/kg 2. FFP: 15–20 mL/kg	1. FFP: 15–20 mL/kg
V	1. FFP: 15–20 mL/kg	1. FFP: 15–20 mL/kg
VII	1. rFVIIa: 15–30 mcg/kg every 4–6 hours	1. rFVIIa: 15–30 mcg/kg every 4–6 hours
X	1. PCC: 20–30 U/kg 2. FFP: 15–20 mL/kg	1. PCC: 20–30 U/kg 2. FFP: 15–20 mL/kg
XI	1. FFP: 15–20 mL/kg	1. FFP: 15–20 mL/kg
XIII	1. Pasteurized plasma concentrate: 10–20 U/kg 2. FFP: 15–20 mL/kg 3. Cryoprecipitate (1 bag per 10 kg)	1. FFP: 3–5 mL/kg

Numbers indicate lines of therapy. FFP, fresh frozen plasma; PCC, prothrombin complex concentrates.

▶ *Pharmacologic Therapy*

Less severe hemorrhages may be treated successfully either with antifibrinolytic amino acids alone or in combination with factor replacement therapy. Tranexamic acid and aminocaproic acid may be administered IV or orally (for doses, see vWD, Pharmacologic Therapy mentioned earlier).

PLATELET DISORDERS

Platelets, in combination with other factors such as blood vessel wall and coagulation factors, play a key role in hemostasis. Normal platelet count is 150 to 450 × 10^3/mm^3 (150–450 × 10^9/L). Thrombopoietin, a hormone synthesized in the liver, regulates platelet production. Several congenital and iatrogenic disorders may result in low platelet count; among them, drug-induced thrombocytopenia, infection-induced thrombocytopenia, disseminated intravascular coagulation (DIC), congenital thrombocytopenia, and idiopathic immune thrombocytopenia (ITP). Two types of thrombocytopenic disorders and their treatments are discussed below.

IMMUNE THROMBOCYTOPENIA

Epidemiology and Etiology

ITP is one of the most common causes of acquired thrombocytopenia. The estimated incidence is 1.9 to 6.4 cases per 100,000 persons in children and 3.3 cases per 100,000 in adults.[41] ITP is an acquired disorder caused by immune-mediated destruction of platelets, resulting in shortened platelet life span.

Childhood-onset and adult-onset ITP present very differently. Adult-onset ITP is generally chronic (longer than 6 months) and affects women two to three times more often than men. By contrast, childhood-onset ITP is acute in onset and usually follows an infectious illness, and both sexes are equally affected. Childhood ITP typically resolves on its own within 4 to 6 weeks without major sequelae. ITP occurs in about 1 of every 1000 pregnancies. In pregnant women with preexisting ITP, both maternal and fetal complications may occur, requiring separate management.

Pathophysiology

ITP can be primary or secondary. Primary ITP can occur due to the formation of autoimmune IgG antibodies directed at patient's platelets' surface glycoproteins, GPIIb/IIIa and GP1b/IX/V; abnormal production of megakaryocytes in the bone marrow; or T-cell defects that lead to destruction of platelets. The majority of adult ITP cases are due to primary causes.

Secondary ITP occurs due to an underlying disorder, such as autoimmune (eg, rheumatoid arthritis, systemic lupus erythematosus [SLE]) or infectious diseases (eg, human immunodeficiency virus [HIV], hepatitis C virus [HCV],

Patient Care Process: Hemophilia A/B, vWD, and RICD

Collect Information:

- Obtain complete medical and medication history.
- Evaluate CBC, vital signs, and coagulation studies. If a bleeding disorder is diagnosed, evaluate specific coagulation assays to determine the etiology of the bleeding disorder.

Assess the Information:

- Identify appropriate goals of therapy based on patient's presentation.
- Based on patient data, determine if patient has contraindications to potential therapeutic options.

Develop a Care Plan:

- Institute nonpharmacological therapy to minimize minor bleeding.
- Depending on the diagnosis and disease severity, select appropriate pharmacotherapy with desmopressin, antifibrinolytic medications, and/or disease-specific factor replacement therapies.
- Recommend prophylactic therapies before major and minor surgical procedures based on bleeding risk assessment.
- Evaluate pain and treat if necessary, selecting medications that do not increase the risk of bleeding.

Implement the Care Plan:

- Address any patient's concerns about coagulation disorder and its management.
- Educate the patient and/or patient's caregivers about coagulation disorder, efficacy/safety of replacement therapies, and medication/activities to avoid.
- Discuss importance of medication adherence and follow-up monitoring to achieve optimal outcomes. Determine whether there are any barriers to adherence.
- Review vaccination history and recommend appropriate vaccinations.
- Determine the patient's ability to afford prescribed pharmacotherapy.

Follow-up: Monitor and Evaluate:

- If clotting factor replacement is utilized, continuously evaluate its efficacy and test for inhibitors development if loss of efficacy is observed.
- Monitor number/severity of bleeding episodes, joint count/joint destruction, and pain associated with some coagulation/bleeding disorders.
- Determine whether the patient is experiencing any adverse reactions or drug interactions.

or *Helicobacter pylori* infections).[42] Platelets survival time is significantly shorter in patients with ITP (from minutes to 2–3 days compared with normal 7–10 days). Sequestration in spleen, liver, and bone marrow is partially responsible for decreased platelet survival.

Treatment

▶ *Desired Outcomes*

The goal of ITP treatment is to maintain sufficient hemostasis, keeping in mind patient's preferences and ensuring adequate quality of life.[43]

▶ *General Approach to Treatment*

KEY CONCEPT The treatment of ITP is determined by platelet count and intensity of bleeding. (Table 70–8). In some cases, especially in children where up to 80% of cases resolve spontaneously regardless of pharmacologic interventions, observation might be sufficient. In patients, who are corticosteroid-dependent and whose thrombocytopenia does not resolve within 3 months, the selection of a second-line treatment should be personalized with consideration of availability of medical and social infrastructure,

Patient Encounter 1, Part 3: vWD: Creating a Care Plan

Based on the information presented, create a care plan for this patient.

What additional pharmacologic interventions can be considered for this patient if first line fails?

Clinical Presentation and Diagnosis of ITP

General

The typical patient is well with the exception of bleeding.

Symptoms

- Petechiae
- **Purpura**, **wet purpura**
- **Ecchymosis**
- Cutaneous bleeding
- Mucosal site bleeding
- Epistaxis
- Gingival bleeding
- Hematuria
- Menorrhagia
- Intracranial hemorrhage (rare)

Diagnostic Criteria

- Platelet count less than $100 \times 10^3/\text{mm}^3$ ($100 \times 10^9/\text{L}$)
- Otherwise normal complete blood count with differential
- Normal reticulocyte count
- Normal peripheral blood smear (no hemolysis or blast cells)
- History and physical examination ruling out other possible causes of thrombocytopenia[30]

Other Laboratory Testing

Laboratory testing to evaluate other causes that can lead to secondary ITP, such as HCV, HIV, and *Helicobacter pylori*.

Table 70–8

Guidelines for the Management of Adult ITP

Platelets ≥ $30 \times 10^3/\text{mm}^3$ (30×10^9/L), no bleeding or minor mucocutaneous bleeding	Observation
Platelets < $30 \times 10^3/\text{mm}^3$ (30×10^9/L), no bleeding or minor mucocutaneous bleeding	Prednisone (0.5–2 mg/kg/day IV/PO) or dexamethasone (40 mg IV/PO × 4 days) If corticosteroids contraindicated: Anti-D immune globulin (50–75 mcg/kg/day IV × one dose) IVIg (1 g/kg/day IV × one dose, repeat as necessary)
Platelets < $30 \times 10^3/\text{mm}^3$ (30×10^9/L), bleeding symptoms after an adequate trial of first-line agents	Splenectomy Rituximab (375 mg/m² IV once weekly for four doses) Eltrombopag (25–75 mg PO daily) Romiplostim (1–10 mcg/kg subcutaneously once weekly) Immunosuppressants
Hemorrhage	Platelet transfusion IVIg (1 g/kg/day IV × one dose, repeat as necessary) Methylprednisolone (1 g/day IV for 3 days)

disease duration, severity and frequency of bleedings, and patient's values and preferences.[43]

▶ *Nonpharmacologic Therapy*

Splenectomy In adults, splenectomy is generally considered after 3 to 6 months if the patient continues to require 10 to 20 mg/day of prednisone to maintain the platelet count greater than $30 \times 10^3/\text{mm}^3$ (30×10^9/L). Splenectomy may also be considered for urgent treatment of neurologic symptoms or for managing a relapse despite an adequate trial of corticosteroids, IV immunoglobulin (IVIg), or anti-Rh(D). Even though individual patient response cannot be predicted, the majority (66%–88%) of refractory adult patients have a favorable response to splenectomy within several days; however, some patients will have no response or will experience a relapse sometime after splenectomy.

In children, splenectomy is usually reserved due to the self-limited nature of ITP and risk of infectious complications following splenectomy. However, splenectomy is recommended in children with an ITP duration greater than 1 year with significant bleeding symptoms and unresponsive or intolerant of pharmacological therapies. Between 70% and 80% of children attain complete remission following splenectomy. Laparoscopic splenectomy is preferable to open splenectomy because it speeds the recovery and shortens the duration of hospitalization. The major complication of splenectomy is bacterial sepsis, occurring at incidence rates of approximately 1%. Immunizations with *Haemophilus influenzae* type b, pneumococcal, and meningococcal vaccines are indicated in all patients 2 weeks prior to splenectomy.[44] Additional complications include thrombosis and pulmonary hypertension.

Patient Encounter 2, Part 1: ITP

A 23-year-old female with history of a short respiratory illness presented with gingival bleeding, requiring swishing with icy water and nonitchy ecchymotic rash on her left forearm. Patient denied any history of hematemesis, epistaxis, hemoptysis, hematuria, melena, or trauma.

What patient information is suggestive of ITP?

What additional information for developing a treatment plan do you need to collect?

Platelets Transfusions Platelets transfusions are indicated if a patient has severe life-threatening bleeding, such as intracranial hemorrhage. In such situations, platelets transfusions are administered along with IVIg and glucocorticoids (discussed later).[45]

Additional Considerations Patients with severe thrombocytopenia may need to restrict their participation in extreme contact sports. Medications that inhibit platelet aggregation (eg, NSAIDs) should be avoided.

▶ *Pharmacologic Therapy*

The general approach to management of ITP in adults is summarized in Table 70–8.

Glucocorticoids Glucocorticoids may decrease splenic sequestration of antibody-coated platelets, diminish antibody generation, and increase platelet output by the bone marrow. In adults, the response rate to oral prednisone (1 mg/kg/day) is 50% to 75%, with patients usually responding within the first 1 to 2 weeks. The duration of therapy depends on the platelet count response. Guidelines advocate for a longer course of prednisone therapy (21 days), followed by a taper. High-dose dexamethasone (40 mg orally or intravenously daily) administered for 4 days in 14- to 28-day cycles has also been used successfully and may be superior to prednisone especially in cases when rapid response is desired.[46] In children, oral or parenteral corticosteroids (prednisone, dexamethasone, methylprednisolone) can be used; various dosage regimens have been studied with no drug or dosage regimen showing superiority.[43]

IV Immunoglobulin (IVIg) IVIg impairs the clearance of platelets coated with IgG by activating inhibitory receptor FcRγIIb. Roughly 80% of adults will respond to IVIg, but remission usually is not sustained. In adults, IVIg infusion (1 g/kg/day given as a single dose, repeated if necessary) is reserved for situations, in which rapid increase in platelet count is necessary, such as life-threatening bleeding and very low platelet count, or for patients who have contraindications to glucocorticoids. If treatment is indicated in children, a single dose of IVIg (0.8–1 g/kg) is usually effective. The use of IVIg is complicated by serious adverse effects, shortages and high cost.

Anti-Rh(D) Anti-Rh(D) can be used only in Rh(D)-positive patients who have not had splenectomy. It is as efficacious as IVIg and is generally less expensive. Anti-Rh(D) is a desirable

Patient Encounter 2, Part 2: ITP

PE/ROS:

Wt 60 kg; vital signs within normal limits.

Skin: round, macular, bluish in color, ecchymotic rash, 4 cm in diameter, located on left forearm. Oral cavity: bleeding gingival surfaces noted.

The rest of the examination is unremarkable.

Medications: None

Allergies: NKA

Labs:

WBC: $5.8 \times 10^3/\text{mm}^3$ (5.8×10^9/L) (normal $3.5–10.5 \times 10^3/\text{mm}^3$ [$3.5–10.5 \times 10^9$/L])

Platelet count: $9 \times 10^3/\text{mm}^3$ (9×10^9/L); manual count: $15 \times 10^3/\text{mm}^3$ (15×10^9/L) (normal $140–440 \times 10^3/\text{mm}^3$ [$140–440 \times 10^9$/L])

Platelet count 2 months prior: $240 \times 10^3/\text{mm}^3$ (240×10^9/L)

aPTT: 35 seconds (normal 25–40 seconds)

PT: 11 seconds (normal 10–12 seconds)

Hgb: 12.1 g/dL (121 g/L or 7.5 mmol/L) (normal 12.0–15.5 g/dL or 120–155 g/L or 7.50–9.61 mmol/L)

Hct: 35% (normal 34.9%–44.5%)

Peripheral blood smear:

WBC: few activated lymphocytes and neutrophils with left shift

RBC: normocytic and normochromic

Platelets: giant platelets seen

Disseminated intravascular coagulation ruled out based on laboratory test and blood film

HCV: negative

HIV: negative

Helicobacter pylori **antibody:** negative

Pregnancy: negative

Given this additional information, is this patient's presentation consistent with ITP?

Define treatment goals for this patient.

modality in chronic ITP when the goal is to circumvent long-term exposure to corticosteroids. The initial dose is 50 mcg/kg intravenously, with dose adjustment based on hemoglobin levels. Administration of anti-Rh(D) may increase the platelet count in about 70% to 80% of children with ITP. Response to anti-Rh(D) lasts for about 3 to 5 weeks, and substantial numbers of patients treated repetitively with anti-Rh(D) can postpone or avoid splenectomy. Rare fatal intravascular hemolysis has been reported with the use of anti-Rh(D); close monitoring for 8 hours after drug administration is recommended.

Immunosuppressants Immunosuppressant therapy is generally utilized for patients who are refractory to or intolerant of all other ITP treatments. Rituximab, an anti-CD20 antibody, at a dose of 375 mg/m^2 once weekly for four doses, can induce long-term response in 21% to 27% of patients.[43] Progressive multifocal leukoencephalopathy (PML) has been rarely reported with rituximab use. Rituximab can be considered a second- or third-line therapy in patients who have experienced treatment failure with corticosteroids, IVIg, or splenectomy. Screening for hepatitis B infection is required prior to rituximab initiation.

Azathioprine and cyclophosphamide produce response rates of 20% to 40% in adult patients who are treated for 2 to 6 months. Other medications used in ITP include vincristine, vinblastine, cyclosporine, danazol, and mycophenolate mofetil; due to major toxicities and lack of adequate evidence-based recommendations, their use is reserved for refractory ITP.

All immunizations should be up to date prior initiating immunosuppressant therapy because these medications increase susceptibility to infections.

Thrombopoietic Growth Factors Thrombopoietic growth factors stimulate the bone marrow to produce enough platelets to overcome the body's premature destruction of platelets. Romiplostim and eltrombopag are thrombopoietin (TPO) mimetics that have been approved for the treatment of thrombocytopenia in adult and pediatric patients with chronic ITP whose degree of thrombocytopenia and clinical condition increase the risk for bleeding, and who have had an insufficient response to corticosteroids, immunoglobulins, or splenectomy.

Romiplostim is a TPO peptide mimetic that binds to and activates the human TPO receptor. Romiplostim works by stimulating megakaryopoiesis, which results in enhanced platelet production. The initial dose of romiplostim is 1 mcg/kg subcutaneously once weekly based on the actual body weight. The dose can be adjusted weekly by increments of 1 mcg/kg until the patient achieves a platelet count greater than or equal to $50 \times 10^3/\text{mm}^3$ (50×10^9/L). The maximum dose is 10 mcg/kg/week.[47] Studies have demonstrated efficacy of romiplostim over treatment periods of 5 years.[48]

Eltrombopag is a nonpeptide TPO receptor agonist with a low immunogenic potential that stimulates megakaryocyte proliferation and differentiation. Eltrombopag has been shown to increase platelet counts and decrease bleeding episodes in patients with ITP.[49] The usual starting dose is 50 mg by mouth once daily; it can be increased to a maximum dose of 75 mg daily in order to achieve and maintain a platelet count greater than or equal to $50 \times 10^3/\text{mm}^3$ (50×10^9/L). The starting dose should be reduced by 50% in patients with mild-to-severe hepatic impairment and in individuals of Asian descent. Eltrombopag can be taken regardless of a meal if the meal contains 50 mg or less of calcium. The drug should be administered at least 2 hours before or 4 hours after antacids, dairy, and other foods or supplements containing polyvalent ions eg, iron, zinc, magnesium, selenium, and calcium ($>$ 50 mg).[50] Studies have demonstrated its efficacy lasting over 3 years.[49,51]

Either TPO mimetic should be discontinued if platelet counts do not increase after 4 weeks at a maximum dose.

Although these agents are usually well tolerated, a number of rare but serious risks have been identified, including worsened thrombocytopenia, thrombotic/thromboembolic complications ie, portal vein thrombosis, and progression to acute myelogenous leukemia. In addition, eltrombopag's labeling carries a "boxed warning" regarding the increased risk of hepatotoxicity.

Patient Encounter 2, Part 3: ITP: Creating a Care Plan

Based on the information presented, create a care plan for this patient. If pharmacologic therapy is indicated, list first-line and alternative therapies.

Monitoring of hepatic enzymes every 2 weeks initially, followed by every 4 weeks thereafter, is recommended.

Another oral agent indicated for chronic ITP in adults who have insufficient response to previous treatment is fostamatinib, a kinase inhibitor whose place in therapy remains to be determined.

Outcome Evaluation

- Monitor platelet counts as indicated clinically.
- In adults, the goal of therapy is to maintain platelet count greater than or equal to 30 × 10^3/mm^3 (30 × 10^9/L).
- Monitor for signs and symptoms of bleeding.

THROMBOTIC MICROANGIOPATHIES

Epidemiology and Etiology

Thrombotic microangiopathies (TMAs) include a diverse variety of disorders with different pathophysiological features. Typical presentation includes small vessel (microangiopathic) hemolytic anemia with thrombocytopenia. Microvascular thrombosis occurs due to defects in the endothelium of small vessels, such as arterioles and capillaries.[52]

Primary TMAs include thrombotic thrombocytopenic purpura (TTP), shiga toxin–mediated hemolytic uremic syndrome (ST-HUS), immune or dose-related drug-induced TMA, complement-mediated TMA, metabolism-mediated TMA, and coagulation-mediated TMA. Classification and causes of primary TMA are summarized in Table 70–9. Here, we will focus on TTP and complement-mediated TMAs.

Thrombotic Thrombocytopenic Purpura

TTP is a severe systemic disorder characterized by thrombi formation within the circulation that results in the platelet consumption and subsequent thrombocytopenia.[41] TTP can occur in all ages and can be hereditary or acquired. Both types of TTP are very rare; the estimated annual incidence of acquired TTP (aTTP) is three cases per million adults.[53]

▸ *Pathophysiology*

Endothelial cells normally synthesize vWF in the form of a high-molecular-weight multimer composed of smaller identical monomers. Each monomer is able to bind platelets, and the number of monomers on the vWF multimer is directly proportional to its platelet-binding capacity. Consequently, particularly adherent ultra-large molecules of vWF (ULvWF) are broken down to smaller size by vWF-cleaving proteases such as ADAMTS13 (a disintegrin and metalloprotease with thrombospondin type 1 repeats) to avoid undesired clot formation. TTP results from inherited deficiency in the vWF-cleaving protease ADAMTS13 activity or development of autoimmune inhibitors to ADAMTS13. This, in turn, elevates circulating levels of ULvWF, leading to inappropriate platelet agglutination. Thrombocytopenia develops because the rate of aggregated platelet consumption is faster than production of megakaryocytes in the bone marrow. Microangiopathic hemolytic anemia generally follows as a consequence of red blood cells damage by platelet clumps that occlude the microcirculation. Occlusive ischemia of the brain or gastrointestinal tract is common. TTP is distinguished from other TMAs for rarely causing renal abnormalities.

▸ *Desired Outcomes*

The main goal of TTP treatment is to prevent end-organ damage.

▸ *Nonpharmacologic Therapy*

KEY CONCEPT The standard treatment for hereditary TTP is plasma infusion containing ADAMTS13 protease. For acquired TTP, urgent plasma exchange (PEX) is needed to remove ADAMTS13 inhibitor. If PEX is unavailable, treatment with plasma infusion and glucocorticoids is indicated until PEX is available.[54]

Plasma Exchange The procedure involves the removal of the patient's plasma and its substitution with donor plasma. In this manner, circulating antibody inhibitor to ADAMTS13 is removed and enzyme is replenished. PEX involves placement of two IV lines (cannulae) into two separate veins. Blood removed through one cannula is centrifuged to separate the blood cells from the plasma. The blood cells are mixed subsequently with donor plasma and returned to the patient via the second cannula. The goal is to exchange 1 to 1.5 plasma volumes (40–60 mL/kg). Generally the procedure is repeated daily until neurologic symptoms resolve and normal lactate dehydrogenase (LDH) and platelet counts are maintained for several days. Once complete remission is achieved, PEX frequency can be reduced to every other day for additional few days, with subsequent PEX discontinuation and

Table 70–9

Thrombotic Microangiopathy Syndromes

Name	Notes
• TTP (ADAMTS13 deficiency)	Hereditary presents in children, acquired usually presents in adults.
• Shiga toxin–mediated hemolytic uremic syndrome (ST-HUS)	Triggered by *Shigella dysenteriae* or *Escherichia coli* Shiga-toxin producing infection.
• Drug-induced	Can be mediated by immune reaction (eg quinine) or related to the increased dose (eg bevacizumab, sunitinib).
• Complement-mediated	Mutations in complement factor H (CFH), CD46, complement factors I (CFI), B (CBF).
• Coagulation-mediated	Genetic abnormalities in proteins mediating coagulation (eg thrombomodulin gene [THBD], diacylglycerol kinase epsilon [DGKE]).

Patient Care Process ITP

Collect Information:

- Conduct physical examination evaluating sites of bleeding. Obtain complete medical and medication history.
- Evaluate CBC, peripheral blood smear, complete metabolic panel, and Rh(D) status; order tests to rule out other diseases commonly associated with thrombocytopenia.

Assess the Information:

- Determine whether ITP is likely due to primary or secondary causes (this may change treatment focus).
- Evaluate platelet count, occupational risks of bleeding, and actual bleeding severity to determine the initial treatment approach.
- Identify relevant goals of therapy based on patient's platelet counts and the presence or absence of bleeding.
- Based on patient data, determine if patient has contraindications to potential ITP therapeutic options.

Develop a Care Plan:

- Choose medications and doses that are optimal for the patient.
- First-line treatment for patients meeting criteria for pharmacotherapy is corticosteroids for up to 21 days. Anti-Rh(D) or IVIg can be considered if corticosteroids are contraindicated or a rapid rise in platelet count is necessary. Alternatives to first-line agents include immunosuppressants and TPO mimetics, which are reserved for patients failing to respond after adequate trial of first-line agents. Surgical splenectomy is reserved for refractory ITP.

Implement the Care Plan:

- Address any patient concerns about ITP and its management.
- Educate the patient about new medications in their regimen, discuss drug administration and side effects, especially focusing on serious effects and their management.
- Discuss importance of medication adherence and follow-up monitoring to achieve optimal outcomes. Determine whether there are any barriers to adherence. Educate patient's caregivers, if applicable.
- Review vaccination history and recommend appropriate vaccinations.
- Determine patient's ability to afford prescribed pharmacotherapy.

Follow-up: Monitor and Evaluate:

- Adhere to prescriber's recommendations on appropriate frequency of follow-up (depends on severity at presentation and pharmacotherapy chosen).
- Review platelet response and bleeding to assess changes in clinical status and evaluate pharmacotherapy for efficacy and safety. In adults, once response is achieved, monitor regularly to ensure platelet counts stay above $30 \times 10^3/\text{mm}^3$ ($30 \times 10^9/\text{L}$).
- Determine whether the patient is experiencing any adverse reactions or drug interactions.

close patient follow-up. When PEX is started immediately upon diagnosis, remission and survival rates at 6 months are approximately 80%. Although generally considered safe, complications from catheter insertion or catheter infection may occur and include hemorrhage, pneumothorax, sepsis, and thrombosis. Allergic reactions to plasma can cause severe hypotension and hypoxia.[55]

Splenectomy Splenectomy is reserved for patients with frequently relapsing disease who are refractory to PEX or immunosuppressive therapy.

▶ *Pharmacologic Therapy*

Glucocorticoids Glucocorticoids can be used for their immunosuppressive effect in combination with PEX; however, as

Clinical Presentation and Diagnosis of Thrombotic Microangiopathies[a]

Onset and typical features will vary depending on precipitating cause.

1. Thrombocytopenia
    - Thrombocytopenic purpura
    - Bleeding
2. Fever (sometimes)
3. Microangiopathic hemolytic anemia
4. Neurologic symptoms (sometimes)
    - Headache, confusion, difficulty speaking, transient paralysis, numbness
5. Renal abnormalities (rare with TTP, common with other TMA types)
    - Proteinuria, hematuria, mild or severe renal insufficiency

Laboratory Testing

- Decreased ADAMTS 13 activity (< 10% or normal)—TTP
- Decreased hemoglobin, hematocrit, and platelets
- Peripheral blood smear showing schistocytes
- Decreased serum haptoglobin
- Elevated LDH
- Elevated indirect bilirubin level
- Elevated reticulocyte count
- Normal PT and aPTT
- Elevated urine protein, red blood cells, and/or serum creatinine, decreased urine output

---

[a] Thrombotic microangiopathies diagnosis can be based on the presence of thrombocytopenia and microangiopathic hemolytic anemia in the absence of other possible causes.

Patient Encounter 3, Part 1: TTP

A 21-year-old African female was seen in the emergency room for severe headache, confusion, chills, nausea and vomiting, and purplish pinpoint nonitchy rash and petechiae on the abdomen. Patient has no history of gingival bleeding, hematemesis, melena, hematochezia, or autoimmune diseases including SLE and is otherwise healthy.

What patient information is suggestive of TTP?

What additional information for developing a treatment plan do you need to collect?

Patient Encounter 3, Part 2: TTP

PE/ROS:

Young WNWD female in no distress

Wt 70 kg, T 101.3°F (38.5°C), BP 128/75 mm Hg, HR 80 beats/min, RR 18 breaths/min

Neuro: patient appears confused but oriented × 3

Skin: disseminated purplish pinpoint nonitchy rash and bruises on the abdomen

The rest of the examination is unremarkable

No familial history of hematologic disorders

Medications: none

Allergies: NKA

Labs:

- Platelet count: 8×10^3/mm^3 (8×10^9/L) (normal 140–440 × 10^3/mm^3 [140–440 × 10^9/L])
- aPTT: 35 seconds (normal 25–40 seconds)
- PT: 11 seconds (normal 10–12 seconds)
- Haptoglobin: 10 mg/dL (100 mg/L) (normal 30–200 mg/dL or 300–2000 mg/L)
- LDH: 1057 U/L (17.62 μkat/L) (normal 100–250 U/L, or 1.67–4.17 μkat/L)
- Hgb: 7.1 g/dL (71 g/L; 4.34 mmol/L) (normal 12.0–15.5 g/dL or 120–155 g/L or 7.50–9.61 mmol/L)
- Hct: 22% (normal 34.9%–44.5%)
- Blood peripheral smear: numerous schistocytes (10–15 per high power field)
- SCr: 0.8 mg/dL (71 μmol/L) (normal 0.6–1.2 mg/dL [53–106 μmol/L])
- ADAMTS13 activity: less than 5% (normal ≥ 60%)
- Anti-ADAMTS13 IgG: 3.2 U/mL (normal ≤ 0.4 U/mL)
- Imaging studies: CT scan head–unremarkable
- Pregnancy test: negative

Given this additional information, is this patient's presentation consistent with TTP?

What is the likely etiology of this patient's TTP?

Define treatment goals for this patient.

Patient Encounter 3, Part 3: TTP: Creating a Care Plan

Based on the information presented, create a care plan for this patient.

monotherapy, they are not efficacious in TTP. The most commonly used agents are methylprednisolone 250 mg/day IV or prednisone 1 mg/kg/day orally for the duration of PEX therapy and for additional 1 to 2 weeks to maintain normalized platelet counts.

Immunosuppressants TTP that fails to respond adequately to PEX can be treated with immunosuppressive agents. Cytotoxic immunosuppressive therapies with the most potential benefit in refractory TTP include cyclosporine and rituximab. Other agents that had been used include bortezomib, vincristine, cyclophosphamide, azathioprine, and mycophenolate mofetil.[54]

Targeted Therapy Caplacizumab is a vWF-directed antibody fragment, recently approved for the treatment of aTTP. Caplacizumab targets the A1-domain of vWF, inhibiting the interaction between vWF and platelets thereby reducing vWF-mediated platelet adhesion and platelet consumption. In clinical trials, bleedings occurred in more than half of the patients treated with the drug. Caplacizumab should be discontinued 7 days prior to an elective procedure including dental work. The drug is administered parenterally in combination with immunosuppressive therapy and plasma exchange. If patient experiences more than two recurrences of aTTP while on treatment, caplacizumab must be discontinued.[56]

Complement-Mediated TMA

This type of TMA results from genetic mutations of various factors responsible for alternative pathway of complement activation. Generally thought to be triggered by an infectious episode in predisposed patients, uncontrolled complement activation leads to the formation of membrane attack complexes that cause endothelial damage, TMA, and renal failure.[57]

▶ *Nonpharmacologic Therapy*

Supportive therapy may include blood or platelet transfusions, maintenance of fluid balance to support adequate end-organ perfusion, and dialysis therapy. Liver–kidney transplantation provides cure for this type of TMA but is associated with significant complications.

▶ *Pharmacologic Therapy*

Eculizumab is a humanized monoclonal antibody that binds to complement component C5, thus preventing formation of C5b and subsequent formation of C5b-9 (membrane attack complex).[58] Complement genetic studies may be helpful in determining whether a patient is a good candidate to receive eculizumab (eg, patients with C5 mutations may not respond as well). For best results, treatment should be started within 48 hours of presentation; the usual adult dose is 900 mg, intravenously once weekly for four doses, followed by 1200 mg on week 5, and 1200 mg every 2 weeks thereafter. All immunizations should be up to date in patients considered for this therapy, as it can increase the risk of serious infections, including meningococcal infection. Alternatively, PEX or plasma infusion can be used if eculizumab therapy is not feasible.

Patient Care Process for Thrombotic Microangiopathy

Collect Information:

- Obtain complete medical and medication history.
- Evaluate CBC, vital signs, neurologic symptoms, complete metabolic panel, and urinalysis for the presence of thrombocytopenia, fever, anemia, and renal abnormalities. Evaluate neurologic symptoms and peripheral blood smear.

Assess the Information:

- Identify the primary cause of TMA to evaluate targeted treatment selection.
- Identify appropriate goals of therapy based on patient's presentation.
- Based on patient data, determine if patient has contraindications to potential therapeutic options.

Develop a Care Plan:

- Choose medication and doses (if applicable) that are appropriate and optimal for the patient.
- If patient meets clinical criteria for the diagnosis of acquired TTP, start daily PEX as soon as possible. Glucocorticoids and other adjunctive therapies may be considered.
- Institute supportive therapy based on patient's presentation and needs.

Implement the Care Plan:

- Educate the patient about new medications in their regimen, discuss drug administration and side effects, especially focusing on serious effects and their management.
- Address any patient concerns about specific TMA and its management.
- Discuss importance of medication adherence and follow-up monitoring to achieve optimal outcomes. Determine whether there are any barriers to adherence. Educate patient's caregivers, if applicable.
- Review vaccination history and recommend appropriate vaccinations.
- Determine patient's ability to afford prescribed pharmacotherapy.

Follow-up: Monitor and Evaluate:

- Adhere to prescriber's recommendations on appropriate frequency of follow-up (depends on severity at presentation and pharmacotherapy chosen). When platelet counts stay above 150 × 10^3/mm^3 (150 × 10^9/L) for 2 days, PEX may be discontinued; glucocorticoids may be continued for additional 1 to 2 weeks.
- Determine whether the patient is experiencing any adverse reactions or drug interactions.
- Follow patients indefinitely with periodic CBC/LDH measurements to screen for possible relapse.

Abbreviations Introduced in This Chapter

ADAMTS13	A disintegrin and metalloprotease with thrombospondin type 1 repeats (vWF-cleaving metalloprotease)
BU	Bethesda units
DDAVP	1-Desamino-8-D-arginine vasopressin (desmopressin acetate)
DIC	Disseminated intravascular coagulation
FFP	Fresh frozen plasma
HCV	Hepatitis C virus
ICH	Intracranial hemorrhage
ITP	Immune thrombocytopenia
IVIg	IV immunoglobulin
PCC	Prothrombin complex concentrate
PEX	Plasma exchange
rFVIIa	Recombinant factor VIIa
rFVIII	Recombinant factor VIII
rFIX	Recombinant factor IX
RICD	Recessively inherited coagulation disorder
TTP	Thrombotic thrombocytopenic purpura
ULvWF	Ultra-large molecules of vWF
vWD	von Willebrand disease
vWF	von Willebrand factor

Sickle Cell Disease

Tracy M. Hagemann and Teresa V. Lewis

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Explain the underlying causes of sickle cell disease (SCD) and their relationship to patient signs and symptoms.
2. Identify the typical characteristics of SCD as well as symptoms that indicate complicated disease.
3. Identify the desired therapeutic outcomes for patients with SCD.
4. Recommend appropriate pharmacotherapy and nonpharmacotherapy interventions for patients with SCD.
5. Recognize when chronic maintenance therapy is indicated for a patient with SCD.
6. Describe the components of a monitoring plan to assess effectiveness and adverse effects of pharmacotherapy for SCD.
7. Educate patients about the disease state, appropriate therapy, and drug therapy required for effective treatment and prevention of complications.

INTRODUCTION

KEY CONCEPT "Sickle cell syndrome" refers to a collection of autosomal recessive genetic disorders that are characterized by the presence of at least one sickle hemoglobin (HbS) gene.[1,2]

Sickle cell disease (SCD) is a chronic illness that is associated with frequent crisis episodes. Acute complications are unpredictable and potentially fatal. Common symptoms include excruciating musculoskeletal pain, life-threatening pneumonia-like illness, cerebrovascular accidents, and splenic and renal dysfunction.[2] As the disease progresses, patients may develop organ damage from the combination of hemolysis and infarction. Because of the complexity and severity of SCD, it is imperative that patients have access to comprehensive care with providers who have a good understanding of the countless clinical presentations and the management options of this disorder.

EPIDEMIOLOGY AND ETIOLOGY

Sickle cell trait (SCT) is the heterozygous form (HbAS) of SCD in which a person inherits one normal adult hemoglobin (*HbA*) gene and one *HbS* gene. These individuals are carriers of the SCT and usually asymptomatic.[2] About 1 in 13 African American babies is born with SCT.[3] Symptomatic disease is seen in homozygous and compound heterozygous genotypes of SCD. Sickle cell anemia (SCA) is the homozygous (HbSS) state of SCD.[2] It is the most common and severe form of SCD. SCD affects both males and females equally because it is not a sex-linked disease.

KEY CONCEPT Around 100,000 Americans have SCD and it occurs in approximately 1 out of every 365 African American births.[3] HbSS (~75%) is the most common genotype, followed by HbSC (~18%), HbSβ^{+}-thalassemia (~5%), and HbSβ^{0}-thalassemia (~2%). Other variants account for fewer than 1% of patients.[2,4] For every infant diagnosed with SCD, 50 are identified as carriers.[4]

Having the *HbS* gene protects heterozygous carriers from succumbing to *Plasmodium falciparum* (malaria) infection.[1] The microorganism cannot parasitize abnormal red blood cells (RBCs) as easily as normal RBCs. Consequently, persons with heterozygous sickle gene (*SCT*) have a selective advantage in tropical regions where malaria is endemic.

The highest incidence of SCD is seen in those with African heritage, but SCD also affects persons of Indian, Saudi Arabian, Mediterranean, South and Central American, and Caribbean ancestry.[4]

Normal HbA is composed of two α-chains and two β-chains (α2β2).[1] A single substitution of the amino acid valine for glutamic acid at position 6 of the β-polypeptide chain is responsible for the production of a defective form of hemoglobin called HbS.[1] Different genetic mutations encode for other hemoglobin variants such as hemoglobin C (HbC).[1] The α-chains of HbS, HbA, and HbC are structurally identical. The chemical differences in the β-chain are responsible for RBC sickling and its associated sequelae.

The HbSS state of SCD occurs when individuals inherit the mutant *HbS* gene from both parents. The progeny of two carriers will have a 25% probability of having SCD and a 50% risk of being a carrier. β-Thalassemia can be found in conjunction with HbS. Patients with HbSS and HbSβ^{0}-thalassemia do not have normal β-globulin production and usually have a more severe course than those with HbSC and HbSβ^{+}-thalassemia.

Impaired circulation, destruction of RBCs, and vascular stasis are three known problems that are primarily responsible for the clinical manifestations of SCD (Figure 71–1).

PATHOPHYSIOLOGY

KEY CONCEPT SCD involves multiple organ systems, and its clinical manifestations vary greatly between and among genotypes.

Sickle Hemoglobin Polymerization

The primary event in the molecular pathogenesis of SCD involves polymerization of deoxygenated HbS. HbS carries oxygen normally, and when oxygenated, the solubility of HbS and HbA are the same. Once the oxygen is unloaded to the tissues, HbS solubility decreases. This promotes hydrophobic interactions between the hemoglobin molecules and polymerization, which leads to the distortion of the RBC into the characteristic crescent or sickle shape.[1]

Viscosity of Erythrocytes and Sickle Cell Adhesion

When HbS becomes reoxygenated, the polymers within the RBCs disappear, and the cells eventually return to normal shape. Vasoocclussion is caused by a combination of factors. Repeated assaults on RBCs from sickling and unsickling can lead to cell membrane damage, loss of membrane flexibility, and rearrangement of surface phospholipids. The life span of sickled RBCs is markedly shorter (10–20 days) than that of normal RBCs (100–120 days). As intracellular membrane viscosity of HbS-containing RBCs increases, blood viscosity increases, which further contributes to vasoocclusion.[5] There is also increasing evidence that suggest sickle cells adhere to vascular endothelium.[1,5] The combined effects of decreased RBC deformability, slow transit through microcirculation, and adhesion to vascular endothelium contribute to obstruction of small and sometimes large blood vessels. The resulting local tissue hypoxia can accentuate the pathologic process of SCD.

Protective Hemoglobin Types

Fetal hemoglobin (HbF) binds oxygen more tightly than HbA and has a decreased propensity to sickling. HbA2 also possesses this characteristic but to a lesser extent. RBCs that contain HbF sickle less readily than cells without. HbF is composed of two α chains and two γ chains; therefore, it is not affected by point mutations on β chains. Irreversibly sickled cells (ISCs) are found to have low HbF concentrations. In some patients, higher HbF may ameliorate the disease.

Other Pathophysiologic Effects

Other factors may be responsible for the pathogenesis of some of the clinical features of SCD. Sickle cells can obstruct blood flow to the spleen leading to functional asplenia. Impaired splenic function can increase the propensity to infection by encapsulated organisms, particularly *Streptococcus pneumoniae*.[1] Additionally, coagulation abnormalities are not uncommon since almost every component of hemostasis is altered in SCD.

Clinical Presentation and Diagnosis of SCT

General

- Generally asymptomatic

Symptoms

- Females may have frequent urinary tract infections

Signs

- Microscopic hematuria occurs rarely
- Gross hematuria may occur spontaneously or with heavy-intensity exercise

Laboratory Tests

- Normal Hgb values

Clinical Presentation and Diagnosis of SCD

General

- Identified by neonatal screening before 2 months of age in the United States

Symptoms

- Painful vasoocclusive crises are the hallmark of SCD
- Dactylitis (hand–foot syndrome) before age 1 year
- May develop infarction of the spleen, liver, bone marrow, kidney, brain, and lungs
- Gallstones
- **Priapism** in males
- Slow-healing lower extremity ulcers after trauma or infection
- Weakness, fatigue

Signs

- Chronic hemolytic anemia is common
- Enlargement of spleen and heart
- Scleral icterus

Laboratory Tests

- Hgb 7.0 to 10.0 g/dL (70–100 g/L or 4.34–.21 mmol/L)
- Low HgF and increased reticulocytes, platelets, and white blood cells (WBCs)
- Presence of sickled cells on blood smear
- Neonatal screening: hemoglobin electrophoresis, isoelectric focusing, or DNA analysis

TREATMENT

Desired Outcomes

Multidisciplinary, regularly scheduled care is required over the lifetime of the patient with SCD, with the goal of reduction of complications and hospitalizations. Comprehensive care should include medical, educational, and psychosocial aspects as well as genetic and medication counseling.

Therapeutic interventions for SCD are targeted at preventing and/or minimizing the symptoms related to the disease and its complications. The goals of treatment are to reduce or eliminate the patient's symptoms; decrease the frequency of sickle crises, including vasoocclusive pain crises; prevent the development of complications; and maintain or improve the quality of life through decreased hospitalizations and decreased morbidity. Specific therapeutic options may:

- Maintain or increase the hemoglobin level to the patient's baseline
- Increase the HbF concentration
- Decrease the HbS concentration
- Prevent infectious complications
- Prevent or effectively manage pain
- Prevent central nervous system (CNS) damage, including stroke

General Approach to Treatment

Patients should be educated to recognize the signs and symptoms of complications that would require urgent evaluation. Patients and parents of children with SCD should be educated to seek immediate medical care when a fever develops or signs of infection occur. With acute illnesses, prompt evaluation is important, as deterioration may occur rapidly. Fluid status should be monitored to avoid dehydration or overhydration, both of which may worsen complications of SCD. Patients in acute distress should maintain oxygen saturation at 92% (0.92) or at their baseline. Any supplemental oxygen requirements should be evaluated.[4]

Nonpharmacologic Therapy

Patients should avoid smoking and excessive alcohol intake. Patients with SCD should maintain adequate hydration to help decrease blood viscosity and should be educated to avoid extreme temperature changes and dress properly in hot and cold weather. Physical exertion that leads to complications should be avoided.[4] Regular examinations, including ophthalmic, dental, renal, pulmonary, and cardiac function, are required to monitor for organ damage. A treatment overview is shown in Table 71–1.

Pharmacologic Therapy

▶ *Health Maintenance*

Immunizations Children with SCD should receive the required immunizations as recommended by the American Academy of Pediatrics and the Advisory Committee on Immunization Practices, including vaccination for meningococcal disease.[6] Additionally, influenza vaccine should be administered yearly to SCD patients 6 months of age and older, including adult patients. All adult patients with SCD should also receive the vaccine for meningococcal disease as well as a one-time dose of *Haemophilus influenzae* type b vaccine. The quadrivalent conjugate meningococcal vaccine (MenACWY) should be administered in two doses at least 2 months apart and should be revaccinated every 5 years.[7] In addition, adults should be vaccinated with the serogroup B meningococcal vaccine with either a two-dose series of MenB-4C at least 1 month apart or a three-dose series of MenB-FHbp at 0, 1 to 2, and 6 months.[7]

Because patients with SCD have impaired splenic function, they are less adequately protected against encapsulated organisms such as *S. pneumoniae*, *H. influenzae*, and *Salmonella*. **KEY CONCEPT** The use of pneumococcal vaccine in combination with penicillin prophylaxis in SCD patients has dramatically decreased the rates of morbidity and mortality; however, there are still groups of SCD children who continue to have high rates of invasive pneumococcal infections.[8,9] Infection is the leading cause of death in children with SCD younger than 3 years of age.[9] Two pneumococcal vaccines are available. The 13-valent pneumococcal conjugate vaccine (PCV 13: Prevnar) is routinely administered to infants and children and provides good protection against the 13 most common isolates seen in this age range. Administer the first dose of PCV 13 between 6 weeks and 6 months of age, followed by two additional doses at 2-month intervals and a fourth dose at 12 to 15 months of age. The 23-valent polysaccharide vaccine (PPSV 23: Pneumovax 23) is indicated for children older than 2 years and adults. Because PPSV 23 is a polysaccharide vaccine, children younger than 2 years do not respond well. 23-Valent pneumococcal polysaccharide vaccine (PPV 23) contains the 23 most common isolates of *S. pneumoniae* seen in older children and adults. Because of the different serotypes seen in the two vaccines, it is recommended that children with SCD receive both vaccines, with a dose of PPSV 23 administered after the child turns 2 years of age. The dose of PPSV 23 should be separated from the last dose of PCV 13 by at least 2 months. An additional dose of PPSV 23

Table 71–1

Management of SCD

Options and Comments	
Health Maintenance	
Infection prophylaxis	• Pneumococcal vaccines (PCV 13 and PPV 23) • Penicillin prophylaxis for children younger than 5 years of age • Annual influenza vaccine
Induction of fetal hemoglobin	• Hydroxyurea is the primary agent • Other agents are butyrates (arginine butyrate and sodium phenylbutyrate), decitabine, clotrimazole, and erythropoietin. Most not FDA approved • Combination HbF inducers have been proposed
Chronic transfusion therapy	• Primary indication: stroke prevention in pediatric patients • May also reduce pain crisis and acute chest syndrome • Goal: maintain HbS < 30% (0.30)
Emerging Therapies	
Transplantation	• May potentially cure the disease • Most experience is with HLA-matched donors; umbilical cord blood transplantation is being evaluated
L-Glutamine	• Decreases complications • FDA approved 2017
Voxelotor	• Increases hemoglobin • FDA approved 2019
Crizanlizumab	• Decreases vaso-occlusion • FDA approved 2019
Crises and Complications	
Fever and infection	• Broad-spectrum antibiotic: cefotaxime or ceftriaxone (clindamycin for cephalosporin allergy); vancomycin for staphylococcal and resistant pneumococcal organisms • Fluids
Stroke	• Acetaminophen or ibuprofen for fever • Exchange transfusion • Initiate chronic transfusion therapy to prevent recurrent strokes
Acute chest syndrome	• Broad-spectrum antibiotics (include Mycoplasma coverage) • Bronchodilator if wheezing or history of reactive airway disease • Fluids • Pain management • Transfusion
Pain crisis	• Hydration • Analgesics

should be given to children 3 to 5 years of age to ensure antibody response. This second dose should be administered 5 years after the first PPSV 23 dose. All adults with SCD should be vaccinated with both PCV 13 as well as PPSV 23. Adults and children who have not previously received PCV 13 or PPSV 23 should receive one dose of PCV 13 followed by a single dose of PPSV 23 at a minimum of 8 weeks later then an additional dose of PPSV 23 at least 5 years after the previous PPSV 23 dose.[7] If an adult or child with SCD has already received at least one dose of PPSV 23, they should additionally receive one dose of PCV 13 at least 1 year after the dose of PPSV 23.

Penicillin KEY CONCEPT Children with SCD should receive prophylactic penicillin until at least the age of 5 years, even if they have been appropriately immunized against pneumococcal infections. Penicillin V potassium is typically initiated at age 2 months, with a dose of 125 mg orally twice daily until age 3 years, then 250 mg orally twice daily until 5 years of age. Amoxicillin 20 mg/kg/day divided every 12 hours (maximum of 250 mg/dose) can also be used. The intramuscular use of benzathine penicillin 600,000 U every 4 weeks from age 6 months to 6 years is also an option for nonadherent patients. Penicillin-allergic patients may receive erythromycin 10 mg/kg twice daily. Penicillin prophylaxis usually is not continued in children older than 6 years but may be considered in patients with a history of invasive pneumococcal infection or surgical splenectomy.[4,10]

Folic Acid Folic acid supplementation with 1 mg daily is generally recommended in adult SCD patients, women considering pregnancy, and any SCD patient with chronic hemolysis.[4] Because of accelerated erythropoiesis, these patients have an increased need for folic acid. There are conflicting studies in the SCD population, especially among infants and children, but if the child has chronic hemolysis, supplementation is recommended.[11]

Fetal Hemoglobin Inducers HbF induction in patients with SCD, especially those with frequent crises, has been shown to decrease RBC sickling and RBC adhesion. A direct relationship between HbF concentrations and the severity of disease has been demonstrated in studies.[2]

Hydroxyurea Hydroxyurea is a ribonucleotide reductase inhibitor that prevents DNA synthesis and traditionally has been used in chemotherapy regimens. Studies in the 1990s found that hydroxyurea increases HbF levels as well as increasing the number of HbF-containing reticulocytes and intracellular HbF. Other beneficial effects of hydroxyurea include antioxidant properties, reduction of neutrophils and monocytes, increased intracellular water content leading to increased red cell deformability, decreased red cell

Patient Encounter 1

A 4-year-old girl with SCD is currently taking penicillin V potassium 125 mg orally twice daily, acetaminophen as needed for pain, loratadine 5-mg chewable tablet once daily for allergies, and a gummy multivitamin daily. She fully completed all her routine childhood vaccinations, including PCV 13, and is up to date. She was hospitalized at 9 months for dactylitis and also had tympanostomy tubes placed last year.

What are the general prophylaxis recommendations for children with SCD?

What interventions do you want to make today to her medication/immunization regimens?

Design an infection prevention plan for this patient.

adhesion to endothelium, and increased levels of nitric oxide, which is a regulator involved in physiologic disturbances.[12]

KEY CONCEPT Hydroxyurea reduced the frequency of hospitalizations and the incidences of pain, acute chest syndrome (ACS), and blood transfusions by almost 50% in a landmark trial in adult SCD patients with moderate-to-severe disease. Hemoglobin and HbF concentrations increased and hemolysis decreased.[12] A follow-up study demonstrated a 40% reduction in mortality over a 9-year period in patients continuing to receive hydroxyurea.[13] Not all patients responded equally; therefore, hydroxyurea may not be the best option for all patients.

The use of hydroxyurea in children and adolescents with SCD has shown similar results as in adult trials, with no adverse effects on growth and development.[4,14,15] Hydroxyurea is recommended for children with moderate-to-severe SCD and can be used in children as young as 6 months of age.[16]

The most common adverse effect of hydroxyurea is myelosuppression. Long-term adverse effects are unknown, but myelodysplasia, acute leukemia, and chronic opportunistic infections have been reported.[12] Hydroxyurea is teratogenic in high doses in animal studies and this is a concern, which should be addressed with patients. Normal pregnancies with no birth defects have been reported in some women receiving hydroxyurea, but close monitoring and weighing risk versus benefit to the patient are vitally important. Hydroxyurea is excreted in breast milk and should be avoided in lactating mothers.[12] Women of child-bearing years who take hydroxyurea should have a negative pregnancy test prior to starting hydroxyurea and should use reliable birth control during treatment.

Hydroxyurea should be considered in SCD with frequent vasoocclusive crises, repeated history of ACS, or other history of severe vasoocclusive crisis (VOC) complications.[4] The prevention of organ damage or reversal of previous damage has not been shown to occur with chronic use of hydroxyurea.[13] However, hydroxyurea treatment should be considered in all infants 9 months of age and older, as well as children and adolescents with SCD regardless of their clinical severity to reduce complications related to SCD.[17] The goals of therapy with hydroxyurea are to decrease the acute complications of SCD, improve quality of life, and reduce the number and severity of pain crises.

Hydroxyurea is available in 200-, 300-, 400-, and 500-mg capsules and as 1000-mg tablet. Extemporaneous liquid preparations can be prepared for children who cannot swallow capsules. Doses should start at 10 to 15 mg/kg daily in a single oral dose, which can be increased after 8 to 12 weeks if blood counts are stable, and there are no side effects. Individualize the dosage based on the patient's response and the toxicity seen. With close monitoring, doses can be increased by 5 mg increments up to 35 mg/kg/day.[12] In patients with renal failure, initial dosing of hydroxyurea will need to be adjusted according to the creatinine clearance, as shown in Table 71–2, with subsequent dosing titrated to response.

Closely monitor patients for efficacy and toxicity while they are receiving hydroxyurea. Monitor mean corpuscular volume (MCV), since it typically increases as the level of HbF increases. If the MCV does not increase with hydroxyurea use, the bone marrow may be unable to respond, the dose may not be adequate, or the patient may be nonadherent.[12] However, lack of increase in MCV or in HbF is not an indication to discontinue therapy; the clinical response to therapy may take 3 to 6 months. A 6-month trial on the maximum tolerated dose is required prior to consideration of discontinuation due to treatment failure, whether secondary to lack of adherence or failure to respond to therapy. HbF levels can also be monitored to assess response with a goal of increasing HbF to 15% to 20% (0.15–0.20). Assess blood counts every 2 weeks during dose titration and then every 4 to 6 weeks once the dose is stabilized. Temporary discontinuation of therapy is warranted if hemoglobin level is less than 4.5 g/dL (45 g/L or 2.79 mmol/L), absolute neutrophil count is less than $2 \times 10^3/\text{mm}^3$ (2×10^9/L), platelets are less than $80 \times 10^3/\text{mm}^3$ (80×10^9/L), or the reticulocytes are less than $80 \times 10^3/\text{mm}^3$ (80×10^9/L). Monitor for increases in serum creatinine and transaminases. Once the patient's blood counts have returned to baseline, hydroxyurea may be restarted with a dose that is 2.5 to 5 mg/kg less than the dose associated with the patient's toxicity. Doses may then be increased by 2.5 to 5 mg/kg daily after 12 weeks with no toxicity.

Administer prophylactic folic acid supplementation to SCD patients receiving hydroxyurea, because folate deficiency may be masked by the use of hydroxyurea.

5-Aza-2′-Deoxycytine (Decitabine) For patients who do not respond to hydroxyurea, or cannot tolerate the side effects of hydroyurea, 5-azacytidine, and 5-aza-2′-deoxycytidine (decitabine) may be considered, although it has not been approved by the FDA for this indication. Both induce HbF by inhibiting methylation of DNA, preventing the switch from γ- to β-globin production. Decitabine appears to be safer and more potent than 5-azacytadine. In a small study in adults refractory to hydroxyurea, decitabine 0.2 mg/kg subcutaneously one to three times weekly was associated with an increase in HbF in all patients. Additionally, RBC adhesion was reduced. Neutropenia was the only significant toxicity reported.[25]

L-Glutamine Therapy FDA approved to reduce acute complications of SCD in adults and children 5 years of age and older, L-glutamine is available as an oral powder that is administered twice daily based on body weight. The dose should be mixed immediately prior to administration with 8 oz of cold or room temperature water, milk or apple juice, or can be mixed into 4 to 6 oz of soft food, such as applesauce or yogurt. Clinical studies demonstrated significant decreases in the number of pain crises, vaso-occlusive crises hospitalizations, hospitalizations, ACS, and time to first sickle cell crisis. Adverse effects seen in studies included constipation, nausea, headache, and abdominal pain. A majority of the patients in clinical trials were also receiving hydroxyurea.[26]

Voxelotor In patients who are older than 12 years that are taking appropriately dosed hydroxyurea and continue to have vaso-occlusive crises, voxelotor is an FDA-approved option. Voxelotor

Table 71–2

Dosage Adjustments for Renal and Hepatic Dysfunction

Medication	Renal Adjustment	Hepatic Adjustment
Decitabine (Decagon)	For Scr ≥ 2 mg/dL (177 μmol/L): hold therapy until values return to baseline	For serum alanine transaminase (ALT), serum glutamic pyruvic transaminase (SGPT), or total bilirubin values more than two times the upper limit of normal: hold therapy until values return to baseline
Deferoxamine (Desferal)	Cl_{cr} 10–50 mL/min (0.17–0.83 mL/s): administer 25%–50% of usual dose Cl_{cr} < 10 mL/min (0.17 mL/s): do not use	No adjustment recommended
Deferasirox Children	> 33% increase in Scr (on two consecutive readings) and above the age-appropriate upper limits of normal: decrease daily dose by 10 mg/kg (Exjade) or 7 mg/kg (Jadenu) Scr ≥ 2 times age-appropriate upper limits of normal: discontinue treatment	Severe or persistent elevations in liver function tests: decrease the daily dose or discontinue therapy
Adults	> 33% increase in Scr above pretreatment values on two consecutive readings: decrease daily dose by 10 mg/kg (Exjade) or 7 mg/kg (Jadenu) CL < 40 mL/min (0.38 mL/s): discontinue treatment	Severe or persistent elevations in liver function tests: decrease the daily dose or discontinue therapy
Deferiprone	No adjustment necessary	No adjustment necessary
Folic acid	No adjustment necessary	No adjustment necessary
Hydroxyurea	Cl_{cr} < 60 mL/min (1.00 mL/s): initial dose of 7.5 mg/kg/day Hemodialysis: 7.5 mg/kg/day given after dialysis	Monitor patient for bone marrow toxicity
Voxelotor	No adjustment necessary	Child Pugh class C impairment: decrease dose to 1 g daily
Crizanlizumab	No adjustment necessary	No adjustment necessary

Data from Refs. [18-24,28,31].

inhibits HbS polymerization by binding to the alpha chain of HbS and increases oxygen binding. While voxelotor does not decrease VOC episodes, it does improve hemoglobin levels and reduces signs of hemolysis. It is administered once daily in oral doses of 1500 mg and can be given with or without hydroxyurea. Lower doses of 1000 mg should be given to patients with severe hepatic impairment. It is important to avoid concomitant inducers or inhibitors of hepatic CYP3A4 as there are a number of drug interactions. Adverse effects include headache, diarrhea, abdominal pain, and nausea.[27,28]

Crizanlizumab For patients who do not respond to hydroxyurea or L-glutamine, cirzanlizumab may help reduce vaso-occlusive pain crises. Crizanlizumab is a monoclonal antibody that acts against P-selectin, an adhesion molecule that is expressed on activated endothelial cells and platelets. It is FDA approved for patients greater than or equal to 16 years of age and administered as an infusion of 5 mg/kg over 30 minutes on week 0, week 2, and then every 4 weeks. The most common adverse effects include nausea, arthralgia, and fever. [29-31]

Chronic Transfusion Therapy Chronic transfusion therapy is warranted to prevent serious complications from SCD, including stroke prevention and recurrence. KEY CONCEPT Especially in children, chronic transfusions have been shown to decrease stroke recurrence from approximately 50% to 10% over 3 years. Without chronic transfusions, approximately 70% of ischemic stroke patients will have another stroke. Chronic transfusion therapy also may be used to prevent vasoocclusive pain and ACS, as well as prevent progression of organ damage.[4]

The goal of chronic transfusion therapy is to maintain the HbS level at less than 30% (0.30) of total hemoglobin concentration. Transfusions are usually administered every 3 to 4 weeks depending on the HbS concentration. For secondary stroke prevention, current studies have indicated that lifelong transfusion may be required, with increased incidence of recurrence once transfusions are stopped.[4,17]

The benefits of transfusion should be weighed with the risks. Risks associated with transfusions include alloimmunization (sensitization to the blood received), hyperviscosity, viral transmission, volume overload, iron overload, and transfusion reactions. Although the risk of contracting AIDS has decreased dramatically, hepatitis C remains a concern. All SCD patients should be vaccinated for hepatitis A and B and should be serially monitored for hepatitis C and other infections. Parvovirus occurs in 1 of every 40,000 U of RBCs and can be associated with acute anemia and multiple sickle cell complications.[4] Iron overload is a risk for patients maintained on chronic transfusions for more than 1 year. Counsel patients to avoid excessive dietary iron, and monitor serum ferritin regularly. Chelation therapy with deferoxamine, deferasirox, or deferiprone should be considered when the serum ferritin level is greater than 1500 to 2000 ng/mL (1500–2000 mcg/L; 3400–4500 pmol/L). Deferoxamine should be initiated at 20 to 40 mg/kg daily (to a maximum of 1–2 g/day) over 8 to 12 hours subcutaneously and has been associated with growth failure.[4] Monitor children receiving deferoxamine for adequate growth and development on a regular basis. Additionally, patients receiving deferoxamine should receive supplemental ascorbic acid starting 1 month after deferoxamine initiation; the ascorbic acid will increase the availability of iron for chelation. Patients with preexisting cardiac conditions should not receive ascorbic acid supplementation. Deferasirox is available in three dosage forms: a tablet (Exjade) that should be

Patient Encounter 2, Part 1

A 27-year-old African American woman with SCD is admitted to the hospital for progressive shoulder and chest pain that began 3 days ago. The patient denies injury. She complains of a nonproductive cough and a slight headache.

PMH: Sickle cell disease (HbSS); admitted for vasoocclusive crises twice over the past year; acute chest syndrome at ages 8, 9, 12, 15, 17, and 25; multiple blood transfusions

PSH: Cholecystectomy at age 13

FH: Father with SC trait. Mother with SCD.

Allergies: Sulfa drugs—hives

SH: Denies alcohol use. Is sexually active, recently married

Home Meds: Hydrocodone/Acetaminophen 7.5/325 mg two tablets every 6 hours as needed for pain; folic acid 1 mg daily by mouth; hydroxyurea 2 g orally once daily; levonorgestrel 90 mcg and ethinyl estradiol 20-mcg tablets once daily

PE:

VS: T 40.1°C (104.1°F), BP 113/62 mm Hg, P 80 beats/min, RR 29 breaths/min, O_2 Sat 96% (0.97) on 3 L nasal cannula, Ht 160 cm (5′3″), Wt 60 kg (134 lb)

Gen: Awake, alert × 3, in some distress, and obviously in pain

HEENT: Normocephalic, atraumatic. PERRLA. No lymphadenopathy

Chest: Normal to inspection and palpation. Moderate rales and wheezes

CV: RRR, no m/g/r

Abd: Soft, NT/ND

Ext: No clubbing, cyanosis, or edema. Shoulder pain with palpation

Neuro: Cranial nerves II through XII are grossly intact. Nonfocal

Labs: Hgb 6.8 g/dL (68 g/L or 4.22 mmol/L), Hct 20% (0.2 fraction), WBC 19 × 10^3/μL (19 × 10^9/L), BMP WNL

Chest X-ray shows pulmonary infiltrates.

What is your assessment of this patient's condition?

List treatment goals for this patient.

Devise a detailed therapeutic plan for this patient's hospital management.

dispersed in water, orange juice, or apple juice and taken orally 30 minutes before food, a tablet (Jadenu) that can be swallowed whole and granules (Jadenu Sprinkle) which are sprinkled on soft food.[32] Exjade should be initiated at 20 mg/kg once daily and titrated every 3 to 6 months by 5 to 10 mg/kg/day up to a maximum dose of 40 mg/kg/day. Jadenu and Jadenu Sprinkle should be initated at 14 mg/kg once daily and titrated every 3 to 6 months by 3.5 or 7 mg/kg/day to a maximum dose of 28 mg/kg/day. Exjade and Jadenu are not bioequivalent on an mg to mg basis because of bioavailability differences: when converting from one dosage form to the other, the dose for Jadenu should be about 30% less than the Exjade dose. For both products, the dose should be rounded to the whole tablet dosage form available. Exjade is available in 125, 250, and 500 mg dispersible tablets. Jadenu and Jadenu Sprinkle are available in 90-, 180-, and 360-mg tablets and packets. Deferiprone is approved for use in adults with thalassemia syndromes who have not responded adequately to other chelation therapies.[33] It is administered three times daily as an oral dosage form. Some recent studies have evaluated combination therapy for treatment of transfusion-associated iron overload. A synergistic effect has been demonstrated with the concomitant use of deferoxamine and deferiprone.[34] Monitor all chelation patients for auditory and ocular changes on a yearly basis. Exchange transfusions may also be helpful in cases of iron overload.

Patient Encounter 2, Part 2

The patient recovers from her hospitalization and comes to clinic for follow-up 2 weeks after discharge. She was discharged on her home medications. She has been feeling pretty well and her symptoms have returned to baseline. Routine laboratory tests indicate that her Clcr is now 35 mL/min/1.73 m^2 (0.33 mL/s/m^2) and her transaminases are slightly elevated. All her other laboratory values are within normal limits. She also indicates that she is interested in another form of birth control since she keeps forgetting to take her pills.

How should her medications be adjusted?

Sickle cell hemolytic transfusion reaction syndrome is a unique problem in SCD patients. Due to alloimmunization, an acute or delayed transfusion reaction may occur 5 to 20 days posttransfusion. Patients may develop symptoms suggestive of a pain crisis or worsening symptoms if they are already in crisis. A severe anemia after transfusion also may occur due to a rapid decrease in hemoglobin and hematocrit, along with a suppression of erythropoiesis. Further transfusions may worsen the clinical picture due to autoimmune antibodies. Recovery may occur only after ceasing all transfusions and is evidenced by a gradual increase in hemoglobin with reticulocytosis, which indicates the patient is now making their own RBCs.[4]

Allogeneic Hematopoietic Stem Cell Transplant Allogeneic hematopoietic stem-cell transplantation (HSCT) is the only potential cure for SCD. The best candidates are children with SCD who are younger than 16 years of age with severe complications, who have an identical human leukocyte antigen (HLA)-matched donor, usually a sibling. The transplant-related mortality rate is between 5% and 10%, and graft rejection is approximately 10%. In a recent review, the overall survival rate was 95% and the event-free survival was 92% in children with SCD who received a transplant from an HLA-matched sibling.[35] Other risks include secondary malignancies, development of seizures or intracranial bleeding, and infection in the immediate posttransplant period.[4,36]

Experience with HSCT in adult patients with SCD is still somewhat limited. The use of less intense preparative regimens has made HSCT more available for the older patient with SCD. The best results have been seen in the use of progenitor cells (from bone marrow, cord blood, or peripheral blood stem cells) from matched sibling or related donors. The largest published trial to date in adults undergoing nonmyeloablative transplant involved 30 patients with an 87% rate of disease-free survival.[36]

▶ *Acute Complications*

Transfusions for Acute Complications Red cell transfusion is indicated in patients with acute exacerbations of baseline anemia; in cases of severe vasoocclusive episodes, including ACS, stroke, and acute multiorgan failure; and in preparation for procedures that will require the use of general anesthesia or ionic contrast products. Transfusions also may be useful in patients with complicated obstetric problems, refractory leg ulcers, refractory and prolonged pain crises, or severe priapism. Hyperviscosity may occur if the hemoglobin level is increased to greater than 10.0 to 11.0 g/dL (100–110 g/L or 6.21–6.83 mmol/L). Volume overload leading to congestive heart failure is more likely to occur if the anemia is corrected too rapidly in patients with severe anemia and should be avoided.[4]

Infection and Fever KEY CONCEPT Any fever greater than 38.5°C (101.3°F) in an SCD patient should be immediately evaluated, and the patient should have a blood culture drawn and be started on antibiotics that provide empirical coverage for encapsulated organisms.[4]

Patients who should be hospitalized include the following:

- Infants younger than 1 year of age
- Patients with a previous sepsis or bacteremia episode
- Patients with temperatures in excess of 40°C (104°F)
- Patients with white blood cell (WBC) counts greater than $30 \times 10^3/\text{mm}^3$ ($30 \times 10^9/\text{L}$) or less than $0.5 \times 10^3/\text{mm}^3$ ($0.5 \times 10^9/\text{L}$) and/or platelets less than $100 \times 10^3/\text{mm}^3$ ($100 \times 10^9/\text{L}$) with evidence of other acute complications
- Acutely ill-appearing individuals

Broad IV antibiotic coverage for the encapsulated organisms can include ceftriaxone or cefotaxime. For patients with true cephalosporin allergy, clindamycin may be used. If staphylococcal infection is suspected due to previous history or the patient appears acutely ill, vancomycin should be initiated. Macrolide antibiotics, such as erythromycin or azithromycin, may be initiated if mycoplasma pneumonia is suspected. While the patient is receiving broad-spectrum antibiotics, their regular use of penicillin for prophylaxis can be suspended. Fever should be controlled with acetaminophen or ibuprofen. Because of the risk of dehydration during infection with fever, increased fluid may be needed.[1,4]

Bone infarcts or sickling in the periosteum usually is indicated by pain and swelling over an extremity. Osteomyelitis should also be considered. *Salmonella* species are the most common cause of osteomyelitis in children with SCD, followed by *Staphylococcus aureus*.[1] Select an appropriate antibiotic to cover the suspected organisms empirically.

Cerebrovascular Accidents Acute neurologic events, such as stroke, will require hospitalization and close monitoring. Patients should have physical and neurologic examinations every 2 hours.[4] Acute treatment may include exchange transfusion or simple transfusion to maintain hemoglobin at approximately 10.0 g/dL (100 g/L or 6.21 mmol/L) and HbS concentration at less than 30% (0.30). Patients with a history of seizure may need anticonvulsants, and interventions for increased intracranial pressure should be initiated if necessary. Children with history of stroke should be initiated on chronic transfusion therapy.[4]

Early detection of ischemic stroke can be done with the use of transcranial Doppler ultrasonography. In the Stroke Prevention Trial in Sickle Cell Anemia (STOP) study, screening with this method followed by chronic transfusion therapy significantly reduced the incidence of stroke.[37-39] Screening is recommended in all patients older than 2 years.

Clinical Presentation and Diagnosis of ACS in SCD

General

- Occurs in 15% to 43% of patients and is responsible for 25% of deaths
- Risk factors include young age, low HbF level, high Hgb and WBCs, winter seasons, reactive airway disease
- Recurrences are up to 80% and can lead to chronic lung disease

Symptoms

- Patients may complain of cough, fever, dyspnea, chest pain

Signs

- Temperature greater than 38.5°C (101.3°F)
- Hypoxia
- New infiltrate on chest X-ray

Laboratory Tests

- CBC with reticulocyte count
- Blood gases
- Oxygen saturation
- Cultures (blood and sputum)

Other

- Closely monitor pulmonary status

Acute Chest Syndrome ACS will require hospitalization for appropriate management of symptoms and to avoid complications. Patients should be encouraged to use incentive spirometry at least every 2 hours. Incentive spirometry helps the patient take long, slow breaths to increase lung expansion. Appropriate management of pain is important, but analgesic-induced hypoventilation should be avoided. Patients should maintain appropriate fluid balance because overhydration can lead to pulmonary edema and respiratory distress. Infection with gram-negative, gram-positive, or atypical bacteria is common in ACS, and early use of broad-spectrum antibiotics, including a macrolide, quinolone, or cephalosporin, is recommended. Fat emboli, from infarction of the long bones, may lead to ACS. Oxygen therapy should be utilized in any patient presenting with respiratory distress or hypoxia. Oxygen saturations, measured by pulse oximeter, should be maintained at 92% (0.92) or above. Exchange transfusions are often indicated when there is a rapid progression of ACS symptoms, such as increased needs for supplemental oxygen, increased respiratory distress, or progression of pulmonary infiltrates, and patients who present with wheezing may require inhaled bronchodilators.[4,40]

The use of corticosteroids is controversial. Although they may decrease the inflammation and endothelial cell adhesion seen with ACS, their use has also been associated with higher readmission rates for other complications.

Clinical Presentation and Diagnosis of Priapism in SCD

General

- Mean age of initial episode is 12 years of age
- Most male patients with SCD will have one episode by age 20
- Repeated episodes can lead to fibrosis and impotence

Symptoms

- Patients may complain of painful and unwanted erection lasting anywhere from less than 2 hours (stuttering type) to more than 2 hours (prolonged type)

Signs

- Urinary obstruction

Laboratory Tests

- CBC with reticulocyte count

Other

- Monitor for duration of episode
- Prolonged episodes should be considered medical emergencies

Priapism By age 18, approximately 90% of male patients with SCD will have had at least one episode of priapism. Stuttering priapism, where erection episodes last anywhere from a few minutes to less than 2 hours, resolves spontaneously. Erections lasting more than 2 hours should be evaluated promptly. Goals of therapy are to provide pain relief, reduce anxiety, provide detumescence, and preserve testicular function and fertility. Initial treatment should include aggressive hydration and analgesia. Transfusion may or may not be helpful but should be considered in anemic patients. Avoid the use of ice packs due to the risk of tissue damage.[4]

Both vasoconstrictors and vasodilators have been used in the treatment of priapism. Vasoconstrictors are thought to work by forcing blood out of the cavernosum and into the venous return. Aspiration of the penile blood followed by intracavernous irrigation with epinephrine (1:1,000,000 solution) has been effective with minimal complications.[37] In severe cases, surgical intervention to place penile shunts has been used, but there is a high failure rate, and the risk of complications, from skin sloughing to fistulas, limits its use.

Pseudoephedrine dosed at 30 to 60 mg daily taken at bedtime has been used to prevent or decrease the number of episodes of priapism.[4] Terbutaline 5 mg has been used orally to prevent priapism, with mixed results.[41,42] Leuprolide, a gonadotropin-releasing hormone, also has been used for this indication. Hydroxyurea may be helpful in some patients.[41,43] The use of antiandrogens is under investigation.[4]

▶ *Treatment of Acute Complications*

Aplastic Crisis Most patients in aplastic crisis will recover spontaneously, and therefore, treatment is supportive. If anemia is severe or symptomatic, transfusion may be indicated. Infection with human parvovirus B19 is the most common cause of aplastic crisis. Isolate infected patients because parvovirus is highly

Clinical Presentation and Diagnosis of Acute Aplastic Crisis in SCD

General

- Transient suppression of RBC production in response to bacterial or viral infection
- Most commonly due to infection with parvovirus B19

Symptoms

- Patients may complain of headache, fatigue, dyspnea, pallor, or fever
- Patients may also complain of upper respiratory or GI infection symptoms

Signs

- Temperature greater than 38.5°C (101.3°F) may occur
- Hypoxia
- Tachycardia
- Acute decrease in Hgb with decreased reticulocyte count

Laboratory Tests

- CBC with reticulocyte count
- Chest X-ray
- Parvovirus titers
- Cultures (blood, urine, and throat)

Clinical Presentation and Diagnosis of Sequestration Crisis in SCD

General

- Acute exacerbation of anemia due to sequestration of large blood volume by the spleen
- More common in patients with functioning spleens
- Onset often associated with viral or bacterial infections
- Recurrence is common and can be fatal

Symptoms

- Sudden onset of fatigue, dyspnea, and distended abdomen
- Patients may present with vomiting and abdominal pain

Signs

- Rapid decrease in Hgb and Hct with elevated reticulocyte count
- Splenomegaly
- May exhibit hypotension and shock

Evaluation

- Vital signs
- Spleen size changes
- Oxygen saturations
- CBC with reticulocyte count
- Cultures (blood, urine, throat)

contagious. Pregnant individuals should avoid contact with infected patients because midtrimester infection with parvovirus may cause hydrops fetalis and still birth.[1,4]

Sequestration Crisis RBC sequestration in the spleen in young children may lead to a rapid drop in hematocrit, resulting in hypovolemia, shock, and death. Treatment is RBC transfusion to correct the hypovolemia, as well as broad-spectrum antibiotics, because infections may precipitate the crisis.[1,4]

Recurrent episodes are common and can be managed with chronic transfusion and splenectomy. Observation is used commonly in adults because their episodes are milder. Splenectomy is usually delayed until after 2 years of age to lessen the risk of postsplenectomy septicemia. Patients with chronic hypersplenism should be considered for splenectomy.[4,44]

Vasoocclusive Pain Crisis The mainstay of treatment for VOC includes hydration and analgesia (Table 71–3). Pain may involve the extremities, back, chest, and abdomen. **KEY CONCEPT** Patients with mild pain crisis may be treated as outpatients with rest, warm compresses to the affected (painful) area, increased fluid intake, and oral analgesia. Patients with moderate-to-severe crises should be hospitalized. Infection should be ruled out because it may trigger a pain crisis, and any patient presenting with fever or critical illness should be started on empirical broad-spectrum antibiotics. Patients who are anemic should be transfused to their baseline. IV or oral fluids at 1.5 times maintenance are recommended. Close monitoring of the patient's fluid status is important to avoid overhydration, which can lead to ACS, volume overload, or heart failure.[4]

Aggressive pain management is required in patients presenting in pain crisis. Assess pain on a regular basis (every 2–4 hours), and individualize management to the patient. The use of pain scales may help with quantifying the pain rating. Obtain a good medication history of what has worked well for the patient in the past. Use acetaminophen or a nonsteroidal anti-inflammatory drug (NSAID) for treatment of mild-to-moderate pain. Patients with bone or joint pain who require IV medications may be helped by the use of ketorolac, an injectable NSAID. Because of the concern for side effects, including GI bleeding, ketorolac should be used only for a maximum of 5 consecutive days.

Table 71–3

Management of Acute Pain of SCD

Principles

Treat underlying precipitating factors.
- Avoid delays in analgesia administration.
- Use pain scale to assess severity.
- Choice of initial analgesic should be based on previous pain crisis pattern, history of response, current status, and other medical conditions.
- Schedule pain medication; avoid as-needed dosing.
- Provide rescue dose for breakthrough pain.
- If adequate pain relief can be achieved with one or two doses of morphine, consider outpatient management with a weak opioid; otherwise hospitalization is needed for parenteral analgesics.
- Frequently assess to evaluate pain severity and side effects; titrate dose as needed.
- Treating adverse effects of opioids is part of pain management.
- Consider nonpharmacologic intervention.
- Transition to oral analgesics as the patient improves; choose an oral agent based on previous history, anticipated duration, and ability to swallow tablets; if sustained-release products are used, a fast-release product is also needed for breakthrough pain.

Analgesic Regimens

Mild-to-moderate pain:

Hydrocodone + acetaminophen:
- Dose based on hydrocodone—children: 0.2 mg/kg per dose every 6 hours; adults: 5–10 mg/dose

Anti-inflammatory agents:
- Use with caution in patients with renal failure (dehydration) and bleeding
- Ibuprofen (oral): children: 10 mg/kg every 6–8 hours; adults: 200–400 mg/dose
- Naproxen: 5 mg/kg every 12 hours; adults: 250–500 mg/dose
- Ibuprofen + hydrocodone: Each tablet contains 200 mg ibuprofen and 7.5 mg hydrocodone per tablet; only for older children who can swallow tablets

Moderate-to-severe pain:

Morphine—children:
- 0.1–0.15 mg/kg per dose every 3–4 hours; adults: 5–10 mg/dose
- Continuous infusion: 0.04–0.05 mg/kg/hour; titrate to effect

Hydromorphone—children:
- 0.015 mg/kg per dose every 3–4 hours; adults: 1.5–2 mg/dose
- Continuous infusion: 0.004 mg/kg/hour; titrate to effect

IV anti-inflammatory agents:
- Ketorolac: 0.5 mg/kg up to 30 mg/dose every 6 hours

Patient-controlled analgesics:
- Morphine: 0.01–0.03 mg/kg/hour basal; demand 0.01–0.03 mg/kg every 6–10 minutes; 4 hours lockout 0.04–0.06 mg/kg
- Hydromorphone: 0.003–0.005 mg/kg/hour basal; demand 0.003–0.05 mg/kg every 6–10 minutes; 4 hours lock out 0.4–0.6 mg/kg

Clinical Presentation and Diagnosis of Vasoocclusive Crisis in SCD

General

- Most often involves the bones, liver, spleen, brain, lungs, and penis
- Precipitating factors include infection, extreme weather conditions, dehydration, and stresses
- Recurrent acute crises result in bone, joint, and organ damage and chronic pain

Symptoms

- Patients may complain of deep throbbing pain, local tenderness

Signs

- Erythema and swelling of painful area
- Dactylitis in young infants
- Temperature greater than 38.5°C (101.3°F)
- Leukocytosis

Laboratory tests

- CBC with reticulocyte count
- Urinalysis
- Abdominal studies (if symptoms exist)
- Cultures (blood and urine)
- Liver function tests and bilirubin
- Chest X-ray

Monitor the total amount of acetaminophen given daily, because many products contain acetaminophen. Maximum daily dose of acetaminophen for adults is 3 g/day, and for children, five doses over a 24-hour period.[45] Add an opioid if pain persists or if pain is moderate-to-severe in nature. Combining an opioid with an NSAID can enhance the analgesic effects without increasing adverse effects.[46-49]

Severe pain should be treated with an opioid such as morphine, hydromorphone, methadone, or fentanyl. Moderate pain can be effectively treated in most cases with a weak opioid such as codeine or hydrocodone, usually in combination with acetaminophen. Meperidine should be avoided because of its relatively short analgesic effect and its toxic metabolite, normeperidine. Normeperidine may accumulate with repeated dosing and can lead to CNS side effects including seizures.

IV opioids are recommended for treatment of severe pain because of their rapid onset of action and ease in titration. Intramuscular injection should be avoided. Analgesia should be individualized and titrated to effect, either by scheduled around-the-clock doses or continuous infusion. The use of continuous infusion will avoid fluctuations in blood levels between doses observed with bolus dosing. As-needed dosing of analgesia is only appropriate for breakthrough pain or uncontrolled pain. Patient-controlled analgesia (PCA) is commonly used and allows the patient to have control over his or her analgesic breakthrough dosing. As the pain crisis resolves, the pain medications can be tapered. Physical therapy and relaxation therapy can be helpful adjuvants to analgesia.[46–47]

Tolerance to opioids is seen when patients have had continuous long-term use of the medications and can be managed during acute crises by using a different potent opioid or using a larger dose of the same medication. Adverse effects associated with the use of opioids include respiratory depression, itching, nausea and vomiting, constipation, and drowsiness. Patients on continuous infusions of opioids should be on continuous pulse oximeter to assess oxygen saturations. Monitor the patient for oxygen saturations less than 92% (0.92). Oxygen should be administered as needed to keep the saturation above 92% (0.92). Itching can be managed with an antihistamine such as diphenhydramine. Nausea and vomiting can be treated and managed with the administration of antiemetics such as promethazine or 5HT3 antagonists, but the use of promethazine is contraindicated in children younger than 2 years of age. Assess stool frequency in all patients on a continuous opioid, and start stool softeners or laxatives as needed. Excessive sedation is difficult to control, and the concurrent use of an opioid with diphenhydramine or other sedative medications can exacerbate the drowsiness, leading to hypoxemia. A continuous very low dose of naloxone, an opioid antagonist, has been used successfully when the adverse effects such as itching are unbearable.[50]

As patients age and their SCD advances, most will present with some level of chronic pain, which should be treated with the lowest dose of oral analgesic, typically a combination of hydrocodone and acetaminophen on an as-needed basis. Neuropathic pain can result from repeated vaso-occlusive crises and may require the regular use of medications such as gabapentin, amitriptyline, or pregabalin.

OUTCOME EVALUATION

SCD treatment and prevention are considered successful when complications are minimized. The major outcome parameters are a decrease in morbidity and mortality, measured by the number of hospitalizations, and the extent of end-organ damage seen over time. Today, with longer survival for SCD, chronic manifestations of the disease contribute to the morbidity later in life (Table 71–4). Thirty years ago, complications from SCD contributed to high mortality. It was estimated that approximately 50% of patients with SCD did not survive to reach adulthood.[1] Since that time, data suggest improvement in mortality rates for patients with SCD. The survival age for individuals with HbSS has increased to at least the fifth decade of life. Recent reports suggest 85% survival to 18 years of age.[4] SCD is a chronic disease and cannot be cured, except in some patients with transplant.

Starting with birth, SCD patients should have regularly scheduled health assessments and interventions when necessary. Obtain a urine analysis, complete blood count, liver function tests, ferritin or serum iron level and total iron-binding capacity, blood urea nitrogen (BUN), and creatinine on at least a yearly basis and more often for children younger than 5 years of age to monitor for complications. All SCD patients should have regular screening of their hearing and vision.

All patients and parents of children with SCD should have a plan for what to do in the event of symptoms of infection or pain. Obtain a medication history when patients are admitted to the hospital. Assess adherence with prophylactic penicillin and childhood immunization schedules in all pediatric SCD patients.

Table 71–4

Chronic Complications of SCD

System	Complications
Auditory	Sensorineural hearing loss due to sickling in cochlear vasculature with hair cell damage
Cardiovascular	Cardiomegaly, myocardial ischemia, murmurs, and abnormal ECG; patients with SCD have lower BP than the normal population; normal BP values for SCD should be used for diagnosis of hypertension ("relative" hypertension); heart failure usually is related to fluid overload
Dermatologic	Painful leg ulcers; failure to heal occurs in 50% of patients; recurrences are common
Genitourinary	Renal papillary necrosis, hematuria, hyposthenuria, proteinuria, nephrotic syndrome, tubular dysfunction, chronic renal failure, impotence, priapism
Growth and development	Delay in growth (weight and height) and sexual development; decreased fertility; increased complications during pregnancy; depression may be more prevalent than in general population, especially in patients with unstable disease
Hepatic and biliary	Cholelithiasis, biliary sludge, acute and chronic cholecystitis, and cholestasis (can be progressive and life-threatening)
Neurologic	"Silent" brain lesions on MRI are associated with poor cognitive and fine motor functions; pseudotumor cerebri (rare)
Ocular	Retinal or vitreous hemorrhage, retinal detachment, transient or permanent visual loss; central retinal vein occlusion
Pulmonary	Pulmonary fibrosis, pulmonary hypertension, cor pulmonale
Renal	Hematuria, hyposthenuria (inability to concentrate urine maximally), tubular dysfunction, enuresis during early childhood, acute renal failure can also occur
Skeletal	Aseptic necrosis of ball-and-socket joints (shoulder and hip); prostheses may be needed due to permanent damage; bone marrow hyperplasia resulting in growth disturbances of maxilla and vertebrae
Spleen	Asplenia (autosplenectomy or surgical splenectomy)

Patient Care Process

Collect Information:

- Perform a medication history for use of prescription and nonprescription medications and dietary supplements. Identify allergies to medications and other substances.
- Review the medical history and physical assessment findings.
- Speak with the patient and review records to identify lifestyle habits, preferences and beliefs, health goals, and socioeconomic factors that affect medication access and other aspects of care.
- Review available laboratory tests.

Assess the Information:

- Based on physical examination and review of systems, determine whether the patient is experiencing any signs or symptoms of an acute or chronic SCD complication (Tables 71–1 and 71–4).
- Assess the safety, efficacy, and patient adherence of current pharmacotherapy.
- Identify any significant adverse drug effects or interactions.
- Assess the patient's medication history. Does the patient take any medications routinely for SCD? Which analgesics have been helpful to the patient in the past? Are they taking appropriate doses to achieve the desired effect? If not, why?
- Determine if the patient is up to date on their immunizations. Have they received their annual influenza vaccine? Are they missing any vaccines?

Develop a Care Plan:

- Choose medications and doses that are optimal for the patient.
- Select lifestyle modifications that are likely to be effective and safe for the patient.
- Determine whether drug doses are optimal.
- If the patient is having an acute complication of SCD, arrange for referral and/or admission to the hospital.

Implement the Care Plan:

- Educate the patient about changes in drug therapy, medication administration, potential new adverse effects, and how to manage and report adverse effects that occur.
- Address any patient concerns about SCD and its management.
- Discuss the importance of medication adherence and lifestyle modifications to prevent complications of SCD.
- Determine if the patient has prescription coverage or whether recommended agents are included on the institution's formulary.
- Arrange for vaccination if the patient is not up to date with recommendations.

Follow-up: Montor and Evaluate:

- Follow-up at monthly intervals or more frequently to assess effectiveness and safety of therapy, avoid complications from SCD, and improve quality of life for the patient.
- Review medication history and physical examination findings, laboratory tests, and results of other diagnostic tests.
- Assess for adverse effects from medications that the patient is taking.
- Stress the importance of adherence with the therapeutic regimen. Adjust therapeutic regimens as needed based on patient response and adverse effects.

Abbreviations Introduced in This Chapter

ACS	Acute chest syndrome
CNS	Central nervous system
HbA	Adult hemoglobin
HbAS	One normal and one sickle hemoglobin gene
HbC	Hemoglobin C
HbF	Fetal hemoglobin
HbS	Sickle hemoglobin
HbSβ^0-thalassemia	One sickle hemoglobin and one β^0-thalassemia gene
HbSβ^+-thalassemia	One sickle hemoglobin and one β^+-thalassemia gene
HbSC	One sickle hemoglobin and one hemoglobin C gene
HbSS	Homozygous sickle hemoglobin
Hgb	Hemoglobin
HLA	Human leukocyte antigen
HSCT	Hematopoietic stem-cell transplantation
ISC	Irreversibly sickled cell
MCV	Mean corpuscular volume
MenACWY	Quadrivalent meningococcal vaccine
NSAID	Nonsteroidal anti-inflammatory drug
PCA	Patient-controlled analgesia
PCV 13	13-Valent pneumococcal conjugate vaccine
PPV 23	23-Valent pneumococcal polysaccharide vaccine
SCA	Sickle cell anemia
SCD	Sickle cell disease
SCT	Sickle cell trait
STOP	Stroke Prevention Trial in Sickle Cell Anemia
VOC	Vasoocclusive crisis
WBC	White blood cell

Patient Assessment, Antimicrobial Selection, and Stewardship

Angharad Ratliff and Catherine Oliphant

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Describe how antimicrobials differ from other drug classes in terms of their effects on individual patients as well as on society as a whole.
2. Recognize that antimicrobial resistance is an inevitable consequence of antimicrobial therapy.
3. Identify guiding principles to consider when treating patients with antimicrobials, and apply these principles in patient care.
4. Differentiate between microbial colonization and infection based on patient history, physical examination, and laboratory and culture results.
5. Evaluate and apply drug-specific considerations when selecting antimicrobial therapy.
6. Evaluate and apply patient-specific considerations when selecting antimicrobial therapy.
7. Identify and apply principles of patient education and monitoring response to antimicrobial therapy.
8. Discuss causes of patients failing to improve while on antimicrobials.
9. Define antimicrobial stewardship and describe the purpose of such a program.

INTRODUCTION

Antimicrobials are among the most commonly prescribed medications. Antimicrobial is a broad term referring to agents including antibiotics, antivirals, antiprotozoals, and antifungals. In this chapter, we will refer primarily to antimicrobials; however, when an example is specific to the antibiotic class or treatment of a bacterial infection, the term antibiotic will be used. KEY CONCEPT Antimicrobials are different from other classes of pharmaceuticals because they exert their action on microbes infecting the host as opposed to acting directly on the host. Today, there are many antimicrobials available for clinical use. However, in many cases, differences in mechanisms of action between antimicrobials are minor, and the microbiologic properties of the agents are similar. An estimated 50% of hospitalized patients will receive an antimicrobial and about 10% of ambulatory care visits are associated with an antibiotic prescription; however, antimicrobial use is not without risk.[1,2] KEY CONCEPT An inevitable consequence of exposing microbes to antimicrobials is that some organisms will develop resistance to the antimicrobial. The CDC's 2019 Antibiotic Resistance Threats in the United States estimates more than 2.8 million patients per year are infected with resistant pathogens resulting in approximately 35,000 deaths.[3] For several decades, infectious disease–related mortality in the United States has increased, in part owing to increases in antimicrobial resistance. Because antimicrobial use in one patient affects not only that patient but also other patients if they become infected with resistant bacteria, correct selection, use, and monitoring of clinical response are paramount. Antimicrobial stewardship programs promote the optimal use of antimicrobials and the concepts of these programs will be discussed in this chapter.

KEY CONCEPT There are two guiding principles to consider when treating patients with antimicrobials: (a) do no harm and (b) make the correct diagnosis! Patients with infections frequently present with signs and symptoms that are nonspecific and may be confused with other noninfectious diseases. Not only is it important to determine whether a disease process is of infectious origin, but it is also important to determine the specific causative pathogen of the infection. Antimicrobials vary in their spectrum of activity and their ability to inhibit or kill different species of bacteria. Antimicrobials that kill many different species of bacteria are called broad-spectrum antimicrobials, whereas antimicrobials that kill only a few species of bacteria are called narrow-spectrum antimicrobials. One might argue that treating everybody with broad-spectrum antimicrobials will increase the likelihood that a patient will get better even without knowing the bacteria causing infection. However, counter to this argument is the principle of "Do no harm!" Broad antimicrobial overage does increase the likelihood of empirically targeting the causative pathogen; unfortunately, this increases the risk of selecting for antimicrobial-resistant pathogens, which can lead to secondary infections. In addition, adverse events resulting from antibiotic therapy represent 16% of all emergency room visits for adverse drug events; this rate is similar to high-risk medications such as warfarin, digoxin, or insulin.[4] Antibiotics account for roughly one-third of all emergency department visits for adverse events due to systemically administered medications.[1] Therefore, the overall goal of antimicrobial therapy should be to cure the patient's infection; limit harm by minimizing patient risk for adverse events, including secondary infections; and limit societal risk from antimicrobial-resistant bacteria.

PATHOPHYSIOLOGY

Microbiome

Many areas of the human body are colonized with microbes—this is known as the microbiome. Knowing what organisms reside where can help guide empiric antimicrobial therapy (Figure 72–1 describes the microbiome by location). In addition, it is beneficial to know what anatomic sites are normally sterile. These include the cerebrospinal fluid, blood, and urine.

Determining Colonization Versus Infection

Infection refers to the presence of bacteria that are causing disease. Colonization refers to the presence of bacteria that are not causing disease. **KEY CONCEPT** It is important to differentiate infection from colonization because antimicrobial therapy targeting colonization is inappropriate and may lead to the emergence of resistant bacteria.

Endogenous Infection

Infections often arise from one's own microbiome, referred to as an **endogenous infection**. Endogenous infection may occur when there are disruptions of host defenses such as a break or entry in the skin or alterations in the microbiome due to recent antimicrobial use. Endogenous infections can also occur as a result of reactivation of a dormant infection such as tuberculosis or herpes virus infections.

Exogenously Acquired Bacterial Infections

Infections acquired from an external source are referred to as exogenous infections. These infections may occur as a result of human-to-human transmission, contact with exogenous bacterial populations in the environment, and animal contact. Obtaining a patient history is key to knowing what pathogens a patient is at risk for. A thorough patient history should include a review of the patient's recent travel and social history, antibiotic use and recent health care exposure. Clinical presentation should guide the aspects of patient history that are relevant to the infection. Treatment guidelines also recommend an assessment of a patient's risk factors for more resistant pathogens when selecting initial or empiric antimicrobial therapy. Resistant pathogens such as methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant *Enterococcus* spp (VRE) may colonize hospitalized patients or patients who access the health care system frequently. It is important to know which patients have acquired these organisms because patients generally become colonized prior to developing infection, and colonized patients may be placed in isolation to minimize transmission.

CLINICAL PRESENTATION AND DIAGNOSIS

Physical Examination

Findings on physical examination such as rales, altered mental status, localized inflammation, erythema, warmth, edema, pain, and pus, along with the clinical presentation, can help identify the anatomic location of the infection. Once the anatomic site is identified, the most probable pathogens associated with disease can be determined based on likely endogenous or exogenous flora.

Fever often accompanies infection and is defined as a rise in body temperature above the normal 37°C (98.6°F). Fever can be a host response to bacterial pathogens. However, bacterial

FIGURE 72–1. Microbiome.

Clinical Presentation

- Review of symptoms consistent with an infectious etiology.
- Signs and symptoms may be nonspecific (eg, fever) or specific.
- Signs and symptoms that are disease-state specific are reviewed in disease state–specific chapters.

Patient History

- History of present illness (HPI)
- Comorbidities
- Current medications
- Allergies
- Previous antibiotic exposure
- Previous hospitalization or health care utilization
- Travel history
- Social history
- Pet/animal exposure
- Occupational exposure
- Environmental exposure
- Dietary exposure

Physical Findings

- Vital signs
- Physical examination

Diagnostic Imaging

- X-rays
- CT scans
- MRI

Other Nonmicrobiological Laboratory Studies:

- White blood cell count (WBC) with differential
- Erythrocyte sedimentation rate (ESR)
- C-reactive protein (CRP)
- Procalcitonin

Microbiologic Studies: (should be site-specific based on presumed source of infection)

- Gram stain
- Culture and susceptibility testing
    - Rapid diagnostic tests

infections are not the sole cause of fever. Fever also may be caused by fungal or viral infections, or noninfectious etiologies such as medications (eg, penicillins, cephalosporins, salicylates, and phenytoin), trauma, or other medical conditions (eg, autoimmune disease, malignancy, pulmonary embolism, and hyperthyroidism). Some patients with overwhelming infections may present with hypothermia. Certain patients may present as afebrile, including the elderly or those with localized infections, such as uncomplicated urinary tract infections (UTI).[5] For others, fever may be the only indication of infection. Fever may be the only finding in neutropenic patients who may not have the ability to mount a normal immune response to infection that can be identified through routine diagnostics.[6]

Imaging Studies

Imaging studies may help to identify the anatomic location of the infection. These studies are usually performed in conjunction with other tests to establish or rule out the presence of an infection. Chest x-rays are performed commonly to establish the diagnosis of pneumonia, as well as the severity of disease. Computed tomography (CT) or magnetic resonance imaging (MRI) may also be obtained when the source of infection is not easily identified by more cost-effective means such as an x-ray (Table 72–1). For more information regarding specific infections, review the chapters for individual infections.

Nonmicrobiological Laboratory Studies

Nonmicrobiological laboratory tests include the white blood cell count (WBC) and differential, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and procalcitonin levels (Table 72–1). In most cases, the WBC count is elevated (**leukocytosis**), in response to infection, but it may be decreased (**leukopenia**), owing to overwhelming or long-standing infection or diminished host response. The differential is the percentage of each type of WBC (Table 72–2). In response to physiologic stress, neutrophils leave the bloodstream and enter the tissue to "fight" against the offending pathogens resulting in leukocytosis. It is important to recognize that leukocytosis is nonspecific for infection and may temporarily occur in response to noninfectious conditions such as acute myocardial infarction or medications such as steroids. During an infection, bands or immature neutrophils are released at an increased rate to help fight infection, this leads to a "bandemia" or **"left shift."** The WBC count differential is key to determining whether an infection is present as some, particularly elderly, patients may present with a normal total WBC with a left shift. ESR and CRP are nonspecific markers of inflammation that increase as a result of the acute-phase reactant response, which is a response to inflammatory stimuli such as infection or tissue injury. These tests may be used as markers of clinical response because they are elevated when the

disease is acutely active and usually fall in response to successful treatment. This is particularly relevant in infections such as osteomyelitis and infective endocarditis where it is difficult to monitor response to therapy. These tests should not be used to diagnose infection because they may be elevated in noninfectious inflammatory conditions. Procalcitonin, a prohormone of calcitonin, is rapidly produced in response to bacterial infection. More recent data suggests that procalcitonin serum levels, in conjunction with clinical findings, may be a tool to assess when antibiotic therapy may be safely discontinued. American Thoracic Society/Infectious Disease Society of America guidelines on hospital/ventilator associated pneumonia suggest that procalcitonin levels may be used in addition to clinical criteria to guide antimicrobial discontinuation. Additionally, the Surviving Sepsis Guidelines recommend procalcitonin as an adjunctive tool for antibiotic discontinuation in patients without other indicators of infection.[7,8] However, procalcitonin should not be used as an indicator for antimicrobial therapy initiation. Community-acquired pneumonia (CAP) guidelines, also from the American Thoracic Society/Infectious Disease Society of America, recommend that the determination for antibiotic therapy be based off of clinically and radiologically confirmed CAP regardless of procalcitonin.[9]

Patient Encounter 1

HPI: BD is a 56-year-old woman with a 4-day history of an initial dry cough that is now productive, shortness of breath, fevers of 37.8°C to 38.7°C (100°F–101.7°F), malaise, and new right-sided chest pain. She also reports reduced oral intake due to feeling so poorly. She thought she had a cold but now feels significantly worse despite taking over-the-counter cough and cold medication and acetaminophen. Her past medical history includes diabetes, hypertension, hyperlipidemia, and hypothyroidism. She has a history of recurrent urinary tract infections and has received multiple antimicrobials in the previous 6 months including levofloxacin 3 weeks ago.

Allergies: NKDA

Meds:

Metformin 1000 mg ER PO twice daily

Sitagliptin 100 mg PO daily

Hydrochlorothiazide 25 mg PO daily

Lisinopril 10 mg PO daily

Atorvastatin 20 mg PO daily

Levothyroxine 100 mcg PO daily

Nyquil Cold & Flu Nighttime Relief (acetaminophen, dextromethorphan, and doxylamine)

Acetaminophen 500–1000 mg PO Q6–8 hours

What information in the history supports an infectious etiology?

Is this patient at risk for resistant pathogens? Why?

Microbiologic Studies

Microbiologic studies that allow for direct examination of a specimen may aid in a presumptive diagnosis and give an indication of the characteristics of the infecting organism. Specimens that may be collected for culture may include sputum, blood, or urine.

A Gram stain of collected specimens can give rapid information that can be applied immediately to patient care. A Gram stain may identify whether bacteria are present and determine bacterial morphologic characteristics (eg, gram-positive or gram-negative and shape—cocci, bacilli, coccobacilli). The presence of WBCs on a Gram stain indicates inflammation and suggests that the identified bacteria are pathogenic. The Gram stain may be useful in evaluating a sputum specimen's adequacy. For example, the presence of epithelial cells on sputum Gram stain suggests that the specimen is either poorly collected or contaminated. A poor specimen can give misleading information regarding the underlying pathogen and may result in inappropriate antimicrobial use. Certain bacterial specimens do not stain well or at all and must be identified by alternative staining techniques. Some examples of these specimens are *Mycoplasma* spp., *Legionella* spp., and *Mycobacterium* spp. Figure 72–2 identifies bacterial pathogens classified by Gram stain and morphologic characteristics.

Culture and susceptibility testing provide additional information to the clinician to select appropriate therapy. When a pathogen is identified, susceptibility tests can be performed to various antimicrobial agents. The minimum inhibitory concentration (MIC) is a standard susceptibility test. The MIC is the lowest concentration of antimicrobial that inhibits visible bacterial

FIGURE 72–2. Important bacterial pathogens classified according to Gram stain and morphologic characteristics. (From Werth et al,. Laboratory tests to direct antimicrobial pharmacotherapy. In: DiPiro JT, Talbert RL, Yee GC, et al, eds. Pharmacotherapy: A Pathophysiologic Approach, 11th ed. New York, NY: McGraw-Hill; 2020.)

growth after approximately 24 hours. Breakpoint and MIC values determine whether the organism is susceptible (S), intermediate (I), or resistant (R) to an antimicrobial. If the MIC is below the breakpoint, the organism is considered to be susceptible to that agent. If the MIC is above the breakpoint, the organism is said to be intermediate or resistant. Reported culture and susceptibility results may not provide MIC values but generally report the S, I, and R results. When reviewing culture and susceptibility reports, it is important to also consider the other factors discussed in this chapter when selecting an antibiotic. Additionally, susceptibility reports generally only report one in a class of drugs and may not represent all available and appropriate treatment options.

KEY CONCEPT In general, bacterial cultures should be obtained prior to initiating antimicrobial therapy in patients with a systemic inflammatory response, risk factors for antimicrobial resistance, or infections where diagnosis or pathogen is uncertain. The decision to collect a specimen for culture depends on the physical and diagnostic findings, and whether or not the pathogens are readily predictable. For example, culture and susceptibility testing usually is not warranted in a young; otherwise, healthy woman who presents with signs and symptoms consistent with a UTI because the primary pathogen, *Escherichia coli*, is readily predictable. Conversely, cultures and susceptibility testing are routine for sterile-site specimens such as blood or spinal fluid in a patient with concerns for meningitis as well as for material from joints or abscesses that is presumed to be infected.

Rapid diagnostic tests are tools that can quickly identify pathogens and certain antimicrobial resistance patterns in minutes to hours. This can lead to the use of more effective and targeted antimicrobial therapy and reduce unnecessarily prolonged empiric antimicrobial therapy. These tests are best utilized in conjunction with an antimicrobial stewardship team who can properly interpret, assess, and apply to the patient. Studies have shown teamwork between the microbiology lab and antimicrobial stewardship can lead to improved clinical outcomes and reduction in unnecessary antimicrobial use.[10] Available rapid diagnostic tests include, but are not limited to, staphylococcus species, Group A *Streptococcus*, enterococcus, *Clostridioides difficile*, influenza, common respiratory viral pathogens, and extended-spectrum beta-lactamase or carbapenemase-producing Enterobacterales (formerly Enterobacteriaceae). For example, a rapid diagnostic test that can distinguish a coagulase negative staphylococcus from *Staphylococcus aureus* in blood cultures may allow for discontinuation of vancomycin if coagulase negative staphylococcus is deemed to be a contaminant rather than a true pathogen. With conventional cultures, this identification could take up to 2 to 4 days, during which the patient could be receiving suboptimal or inappropriate antimicrobial therapy.

TREATMENT

General Approach to Treatment, Including Nonantimicrobial Treatment

While antimicrobial therapy selection may be a major consideration in treating infectious diseases, it may not be the only therapeutic intervention. Other important therapies may include hydration, ventilatory support, supportive medications, and source control. Source control can be equally or more important than antimicrobials for the treatment of certain infectious diseases. Source control could involve drainage of an abscess or removal of infected tissue or prosthetic materials, such as catheters.

Antimicrobial Considerations in Selecting Therapy

When selecting antimicrobial therapy, it is important to recognize that there are many different antimicrobial regimens that will treat the infection. However, the optimal therapy will address both drug-specific and patient-specific factors to maximize therapeutic efficacy while minimizing potential adverse effects. The following therapy sections provide general factors to consider when selecting antimicrobial regimens. However, excellent and more in-depth resources for selecting specific antimicrobial regimens for a variety of infectious diseases are available through the guidelines developed by national or international organizations, such as the Infectious Diseases Society of America.[11]

KEY CONCEPT Drug-specific considerations in antimicrobial selection include spectrum of activity, collateral damage as it applies to effects on the microbiome, appropriate dose, pharmacokinetic and pharmacodynamic properties, adverse-effect and drug-interaction profile, and cost (Table 72–3).

Table 72–3

Considerations for Selecting Antimicrobial Regimens

Drug-Specific	Patient-Specific
Spectrum of activity and effects on microbiome	Anatomic location of infection
Dosing	Antimicrobial history
Pharmacokinetic properties	Drug allergy history
Pharmacodynamic properties	Renal and hepatic function
Adverse-effect potential	Concomitant medications
Drug-interaction potential	Pregnancy or lactation
Cost	Compliance potential

▶ *Spectrum of Activity*

Initial antimicrobial therapy should target the most likely pathogens based upon infection site as well as local resistance patterns based upon antibiograms. Because of the time required for cultures to identify a pathogen, most initial antimicrobial therapy is empiric. Prompt initiation of appropriate therapy is paramount in hospitalized patients with suspected infection, especially those who are critically ill. Patients who receive appropriate initial antimicrobial therapy survive at twice the rate of patients who receive inadequate therapy.[12] Empiric selection of antimicrobial spectrum of activity should be based on the pathogens most likely causing the infection as well as the severity of the illness. As acutely ill

Patient Encounter 2: Review of Symptoms, Physical Examination, and Laboratory Data

ROS: She has been experiencing a productive cough, shortness of breath, fevers, and chest pain. She denies urinary urgency or pain upon urination, nausea, or vomiting.

PE:

VS: BP 156/88 P110, RR 28, T 38.8°C, O_2 saturation on room air 86%, Ht 5 ft 2 in (157.5 cm), Wt 82 kg

Chest: Rhonchi with decreased breath sounds

CV: Tachycardic with regular rate and rhythm

Labs:

WBC $16.8 \times 10^3/\text{mm}^3$ (16.8×10^9/L), segs 76% (0.76), bands 17% (0.17), lymphs 7% (0.07)

SCr 1.6 mg/dL (142 μmol/L)

Glucose 297 mg/dL (16.5 mmol/L)

Procalcitonin 1.0 mcg/L

Sputum gram-stain: < 10 epis/lpf, > 25 WBCs/lpf, gram-positive cocci

Sputum culture: Pending

Chest radiography: right lower lobe infiltrate

What findings on physical examination are suggestive of an infectious process?

What laboratory findings and/or diagnostic studies have been performed to help establish the presence of an infection?

Are the findings of these laboratory and diagnostic studies suggestive of an infection?

What is your working diagnosis based on this patient encounter?

patients are at risk for more virulent pathogens, they generally require more broad-spectrum initial coverage.[7]

Collateral damage is defined as the alterations in a patient's microbiome as a result of antimicrobial therapy that can lead to secondary infections. *Clostridioides difficile* infection (CDI) is an example of a disease that occurs due to collateral damage. Antibiotics, especially high-risk agents such as fluoroquinolones, can increase the risk of CDI by suppressing intestinal microbiome, resulting in overgrowth of *C. difficile*.[13] If several different antimicrobials possess activity against a targeted pathogen, the antimicrobial that is least likely to be associated with collateral damage may be preferred.

▶ *Pharmacodynamic Properties*

Pharmacodynamics describes the relationship between drug exposure and pharmacologic effect. Antimicrobials are classified as either concentration-dependent or time-dependent based upon their activity. Concentration-dependent activity occurs where higher drug concentrations are associated with greater rates and extents of bacterial killing. Concentration-dependent antimicrobial activity is maximized when peak antimicrobial concentrations are high. Fluoroquinolones, aminoglycosides, and metronidazole are examples of antimicrobials that exhibit concentration-dependent activity. For concentration-dependent antimicrobials, such as aminoglycosides, dosing regimens can be optimized to address maximal concentration. One such example of this is extended interval dosing of aminoglycosides. This approach allows for less frequent dosing and thus decreased toxicity while still maintaining optimal efficacy. In contrast, time-dependent (or concentration-independent) activity refers to a minimal increase in the rate or extent of bacterial killing with an increase in antimicrobial dose. Time-dependent antimicrobial activity is maximized when these antimicrobials are dosed to maintain blood and/or tissue concentrations above the MIC in a time-dependent manner. β-Lactam and glycopeptide antimicrobials exhibit time-dependent activity. For time-dependent antimicrobials, such as β-lactams, dosing strategies such as extending the infusion time of the intravenous antimicrobial may be effective for maximizing efficacy.

▶ *Antimicrobial Dose Selection*

Clinicians should be aware that antimicrobial dosage regimens may differ depending on the site of infection as well as the severity of infection. Appropriately dosed regimens are designed for treatment of the diagnosed infection because they have demonstrated proven efficacy and are most likely to minimize harm. For example, ciprofloxacin, a fluoroquinolone, has various dosage regimens based upon the site of infection. The dosing for uncomplicated UTIs is 250 mg twice daily for 3 days. For pyelonephritis, the dose is 500 mg twice daily for 5 to 7 days. Severe complicated hospital-acquired pneumonia may require a dosage regimen of 750 mg twice daily for 7 days.

▶ *Adverse-Effect and Drug-Interaction Properties*

A major concern when selecting antimicrobial regimens should be the propensity for the regimen to cause adverse effects and the potential for drug interactions. When selecting an antimicrobial regimen, the potential for adverse effects should be weighed against perceived benefit. For example, multiple FDA Drug Safety Communications have been released regarding the safety of fluoroquinolones and recommend against the use of fluoroquinolones in uncomplicated infections due to increased risk of severe adverse effects.[14] Risk factors for adverse events may include the coadministration of other drugs that are associated with a similar type of adverse effect. For example, coadministration of the known nephrotoxin gentamicin with vancomycin increases the risk for nephrotoxicity compared with administration of either drug alone.[15] Other drug interactions may predispose the patient to dose-related toxicity through inhibition of drug metabolism. For example, macrolides have the potential to prolong cardiac QT intervals in a dose-dependent manner, potentially increasing the risk for sudden cardiac death. This risk is further increased when combined with other agents that prolong the QT interval such as citalopram, an antidepressant (see Table 72–4 and 72–5).[16]

▶ *Antimicrobial Cost*

A final consideration in selecting antimicrobial therapy relates to cost. When considering antimicrobial therapy, the least expensive antimicrobial is not necessarily the most cost-effective antimicrobial. Direct antimicrobial costs constitute a relatively small portion of the overall cost of care. If efficacy and potential toxicity is comparable between two antimicrobial regimens, the least expensive regimen should be considered. Another consideration related to cost is hospital or insurance formulary. This may dictate options that are available as well as cost to the patient.

Patient Considerations in Antimicrobial Selection

KEY CONCEPT Key patient-specific considerations in antimicrobial selection include recent antimicrobial exposures, identification of the site of infection, history of drug allergies, pregnancy or breast-feeding status, organ dysfunction that may affect drug clearance, immunosuppression, compliance, and the severity of illness (see Table 72–3).

▶ *Pharmacokinetic Properties*

Pharmacokinetics refers to a patient's drug exposure in vivo in terms of absorption, distribution, metabolism, and elimination. Absorption factors that may affect antimicrobial selection include bioavailability as well as route of administration of the antimicrobial. Bioavailability refers to the amount of a medication that reaches the site of action. Drug-related factors that may affect oral bioavailability include the formulation of the antimicrobial and stability of the drug in the gastrointestinal (GI) tract. In patients with systemic signs of infection such as hypotension, an intravenous route of administration should be used. This is because decreased blood flow to the GI tract could lead to decreased absorption of the antimicrobial. For example, in situations where agents are available both orally and intravenously, patients who have a functioning GI tract and are not hypotensive may be given antimicrobials orally. The use of oral antimicrobials with modest bioavailability may be restricted depending upon the severity of illness and anatomic location of the infection. Many agents in the β-lactam class fall into this category. In sequestered infections like meningitis, where higher systemic concentrations of antimicrobials are necessary to reach the infected source or for antimicrobials with poor bioavailability, intravenous (IV) formulations should be used.

Some antimicrobials are bound to proteins in serum. Only unbound drug is biologically active and will distribute freely between tissues. Protein binding is clinically relevant in highly protein-bound antimicrobials ($> 50\%$) as these agents may not be able to penetrate sequestered compartments, resulting in insufficient concentrations to eradicate bacteria. In addition, some drugs may not achieve sufficient concentrations in specific compartments based on distribution characteristics. Fluoroquinolones, such as levofloxacin, penetrate the prostate well and achieve high concentrations, thus they are preferred agents for the treatment of prostatitis.

Table 72–4

Antimicrobial Adverse Drug Reactions

Antimicrobial	Other Agent(s)	Mechanism of Action/Effect	Clinical Management
Aminoglycosides	Neuromuscular blocking agents	Additive adverse effects	Avoid
	Nephrotoxins (N) or ototoxins (O) (eg, amphotericin B [N], cisplatin [N/O], cyclosporine [N], furosemide [O], NSAIDs [N], radiocontrast [N], vancomycin [N])	Additive adverse effects	Monitor aminoglycoside SDC and renal function
Amphotericin B	Nephrotoxins (eg, aminoglycosides, cidofovir, cyclosporine, foscarnet, pentamidine)	Additive adverse effects	Monitor renal function
Azoles	See Ch 139 from Dipiro's 11e		
Chloramphenicol	Phenytoin, tolbutamide, ethanol	Decreased metabolism of other agents	Monitor phenytoin SDC, blood glucose
Foscarnet	Pentamidine IV	Increased risk of severe nephrotoxicity/hypocalcemia	Monitor renal function/serum calcium
Isoniazid	Carbamazepine, phenytoin	Decreased metabolism of other agents (nausea, vomiting, nystagmus, ataxia)	Monitor drug SDC
Macrolides/azalides	Digoxin	Decreased digoxin bioavailability and metabolism	Monitor digoxin SDC; avoid if possible
	Theophylline	Decreased metabolism of theophylline	Monitor theophylline SDC
Metronidazole	Ethanol (drugs containing ethanol)	Disulfiram-like reaction	Avoid
Penicillins and cephalosporins	Probenecid, aspirin	Blocked excretion of β-lactams	Use if prolonged high concentration of β-lactam desirable
Ciprofloxacin/norfloxacin	Theophylline	Decreased metabolism of theophylline	Monitor theophylline
Quinolones	Classes Ia and III antiarrhythmics	Increased Q-T interval	Avoid
	Multivalent cations (antacids, iron, sucralfate, zinc, vitamins, dairy, citric acid), didanosine	Decreased absorption of quinolone	Separate by 2 hours
Rifampin	Azoles, cyclosporine, methadone propranolol, PIs, oral contraceptives, tacrolimus, warfarin	Increased metabolism of other agent	Avoid if possible
Sulfonamides	Sulfonylureas, phenytoin, warfarin	Decreased metabolism of other agent	Monitor blood glucose, SDC, PT
Tetracyclines	Antacids, iron, calcium, sucralfate	Decreased absorption of tetracycline	Separate by 2 hours
	Digoxin	Decreased digoxin bioavailability	Monitor digoxin SDC; avoid if possible

PI, protease inhibitor; PT, prothrombin time; SDC, serum drug concentrations.

Azalides: azithromycin; azoles: fluconazole, itraconazole, ketoconazole, and voriconazole; macrolides: erythromycin and clarithromycin; protease inhibitors: amprenavir, indinavir, lopinavir/ritonavir, nelfinavir, ritonavir, and saquinavir; quinolones: ciprofloxacin, gemifloxacin, levofloxacin, and moxifloxacin.

Many antimicrobials undergo some degree of metabolism once ingested followed by elimination of active or inactive metabolites. Metabolism may occur via hepatic or other enzymatic processes including the cytochrome P450 system, and may play a role in antimicrobial selection as it relates to patient-specific comorbidities or concomitant drug interactions. The antimicrobial and/or its metabolites then undergo elimination. Route of elimination may be a factor in drug selection for specific infections. For example, sulfamethoxazole/trimethoprim has exclusive renal elimination and thus is an optimal antibiotic for cystitis.

▶ *Age*

Host factors can help to ensure selection of the most appropriate antimicrobial agent. Age can be an important factor in antimicrobial selection as it can affect renal and hepatic function. Populations with diminished renal function include neonates and the elderly. Similarly, hepatic function in the neonate is not fully developed, and drugs that are metabolized by this route may be ineffective or produce adverse effects. For example, sulfonamides and ceftriaxone may compete with bilirubin for binding sites and may result in hyperbilirubinemia and kernicterus. With regards to the elderly population, diminished renal function, increased comorbidities and concomitant medications elevate the risk for adverse effects and drug interactions as it relates to antimicrobial therapy and thus a higher level of vigilance is required when selecting antimicrobials.

▶ *Site of Infection*

Recognizing the presumed site of infection and most common pathogens associated with the infectious source should guide antimicrobial choice, dose, and route of administration. For example, community-acquired pneumonia is caused most commonly by *Streptococcus pneumoniae*, *E. coli* is the primary cause of uncomplicated UTIs, and staphylococci and streptococci are implicated most frequently in skin and skin-structure infections.

Table 72–5

Major Drug Interactions with Antimicrobials

Antimicrobial Class	Adverse Drug Reaction	Monitoring Parameters	Comments
Penicillins	Hypersensitivity reactions and rash, drug fever, diarrhea, emesis, abdominal pain, hepatitis, interstitial nephritis, leukopenia, thrombocytopenia, Coomb's positive-hemolytic anemia, *C. difficile* colitis, electrolyte abnormalities, seizures	Monitor for hypersensitivity reactions (eg, bronchospasm, anaphylaxis, angioneurotic edema, immediate urticaria). During prolonged therapy and/or high-dose regimens, periodically monitor renal function, hepatic function, and CBC	Most serious reaction is immediate IgEmediated anaphylaxis. Incidence is 0.05%, but 5%-10% can be fatal
Cephalosporins	Hypersensitivity reactions and rash, drug fever, diarrhea, interstitial nephritis, Coomb's positive-hemolytic anemia, leukopenia, thrombocytopenia, coagulopathy, hepatitis, *C. difficile* colitis	Monitor for hypersensitivity reactions (eg, bronchospasm, anaphylaxis, angioneurotic edema, immediate urticaria) and rash, renal function, hepatic function, and CBC	Patients with a history of IgE-mediated allergic reactions to penicillins should not receive a cephalosporin
Carbapenems	Hypersensitivity reactions and rash, headache, nausea, diarrhea, seizures, drug fever, eosinophilia, thrombocytopenia, hepatitis, *C. difficile* colitis	Monitor for hypersensitivity reactions (eg, bronchospasm, anaphylaxis, angioneurotic edema, immediate urticaria) and rash, renal function, hepatic function, and CBC	Skin test cross-sensitivity with penicillin reported to be up to 50%, but clinically significant cross-sensitivity reactions in penicillin-allergic patients reported to be as low as 1% Highest incidence of seizures with use of imipenem–cilastatin. More frequent in patients who are elderly, have history of seizure disorders and renal dysfunction
Monobactams	Rash, diarrhea, nausea, hepatitis, thrombocytopenia, *C. difficile* colitis	Monitor renal and hepatic function	May be used in patients with allergy to penicillins/cephalosporins
Aminoglycosides	Tubular necrosis and renal failure, vestibular and cochlear toxicity, neuromuscular blockade, vertigo, anemia, hypersensitivity	Monitor renal function, SDC, serum calcium, magnesium, sodium. Monitor for nausea, vomiting, nystagmus, and vertigo	Nephrotoxicity can be reversible. More frequent in patients with the following risk factors: elderly, history of renal dysfunction, concomitant administration of nephrotoxic drug (ie, cyclosporine, amphotericin B, radiocontrast, vancomycin), and duration of therapy Ototoxicities can be irreversible
Glycopeptides	Red man syndrome, phlebitis, renal dysfunction, neutropenia, leukopenia, eosinophilia, thrombocytopenia, drug fever	Monitor renal function, CBC, and SDC	Red man syndrome is associated with rapid infusion and nonspecific histamine release. May be prevented by prolonging infusions to over at least 60 minutes and pretreatment with antihistamines
Lipopeptides (daptomycin)	Hepatotoxicity, CPK elevation with or without myopathy, diarrhea, eosinophilic pneumonia, *C. difficile* colitis	Monitor LFTs, development of muscle pain/weakness, or neuropathy Obtain serum CPK levels at baseline and weekly (or more frequently in patients with prior or concomitant statin, renal dysfunction, or patients with elevations in CPK)	CPK elevation is dose-dependent. Obtain baseline and weekly CPK levels. Discontinue daptomycin if CPK exceeds 10 times normal level or if patient develops myopathy and CPK >1,000 IU/L (16.7 μkat/L). Consider stopping statin therapy during treatment with daptomycin
Oxazolidinones	Myelosuppression (thrombocytopenia, leukopenia, and anemia), peripheral neuropathy, optic neuropathy, blindness, lactic acidosis, diarrhea, nausea, serotonin syndrome, interstitial nephritis	Monitor for signs and symptoms of serotonin syndrome particularly in patients with prior or concomitant serotonergic agents, CBC with differential. For prolonged therapy, perform visual function tests, monitor visual acuity and visual field defect	Myelosuppression is reversible and associated with treatment duration >2 weeks

(*Continued*)

Table 72–5

Major Drug Interactions with Antimicrobials (*Continued*)

Antimicrobial Class	Adverse Drug Reaction	Monitoring Parameters	Comments
Tetracyclines	GI upset, nausea, vomiting, diarrhea, hepatotoxicity, esophageal ulcerations, photosensitivity, azotemia, visual disturbances, vertigo, hyperpigmentation, deposition on teeth, hemolytic anemia, pseudotumor cerebri, pancreatitis, *C. difficile* colitis	Monitor CBC with differential, LFTs, and renal function	Doxycycline preferred in patients with renal dysfunction Vestibular symptoms more frequent in women than in men Avoid use during pregnancy and in children
Chloramphenicol	Myelosuppression, aplastic anemia, "gray baby syndrome," optic neuritis, peripheral neuropathy, digital paresthesias, GI upset, *C. difficile* colitis, hypersensitivity	Obtain baseline CBC with differential and every 2 days during therapy. Monitor SDC (particularly in children and in patients with hepatic or renal insufficiency), liver and renal function	Bone marrow suppression associated with doses >4 g/day. Serum levels >50 mcg/ mL (mg/L; 155 μmol/L) are associated with increased risk for "gray baby syndrome"
Rifamycines	Discoloration of urine, tears, contact lens, sweat, hepatotoxicity, GI upset, flu-like syndrome, hypersensitivity, thrombocytopenia, leukopenia, drug fever, interstitial nephritis, thrombocytopenia	Monitor LFTs, bilirubin, renal function, CBC at baseline; continue to monitor every 2–4 weeks in patients with hepatic impairment or receiving concomitant hepatotoxic drugs	Increased potential for hepatitis with concomitant hepatotoxic drugs (ie, TB drugs)
Macrolides/azalide	GI intolerance, diarrhea, prolonged QTc, cholestatic hepatitis, reversible ototoxicity, torsade de pointes, rash, hypothermia, exacerbation of myasthenia gravis	Monitor LFTs and ECG in high-risk patients	
Clindamycin	Diarrhea, *C. difficile* colitis, nausea, vomiting, generalized rash, hypersensitivity	For prolonged therapy, monitor liver and renal function	
Fluoroquinolones	GI intolerance, headache, malaise, insomnia, dizziness, photosensitivity, QTc prolongation, tendon rupture, peripheral neuropathy, crystalluria, seizure, interstitial nephritis, Stevens-Johnson syndrome, allergic pneumonitis, *C. difficile* colitis	Monitor renal function, encephalopathic changes (eg, confusion, hallucinations, and tremor)	Tendon rupture more frequently seen in the elderly and kidney, heart, and lung transplant recipients, and with concurrent use of corticosteroids
Polymyxins	Nephrotoxicity, neurotoxicity (paresthesia, vertigo, ataxia, blurred vision, slurred speech), neuromuscular blockade, bronchospasm (administered via inhalation)	Obtain baseline renal function tests and regularly during therapy. Monitor for signs of neuromuscular blockade (eg, respiratory depression, apnea, muscle weakness)	Nephrotoxicity is dose-dependent
Sulfonamides and trimethoprim	GI intolerance, rash, hyperkalemia, bone marrow suppression (anemia with folate deficiency, thrombocytopenia, and leukopenia), serum sickness, hepatitis, photosensitivity, crystalluria with azotemia, urolithiasis, methemoglobinemia, Stevens-Johnson syndrome, toxic epidermal necrolysis, aseptic meningitis, pancreatitis, interstitial nephritis, Sweet syndrome, neurologic toxicity	Monitor for hypersensitivity reactions and rash, CBC, renal and hepatic function, serum potassium, serum glucose	HIV-infected patients are at increased risk for developing adverse drug reactions Methemoglobinemia due to severe G6PD deficiency
Metronidazole	GI intolerance, headache, metallic taste, dark urine, peripheral neuropathy, disulfiram reactions with alcohol, insomnia, stomatitis, aseptic meningitis, dysarthria	Monitor hepatic function, mental/ neurologic status	Peripheral neuropathy is reversible and associated with prolonged treatment

CBC, complete blood count; CPK, creatine phosphokinase; LFT, liver function test; SDC, serum drug concentrations; TB, tuberculosis.

► *Recent Antimicrobial Use and Risk Factors for Resistant Organisms*

Patients with a history of recent antimicrobial use may have an altered microbiome or harbor resistant organisms (see Table 72–6). If a patient develops a new infection while on therapy or fails therapy, it is reasonable to prescribe either a different class of antimicrobial or alternative agent directed at the most likely pathogens. When selecting an antimicrobial for recurrence of a previously treated infection, review of patient history may reveal a need for broader spectrum coverage or identification of pathogen-specific resistance patterns. Factors associated with the acquisition of nosocomial pathogens include previous hospitalization or recent health care utilization through residing in a nursing home, hemodialysis, and outpatient antimicrobial therapy. Nosocomial pathogens are often resistant organisms.[8,9,17-26]

Table 72–6

Risk Factors for Drug-Resistant Organisms

Pathogen	Risk Factors
Methicillin-resistant *Staphylococcus aureus* (MRSA)	• Hospitalization (current/recent within previous 90 days) • ICU admission • MRSA colonization/prior MRSA infection • Recent antimicrobial agent use within previous 90 days • Residence in nursing home/long-term care facility • Invasive indwelling device (urinary catheter, central venous catheter/intravenous catheter) • Open wounds • Hemodialysis • Intravenous drug user (IVDU) • Sharing towels or athletic equipment • Participation in contact sports
Pseudomonas aeruginosa	• Hospitalization during past 90 days • ICU admission • Pseudomonas infection or colonization in past year • Recent antimicrobial agent use in previous 90 days (increased risk with fluoroquinolones, cephalosporins, carbapenems, β-lactams) • Residence in nursing home/long-term care facility • Severe lung disease (prior tracheostomy, bronchiectasis, very severe COPD) • Corticosteroid exposure • Malignancy • Hemiplegia
Extended Spectrum Beta-Lactamase producing Gram-Negative organisms (ESBLs)	• Hospitalization (recent or > 5 days) • ICU admission • Prior infection or colonization with an ESBL-producing organism • Recent antimicrobial agent use • Invasive procedure (urinary catheter, central venous catheter/intravenous catheter, other surgical procedures) • Residence in nursing home/long-term care facility • Age ≥ 65 • Male sex
Carbapenem-Resistant Enterobacterales[a] (CRE)	• Hospitalization • ICU admission • Prior infection or colonization with another multi-drug-resistant organism • Mechanical ventilation • Recent antimicrobial agent use (increased risk with fluoroquinolones, cephalosporins, carbapenems, aminoglycosides) • Residence in nursing home/long-term care facility • Invasive indwelling device (urinary catheter, central venous catheter/intravenous catheter) • Invasive procedure with a scope (endoscopic retrograde cholangiopancreatography [ERCP], duodenal endoscope)
Fluoroquinolone-resistant organisms	• Hospitalization • Prior use of fluoroquinolone in previous 6 months • Residence in nursing home/long-term care facility • Outpatient procedure in previous 30 days • Diabetes • Hepatic cirrhosis • Chronic respir/aableory disease • Urinary catheter • Recurrent urinary tract infections • Male

[a] Enterobacterales is the order of gram-negative bacteria among which Enterobacteriaceae is included. This terminology is newly proposed, and the two terms are often used interchangeably in the literature.

Patient Encounter 3: Empiric Selection of Antibiotics

Based on the information presented, select an empiric antimicrobial regimen for this patient. Your plan should include:

(a) A tentative infectious diagnosis or source, including likely pathogens or resistant organisms.

(b) A specific antimicrobial regimen, including drug(s), dose, and route of administration.

(c) Description of any ancillary treatments.

(d) A rationale for your empiric antimicrobial selection based on drug- and patient-specific considerations.

Drug Allergies

Antimicrobial allergies are some of the most common drug-related allergies reported and have significant potential to cause adverse events.[27] In particular, reported penicillin-related allergy is common and can be problematic as this contributes to the unnecessary or inappropriate use of other antimicrobial agents. Cephalosporins are preferred therapy for surgical prophylaxis in most cases. Recent data highlights that patients who receive a second-choice antimicrobial as a result of a documented penicillin allergy are more likely to experience adverse effects including surgical site infections.[28] A patient's medical history should be reviewed to determine the offending β-lactam and nature of the allergic reaction. Patients with mild or certain nonimmunologic reactions to penicillins may receive a β-lactam antimicrobial. Non-IgE- mediated findings, such as Stevens-Johnson syndrome, toxic epidermal necrolysis, or interstitial nephritis, should not be rechallenged with the offending agent, desensitized to penicillin, or undergo penicillin allergy skin testing. Previously, it was thought that patients with a history of findings consistent with IgE-mediated reactions (type I) such as anaphylaxis, urticaria, or bronchospasm should not be administered any type of β-lactam antimicrobial. However, newer data suggests that β-lactam antimicrobials may be safely administered. Data demonstrate that the actual cross-reactivity between penicillins and cephalosporins is likely less than 1% and slightly lower with carbapenems. Penicillins, cephalosporins, and carbapenems have the β-lactam ring in common; however, it is more likely that the cross-reactivity between penicillins and cephalosporins is secondary to side chain groups (R1 and R2). Therefore, in the majority of patients with a penicillin allergy, cephalosporins with dissimilar side chains, carbapenems, and monobactams may be safely administered.[29,30] Structural side chain similarities among β-lactam agents may be found in the literature.[29] Antimicrobial stewardship programs have worked extensively to improve antibiotic prescribing by delabeling penicillin allergies using various methods, including penicillin skin testing, direct oral challenges, and desensitization.[31]

Renal/Hepatic Function

Renal and/or hepatic function should be considered prior to initiation of antimicrobial therapy. Most antimicrobials undergo renal elimination and dosing adjustments are frequently necessary. Recommendations for dosing adjustments are available in the literature or tertiary databases.[32] Failure to adjust the antimicrobial dose or interval may result in drug accumulation and adverse effects.

Concomitant Medications

Concomitant administration of other medications may influence the selection of the antimicrobial, dose, and monitoring. Medications that commonly interact with antibiotics include, but are not limited to, warfarin, oral contraceptives, phenytoin, digoxin, multivalent cations (eg, calcium, magnesium, and zinc), and sucralfate. Drug interactions between antimicrobials and other medications may occur via the cytochrome P-450 system, protein-binding displacement, and alteration of vitamin K–producing bacteria. Interactions may result in increased or decreased concentrations of one or both agents, increasing the risk of adverse effects or additive toxicity.

Pregnancy/Lactation

Antimicrobial agents must be used with caution in pregnant and nursing women. Fluoroquinolones, tetracyclines, and sulfonamides pose potential threats to the fetus or infant and avoidance during a specific trimester or the entire pregnancy is warranted. For example, avoidance of trimethoprim/sulfamethoxazole in the first and late third trimester is recommended. Pharmacokinetic variables are also altered during pregnancy. Both the clearance and volume of distribution are increased during pregnancy. As a result, increased dosages and/or more frequent administration of certain drugs may be required to achieve adequate concentrations.[33]

Adherence is essential to ensure efficacy. Patients may stop taking their antibiotics once the symptoms subside and save them for a "future" infection. Self-medication with saved antibiotics may be harmful and contribute to antibiotic resistance. Poor adherence may be due to adverse effects, tolerability, cost, complexity of the regimen, and lack of patient education.

Key considerations in selecting antimicrobial regimens start with obtaining a good patient medical and medication history, recognizing drug-specific adverse-event characteristics, and anticipating potential problems proactively. If it is necessary to use an antimicrobial with a relatively high frequency of adverse effects, informing patients of the risks and benefits of therapy, as well as what to do if an adverse effect occurs, may improve patient adherence and safety.

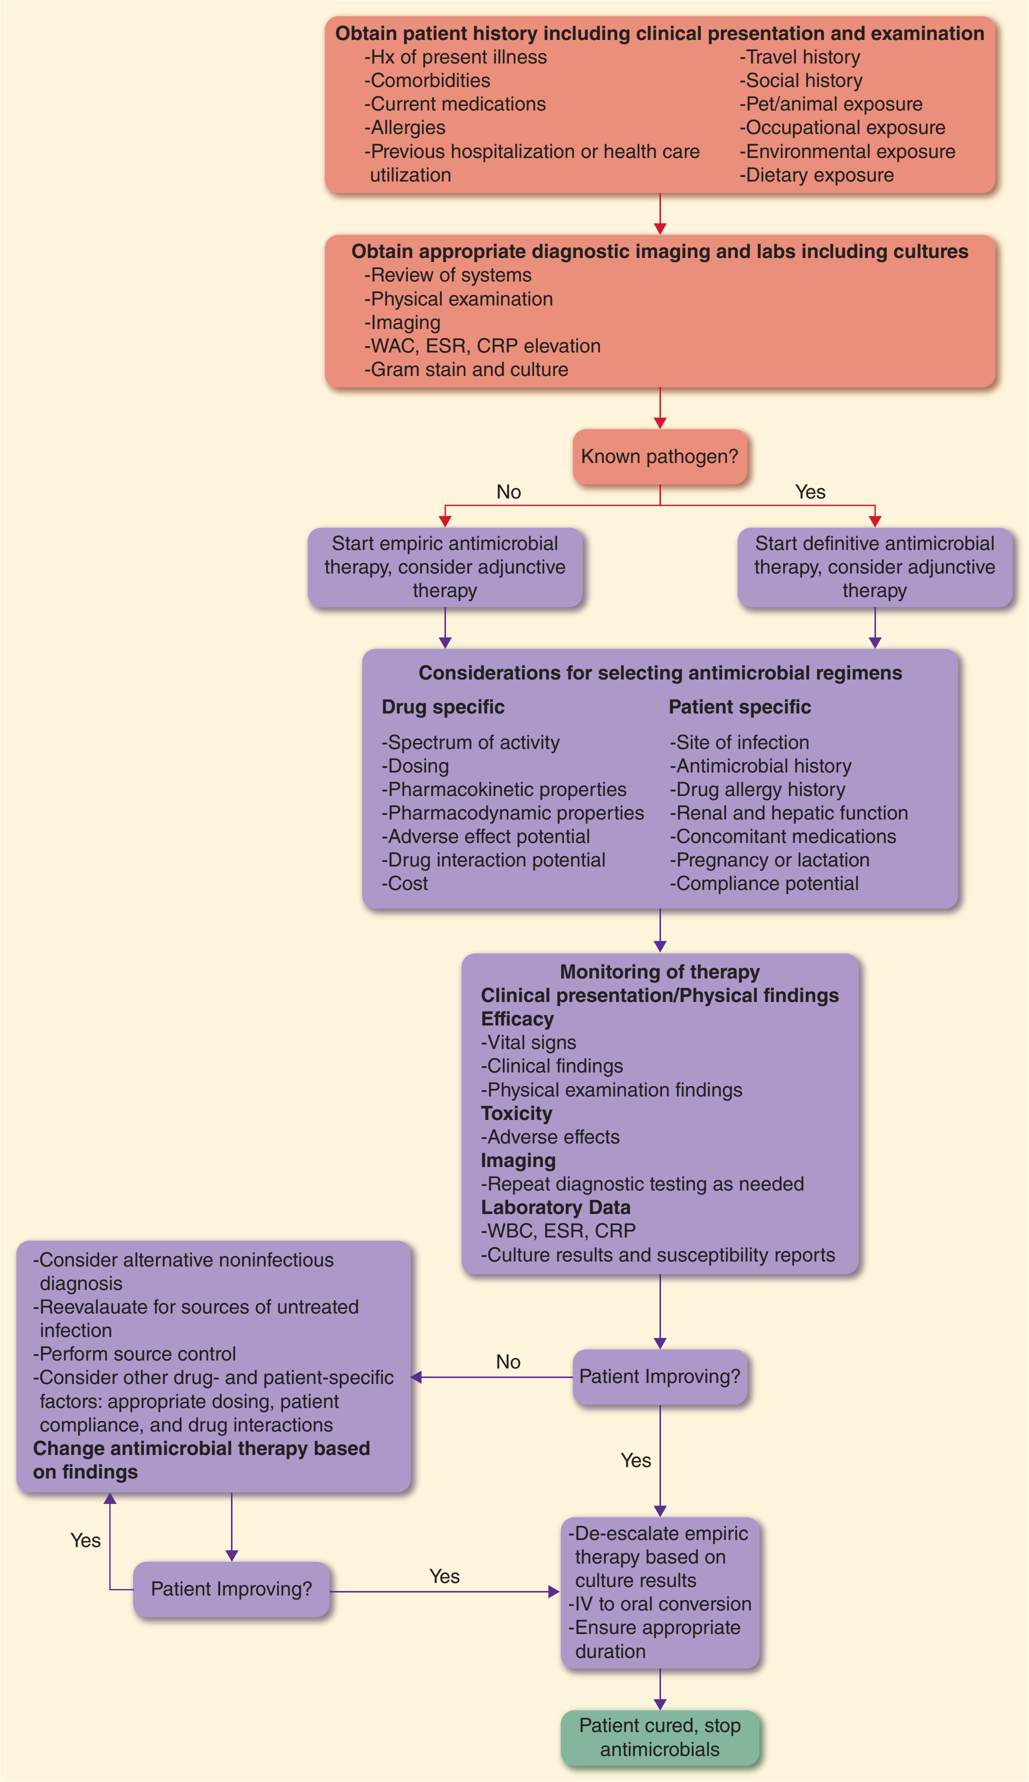
OUTCOME EVALUATION

Figure 72–3 provides an overview of patient- and antimicrobial agent—specific factors to consider when selecting an antimicrobial regimen. It further delineates monitoring of therapy and actions to take depending on the response to therapy.

After selection and initiation of an antimicrobial regimen, there are additional patient care and monitoring considerations that should be addressed to improve the likelihood of a successful outcome. **KEY CONCEPT** Patient education, de-escalation of antimicrobial therapy based on culture results, monitoring for clinical response as well as adverse effects, and appropriate duration of therapy are important.

Modifying Empiric Therapy Based on Cultures and Clinical Response

If culture results are available, therapy should be de-escalated. Antimicrobial de-escalation generally refers to the discontinuation of antimicrobials that provide a spectrum of activity greater than necessary to treat the infection. De-escalation of empiric therapy may also include discontinuing antibiotics based on clinical criteria and negative culture results, such as the absence of antibiotic-resistant pathogens.[34] The purpose of de-escalating



Obtain patient history including clinical presentation and examination
-Hx of present illness
-Comorbidities
-Current medications
-Allergies
-Previous hospitalization or health care utilization
-Travel history
-Social history
-Pet/animal exposure
-Occupational exposure
-Environmental exposure
-Dietary exposure
Obtain appropriate diagnostic imaging and labs including cultures
-Review of systems
-Physical examination
-Imaging
-WAC, ESR, CRP elevation
-Gram stain and culture
Known pathogen?
No
Yes
Start empiric antimicrobial therapy, consider adjunctive therapy
Start definitive antimicrobial therapy, consider adjunctive therapy
Considerations for selecting antimicrobial regimens
Drug specific
-Spectrum of activity
-Dosing
-Pharmacokinetic properties
-Pharmacodynamic properties
-Adverse effect potential
-Drug interaction potential
-Cost
Patient specific

-Vital signs
-Clinical findings
-Physical examination findings
Toxicity
-Adverse effects
Imaging
-Repeat diagnostic testing as needed
Laboratory Data
-WBC, ESR, CRP
-Culture results and susceptibility reports
Patient Improving?
No
-Consider alternative noninfectious diagnosis
-Reevalauate for sources of untreated infection
-Perform source control
-Consider other drug- and patient-specific factors: appropriate dosing, patient compliance, and drug interactions
Change antimicrobial therapy based on findings
Yes
Patient Improving?
Yes
Yes
-De-escalate empiric therapy based on culture results
-IV to oral conversion
-Ensure appropriate duration
Patient cured, stop antimicrobials

FIGURE 72–3. Approach to selection of antimicrobial therapy.

therapy is to prevent the occurrence of adverse events, minimize the risk of *C. difficile* infections and the development of resistance. In cases in which a specific organism is recovered that has a known preferred antimicrobial treatment of choice, therapy might be changed to that specific agent. For example, antistaphylococcal penicillins and first-generation cephalosporins are considered to be the agents of choice for methicillin-susceptible *S. aureus* owing to their bactericidal and narrow-spectrum activity, lower risk for the adverse events, and improved clinical outcomes compared with vancomycin.[35] In other cases, empiric coverage might be discontinued if a specific suspected pathogen is not identified by culture or an alternative, noninfectious diagnosis is established. In addition, IV antimicrobials are associated with an increased risk of adverse events as compared to oral antimicrobials. Therefore, for less severe infections and when patients are clinically stable, it is desirable to convert to oral antimicrobials with a comparable antimicrobial spectrum.[36]

Duration of Therapy

Once the appropriate antimicrobial has been identified, duration of therapy should be considered. Patient clinical response as well as site of infection will help determine the appropriate duration. Studies of several infectious processes have suggested that shorter durations of therapy can result in similar clinical outcomes as longer durations of therapy, frequently with fewer complications or secondary infections.[8,9] In this period of extensive antimicrobial resistance, clinicians should keep abreast of changing recommendations and guidelines emphasizing shorter durations of therapy.

Patient Encounter 4: Patient Care and Monitoring

Update: Ceftriaxone and azithromycin were initiated.

After 48 hours of therapy, the following parameters are obtained:

PE:

VS: BP 132/72, P 70, RR 22, T 37.2°C (98.9°F), O2 saturation on room air of 94%

Labs:

WBC $9.2 \times 10^3/\text{mm}^3$ (9.2×10^9/L)/ differential 85% segs, 10% lymphs, 5% monos

SCr 1.1 mg/dL (97.2 μmol/L)

Glucose 126 mg/dL (6.9 mmol/L)

Sputum culture: *Streptococcus pneumoniae*

Susceptibility Report:

Penicillin MIC 0.25 mcg/mL (breakpoint < 2 mcg/mL)

Ceftriaxone MIC 0.25 mcg/mL (breakpoint < 1 mcg/mL)

Erythromycin MIC 1 mcg/mL (breakpoint 0.25 mcg/mL)

What information suggests improvement in the patient's condition?

Do any of the antimicrobial doses need to be adjusted for changes in organ function?

Should antimicrobial therapy be modified based on the culture results?

Can the antimicrobial therapy be converted from IV to oral therapy?

How long should the duration of antimicrobial therapy be?

Failure of Antimicrobial Therapy

While many infections respond readily to antimicrobials, some infections do not. However, it is important to remember that antimicrobial therapy comprises only a portion of the overall disease treatment, and there may be many factors that contribute to a lack of improvement. Drug- and patient-specific factors such as appropriate dosing, patient compliance, and drug interactions can be associated with therapeutic failure and should be considered. **KEY CONCEPT** In addition, inadequate diagnosis resulting in inappropriate empiric antimicrobial selection, poor source control, or the development of a secondary infection are causes of antimicrobial failure. Failure to improve should warrant broadening the differential diagnosis to include noninfectious causes. Another common cause of failure is poor source control. A diagnostic search for unknown sources of infection, removal of indwelling devices in the infected environment or surgical drainage of abscesses should be undertaken if the patient's condition is not improving. With secondary infections, the patient generally improves, but then relapses and develops a new infection caused by a new pathogen. When a patient fails to respond to initial antibiotic therapy, consideration should be taken to involve an infectious disease physician as studies have shown that specialist involvement improves patient outcomes.[37]

ANTIMICROBIAL STEWARDSHIP

KEY CONCEPT Antimicrobial stewardship promotes the optimal use of antimicrobial agents to reduce the emergence of resistant pathogens, improve the quality of patient care, and reduce costs. Antimicrobial stewardship programs have been implemented in a variety of settings including hospitals, long-term care facilities, and ambulatory care. To reflect the importance of antimicrobial stewardship, a component of Joint Commission accreditation involves creating a program that adheres to the Core Elements of an Antibiotic Stewardship Program. See Table 72–7.

Program leaders are often a physician and a pharmacist trained in infectious diseases. Other key personnel/support include clinicians, infection prevention, quality improvement, microbiology laboratory, information technology, and nursing. However, any clinician can utilize the practices mentioned in this chapter to become an antimicrobial steward. The goal is to support and track optimal antimicrobial use through various interventions and measures. It is imperative that clinicians educate themselves on appropriate use of antimicrobials and become involved in the effort to improve prescribing practices.[34]

Table 72–7

CDC Core Elements of Antibiotic Stewardship Programs

Leadership commitment
Accountability
Drug expertise
Key support groups
Action (implement policies/interventions to improve patient care)
Tracking/reporting antimicrobial use and outcomes
Education

Patient Care Process

Collect Information:

- Review patient symptoms to indicate source of infection.
- Review pertinent patient medical history including significant comorbid conditions.
- Determine patient allergy histories (including reactions and timing).
- Determine and document recent antimicrobial exposure

Assess the Information:

- Review patient labs, including labs obtained for specific infectious syndromes and vital signs.
- Determine if patient has any hardware, prosthetic material or other foreign bodies (eg, central venous catheter, urinary catheter, endotracheal tube).
- Assess the severity of illness.
- Assess patient-specific risk factors based on infection type to aid in determining appropriate empirical therapy.
- Review local antimicrobial susceptibility patterns including antibiograms.

Develop a Care Plan:

- Based on proposed infectious diagnosis combined with above data assessed, select empirical antimicrobial regimen.
- Consider additional diagnostics and culture and susceptibility reports.

Implement the Care Plan:

- Timely antimicrobials are required, especially in those with sepsis.
- Provide patient education regarding importance of adherence to therapy and adverse effects.

Follow-up: Monitor and Evaluate:

- Follow-up on culture and susceptibility reports to determine opportunities to streamline antimicrobial therapy.
- Some antimicrobials may require therapeutic drug monitoring (eg, vancomycin) to evaluate for safety and effectiveness.
- Duration of therapy should be determined based on several factors including but not limited to infection type, culture results, host immune status, and source control (eg, removal of a central venous catheter).

Abbreviations Introduced in This Chapter

CDC	Centers for Disease Control and Prevention
CRP	C-reactive protein
ESR	Erythrocyte sedimentation rate
HPI	History of present illness
MIC	Minimum inhibitory concentration
MRSA	Methicillin-resistant *Staphylococcus aureus*
PMH	Past medical history
UTI	Urinary tract infection
VRE	Vancomycin-resistant *Enterococcus*
WBC	White blood cell count

Central Nervous System Infections

April Miller Quidley and P. Brandon Bookstaver

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. Discuss the pathophysiology of central nervous system (CNS) infections and the impact on antimicrobial treatment regimens (including antimicrobial dosing and CNS penetration).
2. Describe the signs, symptoms, and clinical presentation of CNS infections.
3. List the most common pathogens causing CNS infections and identify risk factors for infection with each pathogen.
4. State the goals of therapy for CNS infections.
5. Outline the initial management strategies for CNS infections.
6. Design appropriate empirical antimicrobial regimens for patients suspected of having CNS infections (taking age, vaccine history, and other patient-specific information into account) caused by each of the following pathogens, and analyze the impact of antimicrobial resistance on both empirical and definitive therapy: *Neisseria meningitidis* meningitis, *Haemophilus influenzae* meningitis, *Listeria monocytogenes* meningitis, group B *Streptococcus* meningitis, gram-negative bacillary meningitis, postneurosurgical infection, CNS shunt infection, herpes simplex encephalitis.
7. Modify empirical antimicrobial regimens based on laboratory data and other diagnostic criteria.
8. Discuss the management of close contacts of patients diagnosed with CNS infections.
9. Identify candidates for vaccines and other prophylactic therapies to prevent CNS infections.
10. Describe the role of adjunctive agents (eg, dexamethasone) in the management of CNS infections.

INTRODUCTION

The term *central nervous system (CNS) infections* describes a variety of infections involving the brain and spinal cord and associated tissues, fluids, and membranes, including meningitis, encephalitis, brain abscess, cerebrospinal fluid (CSF) shunt infections, and postoperative infections. **KEY CONCEPT** CNS infections, such as meningitis, are considered neurologic emergencies that require prompt recognition, diagnosis, and management to prevent death and residual neurologic deficits. Improperly treated CNS infections are associated with high rates of morbidity and mortality. Despite advances in care, the overall mortality of bacterial meningitis in the United States remains at approximately 15%, and at least 10% to 30% of survivors are afflicted with neurologic impairment, including hearing loss, hemiparesis, and learning disabilities.[1,2] Antimicrobial therapy and preventive vaccines have revolutionized management and improved outcomes of bacterial meningitis and other CNS infections dramatically.

EPIDEMIOLOGY AND ETIOLOGY

CNS infections are uncommon and declining in incidence, with a rate of 0.8 per 100,000 persons between 1997 and 2010.[3] However, the severity of these infections demands prompt medical intervention and treatment. CNS infections can be caused by bacteria, fungi, mycobacteria, viruses, parasites, and spirochetes.

Bacterial meningitis is the most common cause of CNS infections. While vaccination has reduced the incidence of disease by many common pathogens, *Streptococcus pneumoniae* (pneumococcus) remains the most common pathogen for bacterial meningitis (0.306 cases per 100,000), followed by *Neisseria meningitidis* (meningococcus, 0.123 cases per 100,000).[3] Staphylococcal species and gram-negative bacteria account for 0.114 and 0.127 cases per 100,000 persons, respectively in the United States.[3] Group B *Streptococcus* (GBS) and *Listeria monocytogenes* remain important causes, but current data on their incidence are lacking.[2] Vaccines directed against bacteria causing meningitis and related infections (eg, pneumonia and ear infections) have reduced the risk of infections due to *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* type B (Hib) dramatically.[2,3] Prior to the availability of Hib conjugate vaccines, Hib meningitis or other invasive disease was documented in one in 200 children by the age of 5 years and due to widespread use, its incidence has decreased such that it is no longer a leading pathogen.[3] Historically, a 7-valent conjugate pneumococcal vaccine (PCV7) was administered, but despite use of the PCV7, *S. pneumoniae* remained the most common pathogen for pediatric bacterial meningitis. In 2010, a 13-valent conjugate pneumococcal vaccine was licensed for use in the United States; however, its impact on the epidemiology of disease in the United States is still unknown. In France, the 13-valent vaccine reduced the incidence of pneumococcal meningitis by 27.4%

and similar reductions were seen in Canada with strains found in the vaccine.[4,5]

Encephalitis may result from viral, bacterial, parasitic, or other noninfectious causes. Herpes simplex virus (HSV) is the most common cause of encephalitis in the United States, accounting for 10% of all cases.[6] The annual incidence of viral encephalitis is 3.5 to 7.4 infections per 100,000 persons.[6] Other pathogens including common bacterial meningitis causes, *Rickettsia* species, enteroviruses, arboviruses, varicella-zoster virus, rotavirus, coronavirus, influenza viruses A and B, West Nile virus, and Epstein-Barr virus may be associated with a meningoencephalopathic presentation.[7] Approximately 20,000 hospitalizations each year are secondary to encephalitis, accounting for $650 million in healthcare costs.[8] Over the past 10 to 20 years, mortality secondary to encephalitis has remained constant, correlating with the increased number of people living with human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS).

Neurosurgical procedures may place patients at risk for meningitis due to bacteria acquired at the time of surgery or in the postoperative period, including *Staphylococcus aureus*, coagulase-negative staphylococci, and gram-negative bacilli. In addition to bacteria, other pathogens may cause meningitis in at-risk patients. Immunocompromised patients, such as solid-organ transplant patients and patients living with HIV infection, are at risk for fungal meningitis with *Cryptococcus neoformans* and encephalitis secondary to *Toxoplasma gondii* and JC virus. Tuberculosis can spread from pulmonary sites to cause clinical disease in the CNS. Life-threatening viral encephalitis and meningitis can occur in otherwise healthy, young individuals, as well as in patients immunocompromised by age or other factors.

Risk factors for CNS infections can be classified as follows:

- *Environmental:* Recent exposures (eg, close contacts with meningitis or respiratory tract infection, contaminated foods), active or passive exposure to cigarette smoke, close living conditions.
- *Recent infection in the patient:* Respiratory infection, otitis media, sinusitis, mastoiditis.
- *Immunosuppression:* Anatomic or functional asplenia, sickle cell disease, alcoholism, cirrhosis, immunoglobulin or complement deficiency, cancer, HIV/AIDS, uncontrolled diabetes mellitus, debilitated state of health.
- *Surgery, trauma:* Neurosurgery, head trauma, CSF shunt, cochlear implant.
- Noninfectious causes of meningitis include malignancy, medications (eg, sulfonamides, nonsteroidal anti-inflammatory drugs [NSAIDs], IV immunoglobulin), autoimmune disease (eg, lupus), and trauma.[6,7]
- The most common pathogens causing bacterial meningitis, by age group and other risk factors, are found in Table 73–1.

Patient Encounter 1, Part 1

NB is a 10-year-old, 35 kg boy without a significant past medical history. He is active in sports and recently returned from a baseball tournament where he lived in shared housing with his teammates. He now presents to the emergency department with a 2-day history of headache, fever, and confusion. Physical findings and laboratory values include temperature of 38.9°C (102°F) and WBC of 18.7×10^3/mm^3 (18.7×10^9/L), with 73% (0.73) polymorphonuclear cells (PMNs). Examination reveals nuchal rigidity and altered mental status. He is up to date on his vaccinations.

What signs and symptoms consistent with meningitis are present in NB?

What causative pathogens should be suspected in NB?

What empiric antimicrobials should be started?

PATHOPHYSIOLOGY

Meningitis is an inflammation of the membranes of the brain and spinal cord (**meninges**) and the CSF in contact with these membranes, whereas encephalitis is an inflammation of the brain tissue. CSF produced in the brain ventricles flows through the subarachnoid space and downward through the spinal cord, insulating and protecting delicate CNS tissue.

To initiate a CNS infection, pathogens must gain entry into the CNS by **contiguous** spread, **hematogenous** seeding, direct inoculation, or reactivation of latent infection. Contiguous spread occurs when infections in adjacent structures (eg, sinus cavities or the middle ear) invade directly through the blood–brain barrier. Hematogenous seeding occurs when a remote infection causes bacteremia that seeds the CSF, such as pneumococcal pneumonia. Reactivation of latent infection results from dormant viral, fungal, or mycobacterial pathogens in the spine, brain, or nerve tracts. Direct inoculation of bacteria into the CNS is the result of trauma, congenital malformations, or complications of neurosurgery.

Once through the blood–brain barrier, pathogens replicate due to limited host defenses in the CNS. Figure 73–1 depicts the pathophysiologic changes associated with meningitis. Neurologic tissue damage is the result of the host's immune reaction to bacterial cellular components, which trigger cytokine production, particularly tumor necrosis factor alpha (TNF-α) and interleukin 1 (IL-1), and other inflammatory mediators.[9] Bacteriolysis resulting from antibiotic therapy further contributes to the inflammatory process. Cytokines increase permeability of the blood–brain barrier, allowing influx of neutrophils and other host defense cells that contribute to the development of cerebral edema and increased intracranial pressure characteristic of meningitis.[10] The increase in intracranial pressure is responsible for the hallmark clinical signs and symptoms of meningitis: headache, neck stiffness, altered mental status, photophobia, and seizures. Untreated, these pathophysiologic changes may result in cerebral ischemia, herniation, and death.

The CNS response to infection is cellular and chemical changes in the CSF. KEY CONCEPT Ideally, lumbar puncture (LP) to obtain CSF for direct examination and laboratory analysis, as well as blood cultures and other relevant cultures, should be obtained before initiation of antimicrobial therapy. However, initiation of antimicrobial therapy should not be delayed if a pretreatment LP cannot be performed.

Normal CSF has a characteristic composition in terms of protein and glucose content, as well as cell count. Table 73–2 lists CSF findings normally observed and in the setting of meningitis.

CLINICAL PRESENTATION AND DIAGNOSIS

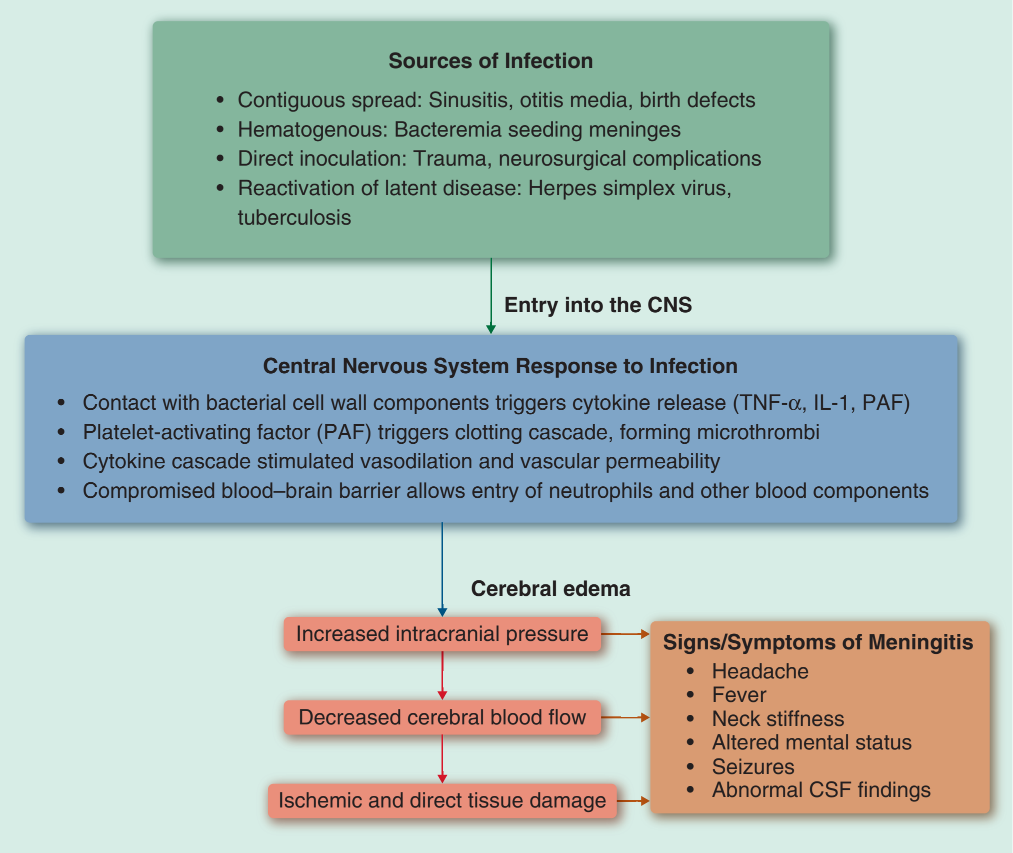
A high index of suspicion should be maintained for patients at risk for CNS infections. Prompt recognition and diagnosis are essential so that antimicrobial therapy can be initiated as quickly as possible. A medical history (including risk factors for infection and history of possible recent exposures) and physical

Table 73–1

Most Likely Pathogens and Recommended Empirical Therapy, by Risk Factor, for Bacterial Meningitis[2,24,25]

Predisposing Factor	Most Likely Pathogens	Recommended Empirical Antibiotic Therapy
Age		
Less than 3 months	Group B *Streptococcus* *Escherichia coli* *Klebsiella pneumoniae* *Listeria monocytogenes*	Ampicillin *plus* cefotaxime *or* aminoglycoside
3 months to less than 18 years	*Streptococcus pneumoniae* *Neisseria meningitidis*	Cefotaxime *or* ceftriaxone *plus* vancomycin
18 years to less than 60 years	*S. pneumoniae* *N. meningitidis*	Cefotaxime *or* ceftriaxone *plus* vancomycin
60 years *or* older	*S. pneumoniae* Gram-negative bacilli *L. monocytogenes*	Cefotaxime *or* ceftriaxone *plus* vancomycin *plus* ampicillin
Immunocompromised	*S. pneumoniae* *N. meningitidis* *L. monocytogenes* Gram-negative bacilli (including *Pseudomonas aeruginosa*)	Cefotaxime *or* ceftriaxone *plus* vancomycin *plus* ampicillin (include agents against *Pseudomonas spp.* if suspected with a consideration for double coverage)
Surgery, Trauma		
Postneurosurgical infection	*S. aureus* (including MRSA) Coagulase-negative *Staphylococcus* (including MRSE) Gram-negative bacilli (including *P. aeruginosa*)	
Penetrating head trauma	*S. aureus* (including MRSA) coagulase-negative *Staphylococcus* Gram-negative bacilli (including *P. aeruginosa*)	Vancomycin *or* linezolid *plus* cefepime or ceftazidime *or* meropenem (consider empiric use of two active antibiotics against *Pseudomonas* spp. if suspected)
CSF shunt	Coagulase-negative *Staphylococcus* (including MRSE) *S. aureus* (including MRSA) Gram-negative bacilli (including *P. aeruginosa*)	

MRSA, methicillin-resistant *Staphylococcus aureus*; MRSE, methicillin-resistant *Staphylococcus epidermidis*.



Sources of Infection
• Contiguous spread: Sinusitis, otitis media, birth defects
• Hematogenous: Bacteremia seeding meninges
• Direct inoculation: Trauma, neurosurgical complications
• Reactivation of latent disease: Herpes simplex virus, tuberculosis
Entry into the CNS
Central Nervous System Response to Infection
• Contact with bacterial cell wall components triggers cytokine release (TNF-α, IL-1, PAF)
• Platelet-activating factor (PAF) triggers clotting cascade, forming microthrombi
• Cytokine cascade stimulated vasodilation and vascular permeability
• Compromised blood–brain barrier allows entry of neutrophils and other blood components
Cerebral edema
Increased intracranial pressure
Decreased cerebral blood flow
Ischemic and direct tissue damage
Signs/Symptoms of Meningitis
• Headache
• Fever
• Neck stiffness
• Altered mental status
• Seizures
• Abnormal CSF findings

FIGURE 73–1. Pathophysiology of bacterial meningitis.

Table 73–2

CNS Response to Infection (CSF Findings)

	Normal CSF	Bacterial Infection	Viral Infection	Fungal Infection	Tuberculosis
WBC ($\times 10^3/\text{mm}^3$ *or* $\times 10^9/\text{L}$)	< 0.005	1.0–greater than 5.0	0.1–1	0.1–0.4	50–500
WBC differential (% or fraction in brackets, predominant cell type)	> 85% (0.85) monocytes	At least 80% (0.80) PMNs	50% (0.50) lymphocytes (PMN early)	> 50% (0.50) lymphocytes	> 80% (0.80) lymphocytes (PMNs early)
Protein (mg/dL, mg/L)	20–45 (200–450)	> 100 (> 1000)	50–100 (500–1000)	100–200 (1000–2000)	40–150 (400–1500)
Glucose (mg/dL, mmol/L)	45–80 (2.5–4.4)	5–40 (0.3–2.2)	30–70 (1. 7–3. 9)	< 30–70 (< 1. 7–3. 9)	< 30–70 (< 1. 7–3. 9)
CSF: serum glucose ratio	At least 0.6 serum glucose	< 0.4 serum glucose	At least 0.6 serum glucose	< 0.4 serum glucose	< 0.4 serum glucose
CSF stain	Negative	Positive Gram stain (60%–90%)	Negative	Positive India ink stain (Cryptococcus)	Positive acid-fast bacilli stain
Opening pressure	< 20 mm Hg	> 20 mm Hg	< 20 mm Hg	> 20 mm Hg	> 20 mm Hg

CSF, cerebrospinal fluid; PMNs, polymorphonuclear neutrophils.

Clinical Presentation and Diagnosis of CNS Infections

General

- Evaluate patient risk factors and recent exposures.
- Evaluate other possible causes: space-occupying lesion (which may *or* may not be malignant), drug-induced CNS pathology autoimmune disease, and trauma.[12,13]

Signs and Symptoms[2]

- Ninety-five percent of patients with bacterial meningitis have two of the following: headache, fever, neck stiffness, and altered mental status.
- Headache (87%)
- Nuchal rigidity (stiff neck) (83%)
- Fever (77%)
- Nausea (74%)
- Altered mental status (ie, confusion, lethargy, and obtundation) (69%)
- Focal neurologic defects (including positive Brudzinski sign and Kernig sign) (33%)
- Seizures
- Malaise, restlessness
- Photophobia
- Skin lesions (diffuse petechial rash observed in 50% of patients with meningococcal meningitis)
- Signs and symptoms in neonates, infants, and young children: nonspecific findings, such as altered feeding and sleep patterns, vomiting, irritability, lethargy, bulging fontanel, seizures, respiratory distress, and petechial/purpuric rash[17]
- Predictors of an unfavorable outcome: seizures, focal neurologic findings, altered mental status, papilledema, hypotension, septic shock, and pneumococcal meningitis[4]

Laboratory Tests[5,18,44]

- CSF examination via lumbar puncture (LP, spinal tap); contraindicated in patients with cardiorespiratory compromise, increased intracranial pressure and papilledema, focal neurologic signs, seizures, bleeding disorders, abnormal level of consciousness, and possible brain herniation (a CT scan should be performed before LP if there is a question of a CNS mass to avoid potential for brain herniation) (see Table 73–2 for specific CSF findings)
- Elevated opening pressure (may be decreased in neonates, infants, and children)
- Cloudy CSF
- Decreased glucose
- Elevated protein
- Elevated WBC (differential provides clues to offending pathogen)
- Gram stain (adequate for diagnosis in 60%–90% of patients with bacterial meningitis)
- Culture and sensitivity (positive in 70%–85% without prior antibiotic therapy, likelihood of positivity reduced by 20% in those who have had prior therapy)
- If CSF Gram stain and/or culture is negative, rapid diagnostic tests (such as latex agglutination) may be useful; these tests are positive even if bacteria are dead
- Polymerase chain reaction (PCR; DNA amplification of the most common bacterial meningitis pathogens) may be useful to help exclude bacterial meningitis
- Elevated CSF lactate and C-reactive protein
- Blood cultures (at least two cultures, one set; positive in 66%)
- Scraping of skin lesions (eg, rash) for direct microscopic examination and culture
- Other cultures should be obtained as clinically indicated (eg, sputum)
- WBC with differential
- Fungal meningitis: CSF culture, CSF and serum cryptococcal antigen titers, microscopic examination of CSF specimens
- Tuberculous meningitis: CSF culture, PCR evaluation (preferred), and acid-fast stain

examination yield important information to help guide the diagnosis and treatment of meningitis. Common signs and symptoms include fever, headache, nuchal rigidity, and photophobia. Infants present with nonspecific signs and symptoms, including excessive irritability or crying, vomiting or diarrhea, tachypnea, altered sleep pattern, and poor eating. Depending on involved pathogens and disease severity, patients may also present with altered mental status, stupor, and seizures.

TREATMENT

Goals of Therapy

Prior to antibiotic therapy and vaccination bacterial meningitis was almost universally fatal, with survivors suffering from debilitating residual neurologic deficits, such as permanent hearing loss.[1,2] Although significant improvements have been made, the fatality rate of meningitis remains above 15% in adults, likely due to its occurrence in debilitated patient populations.[2]

KEY CONCEPT The treatment goals for CNS infections are to prevent death and residual neurologic deficits, eradicate or control causative micro-organisms, ameliorate clinical signs and symptoms, and implement vaccination and suppressive measures to prevent future infections. Surgical debridement should be employed, if appropriate (as in postneurosurgical infections and brain abscess). Supportive care, consisting of hydration, electrolyte replacement, antipyretics, antiemetics, analgesics, antiepileptic drugs, and wound care (for surgical wounds), is an important adjunct to antimicrobial therapy, particularly early in the treatment course.

Treatment Principles

KEY CONCEPT Prompt initiation of IV high-dose bactericidal antimicrobial therapy directed at the most likely pathogen(s) is essential due to the high morbidity and mortality associated with CNS infections. Although there are no prospective studies that relate timing of antibiotic administration to clinical outcome in bacterial meningitis, a longer duration of symptoms and more advanced disease before treatment initiation increase the risk of a poor outcome.[2,11] Initiation of antibiotic therapy as soon as possible after bacterial meningitis is suspected or proven (even before hospitalization) reduces mortality and neurologic sequelae.[11-13]

Patient Encounter 1, Part 2

NB, the 10-year-old patient with signs and symptoms of meningitis underwent lumbar puncture. Initial results from CSF studies are WBC $2 \times 10^3/\text{mm}^3$ ($2 \times 10^9/\text{L}$) with 85% (0.85) PMNs and 39% (0.39) monocytes, protein 182 mg/dL (1820 mg/L), glucose 18 mg/dL (1.0 mmol/L). Gram stain shows gram-positive cocci. Vital signs remain stable in the ED. First doses of antimicrobial therapy are initiated in the ED, and NB is admitted to a pediatric medicine ward for continued treatment and confirmation of final diagnosis. Culture results confirm *Streptococcus pneumoniae* with a penicillin MIC of 1 mg/L and ceftriaxone/cefotaxime susceptibility. Antimicrobials are streamlined and continued for the full duration.

What clues in the CSF results are suggestive of bacterial meningitis?

Would adjunctive steroids offer additional benefit in this patient?

How can his antibiotic regimen be streamlined at this time?

Patient Encounter 1, Part 3

NB has clinically improved on hospital day 3 and would like to be discharged home to continue therapy, but would prefer oral therapy if available. As his teammate's parents learn of his illness, they are concerned about the possibility of their children getting sick and begin to follow up with their own primary care providers. They wonder about medications and vaccinations to prevent the disease.

How long should therapy be continued in NB?

What oral options are viable options for continuation as an outpatient in this case?

Who should receive antimicrobial prophylaxis for Streptococcus pneumoniae?

High-dose parenteral bactericidal antibiotic therapy is required to achieve CSF antibiotic concentrations adequate to rapidly sterilize the CSF and reduce the risk of complications. Data from animal studies and patients demonstrate better outcomes when bactericidal antibiotic therapy (vs bacteriostatic therapy) is used to sterilize the CSF.[14] However, successful treatment of meningitis has been reported with bacteriostatic agents. The presence of infection in the CSF reduces the activity of some classes of antibiotics. For example, the decreased pH of CSF associated with meningitis significantly reduces the activity of aminoglycoside antibiotics.[15]

Antimicrobial pharmacokinetics and pharmacodynamics must be considered when designing treatment regimens for CNS infections. The key of treatment success is the ability of antibiotics to reach and achieve effective concentrations at the infection site. In experimental models of meningitis, maximum bactericidal activity is achieved when CSF concentrations exceed the minimum bactericidal concentration (MBC) of the infecting pathogen by 10- to 30-fold.[16] In general, low-molecular-weight lipophilic antibiotics that are nonionized at physiologic pH and not highly protein bound penetrate best into CSF and other body tissues and fluids.[15,17] In addition to drug characteristics, integrity of the blood–brain barrier determines antibiotic penetration into CSF. The CSF penetration of most, but not all, antibiotics is enhanced by the presence of infection and inflammation. Sulfonamides, trimethoprim, chloramphenicol, rifampin, and most antitubercular drugs achieve therapeutic CSF levels even without meningeal inflammation.[7] Most β-lactams and related antibiotics (ie, carbapenems and monobactams), vancomycin, quinolones, acyclovir, linezolid, daptomycin, and colistin achieve therapeutic CSF levels in the presence of meningeal inflammation.[7] Aminoglycosides, first-generation cephalosporins, second-generation cephalosporins (except cefuroxime), clindamycin, and amphotericin do not achieve therapeutic CSF levels, even with inflammation, but clindamycin does achieve therapeutic brain tissue levels.[7]

An adequate duration of therapy is required to treat meningitis successfully (Table 73–3). **KEY CONCEPT** Parenteral (IV) therapy is administered for the full course of therapy for CNS infections to ensure adequate CSF penetration throughout the course of treatment. Antibiotic treatment (and dexamethasone, if used as a treatment adjunct) reduces the inflammation associated with meningitis, which, in turn, reduces the penetration of some antibiotics into the CSF, and parenteral therapy must be used

Table 73–3

Pathogen-Based Definitive Treatment for CNS Infections[11,24]

Pathogen	Recommended and Alternative Antimicrobial Therapy (Adult Doses)	Adverse Effects/ Safety Monitoring	Renal and Hepatic Dose Adjustment	Duration (Days)
Neisseria meningitidis[a]	*Standard Therapy*			
Penicillin MIC < 0.1 mg/L	Penicillin G 4 million units IV every 4 hours or	Hypersensitivity (rash, anaphylaxis), diarrhea	*Renal*: CrCl < 50 mL/min (0.83 mL/s): 3 million units IV every 4 hours; CrCl < 10 mL/min (0.17 mL/s): 2 million units IV every 4 hours *Hepatic*: No dose adjustment	7
	Ampicillin 2 g IV every 4 hours	Hypersensitivity (rash, anaphylaxis), diarrhea	*Renal*: CrCl < 50 mL/min (0.83 mL/s): 2 g IV every 8 hours; CrCl < 30 mL/min (0.50 mL/s): 2 g IV every 12 hours; CrCl < 10 mL/min (0.17 mL/s): 2 g IV every 24 hours *Hepatic*: No dose adjustment	
	Alternative Therapies			
	Ceftriaxone 2 g IV every 12 hours or	LFT elevation, cholecystitis	*Renal*: No dose adjustment *Hepatic:* Caution in severe hepatic impairment	
	Cefotaxime 2 g IV every 4 hours	Pseudocholelithiasis	*Renal*: CrCl < 80 mL/min (1.34 mL/s): 2 g IV every 6–8 hours; CrCl < 50 mL/min (0.83 mL/s): 2 g IV every 8–12 hours; CrCl < 30 mL/min (0.50 mL/s): 2 g IV every 12 hours; CrCl < 10 mL/min (0.17 mL/s): 2 g IV every 24 hours *Hepatic:* No dose adjustment	
Penicillin MIC 0.1–1 mg/L	*Standard Therapy*			
	Ceftriaxone *or* cefotaxime			
	Alternative Therapies			
	Moxifloxacin 400 mg IV every 24 hours *or*	Nausea/vomiting/diarrhea, dizziness, headache, QT prolongation	*Renal*: No dose adjustment *Hepatic*: Caution in severe hepatic impairment	
	Meropenem 2 g IV every 8 hours *or*	Rash, hypersensitivity, diarrhea, decreased seizure threshold	*Renal*: CrCl < 50 mL/min (0.83 mL/s): 2 g IV every 12 hours; CrCl < 30 mL/min (0.50 mL/s): 500 mg to 1 g IV every 12 hours; CrCl < 10 mL/min (0.17 mL/s): 500 mg to 1 g IV every 24 hours *Hepatic*: No dose adjustment	
	Chloramphenicol 1–1.5 g IV every 6 hours	Rash, diarrhea, seizures, anemia, gray baby syndrome, hypersensitivity, neurotoxicity (last choice due to toxicities)	*Renal*: No dose adjustment *Hepatic*: Reduce dose in moderate to severe impairment; consider serum drug monitoring	
Streptococcus pneumoniae				
Penicillin MIC < 0.1 mg/L	*Standard Therapy*			10–14
	Penicillin G *or* ampicillin			
	Alternative Therapies			
	Ceftriaxone *or* cefotaxime *or* chloramphenicol			
Penicillin MIC 0.1–1 mg/L (ceftriaxone/cefotaxime-sensitive strains)	*Standard Therapy*			
	Ceftriaxone *or* cefotaxime			
	Alternative Therapies			
	Cefepime 2 g IV every 8 hours *or* meropenem	Hypersensitivity (rash, anaphylaxis), decreased seizure threshold	*Renal:* CrCl < 50 mL/min (0.83 mL/s): 2 g IV every 12–24 hours; CrCl < 30 mL/min (0.50 mL/s): 1–2 g IV every 24 hours *Hepatic*: No dose adjustment	

(*Continued*)

Table 73–3

Pathogen-Based Definitive Treatment for CNS Infections[11,24] (*Continued*)

Pathogen	Recommended and Alternative Antimicrobial Therapy (Adult Doses)	Adverse Effects/ Safety Monitoring	Renal and Hepatic Dose Adjustment	Duration (Days)
Penicillin MIC 2 mg/L *or* greater	*Standard Therapy* Vancomycin 15 mg/kg IV every 8–12 hours (with dosing based on serum levels) plus ceftriaxone *or* cefotaxime *Alternative Therapies* Moxifloxacin	Vancomycin: rash, red man syndrome (if infused too quickly) nephrotoxicity, thrombocytopenia	*Renal:* CrCl < 50 mL/min (0.83 mL/s): dosing every 24 hours; CrCl < 20 mL/min (0.33 mL/s): dosing based on serum concentrations; all dose adjustments should be made based on serum concentrations *Hepatic:* No dose adjustment	
Cefotaxime/ ceftriaxone MIC at least 1 mg/L	*Standard Therapy* Vancomycin *plus* ceftriaxone *or* cefotaxime *Alternative Therapies* Moxifloxacin			
H. influenzae β-Lactamase-negative	*Standard Therapy* Ampicillin *Alternative Therapies* Ceftriaxone *or* cefotaxime *or* cefepime *or* moxifloxacin *or* chloramphenicol			7
β-Lactamase-positive	*Standard Therapy* Ceftriaxone *or* cefotaxime *Alternative Therapies* Cefepime *or* moxifloxacin *or* chloramphenicol			
Listeria monocytogenes	*Standard Therapy* Ampicillin *or* penicillin G *plus* gentamicin (5 mg/kg/day, dosing based on serum concentrations)	Gentamicin: nephrotoxicity, ototoxicity	*Renal:* CrCl < 60 mL/min (1.00 mL/s): Use of traditional pharmacokinetic dosing; dose adjustments per serum concentrations *Hepatic:* No dose adjustment	21
	Alternative Therapies Trimethoprim-sulfamethoxazole (10–20 mg/kg trimethoprim) IV per day in divided doses every 6–8 hours *or* meropenem	Trimethoprim-sulfamethoxazole: rash, SJS, bone marrow suppression, hepatotoxicity, elevated serum creatinine, hyperkalemia	*Renal*: CrCl < 50 mL/min (0.83 mL/s): 10–15 mg/kg trimethoprim IV per day divided every 8 hours; CrCl < 10 mL/min (0.17 mL/s): 7–10 mg/kg trimethoprim IV per day divided every 8–12 hours *Hepatic:* No dose adjustment	
Streptococcus agalactiae (group B. *Streptococcus*)	*Standard Therapy* Ampicillin *or* penicillin G *Alternative Therapies* Ceftriaxone *or* cefotaxime			14–21
Enterobacteriaceae	*Standard Therapy* Ceftriaxone *or* cefotaxime *Alternative Therapies* Aztreonam 2 g IV every 6–8 hours	Phlebitis, fever, rash, headache, confusion, seizures	*Renal*: CrCl < 50 mL/min (0.83 mL/s): 2 g IV every 8 hours; CrCl < 30 mL/min (0.50 mL/s): 2 g IV every 12 hours; CrCl < 10 mL/min (0.17 mL/s): 1 g IV every 12 hours *Hepatic:* No dose adjustment	
	Moxifloxacin *or* meropenem *or* trimethoprim-sulfamethoxazole *or* ampicillin

Table 73–3

Pathogen-Based Definitive Treatment for CNS Infections[11,24] (*Continued*)

Pathogen	Recommended and Alternative Antimicrobial Therapy (Adult Doses)	Adverse Effects/ Safety Monitoring	Renal and Hepatic Dose Adjustment	Duration (Days)
Pseudomonas aeruginosa	*Standard Therapy* cefepime *or* ceftazidime 2 g IV every 8 hours *or* meropenem (addition of aminoglycoside should be considered)	Hypersensitivity, rash, anemia, neutropenia, eosinophilia, LFT elevation	*Renal*: CrCl < 50 mL/min (0.83 mL/s): 1–2 g IV every 12 hours; CrCl < 30 mL/min (0.50 mL/s): 1–2 g IV every 24 hours; CrCl < 10 mL/min (0.17 mL/s): 1 g IV every 24 hours *Hepatic*: No dose adjustment	
	Alternative Therapies Aztreonam *or* ciprofloxacin 400 mg IV every 8–12 hours (addition of aminoglycoside should be considered)	Nausea/vomiting/diarrhea, dizziness, headache, rash, confusion, seizures	Ciprofloxacin: *Renal*: CrCl < 30 mL/min (0.50 mL/s): 400 mg IV every 24 hours *or* 200 mg IV every 12 hours *Hepatic*: No dose adjustment	
Staphylococcus aureus	*Standard Therapy*			
Methicillin-susceptible	Nafcillin *or* oxacillin 2 g IV every 4 hours	Rash, nausea/vomiting/ diarrhea, acute interstitial nephritis	*Renal*: No dose adjustment *Hepatic*: No dose adjustment (combined renal and hepatic impairment may require dose adjustment)	
	Alternative Therapies Vancomycin *or* meropenem	Rifampin: Hepatotoxicity, red-orange discoloration of body fluids, skin rash, hepatic enzyme induction		
Methicillin-resistant	*Standard Therapy* Vancomycin *plus* Rifampin 600 mg po *or* IV daily if shunt involved		*Renal*: No dose adjustment *Hepatic*: Caution in moderate/severe hepatic impairment	
	Alternative Therapies Linezolid 600 mg IV every 12 hours *or* trimethoprim-sulfamethoxazole	Linezolid: blood dyscrasias, myalgias, arthralgias, neuropathy	*Renal*: No dose adjustment *Hepatic*: No dose adjustment	
Staphylococcus epidermidis	*Standard Therapy* Vancomycin *plus* rifampin 600 mg po *or* IV daily if shunt involved			
	Alternative Therapies Linezolid			
Herpes simplex virus	*Standard Therapy* Acyclovir 10 mg/kg IV every 8 hours (adults); 20 mg/kg IV every 8 hours (neonates)	Nephrotoxicity, crystalluria, nausea/ vomiting, neurotoxicity, phlebitis	*Renal*: CrCl < 50 mL/min (0.83 mL/s): 10 mg/kg IV every 12 hours; CrCl < 30 mL/min (0.50 mL/s): 10 mg/kg IV every 24 hours; CrCl < 10 mL/min (0.17 mL/s): 5 mg/kg IV every 24 hours *Hepatic*: No dose adjustment	
	Alternative Therapy Foscarnet 120–200 mg/kg IV per day in divided doses every 8–12 hours	Nephrotoxicity, electrolyte imbalances, nausea/ vomiting, headache, penile ulceration, thrombophlebitis, seizures	*Renal*: CrCl: 1.0–1.4 mL/min/kg (0.017–0.023 mL/s/kg): 70 mg/kg IV every 12 hours; CrCl: 0.8–1.0 mL/min/kg (0.013–0.017 mL/s/kg): 50 mg/kg IV every 12 hours; CrCl: 0.6–0.8 mL/min/kg (0.010–0.013 mL/s/kg): 80 mg/kg IV every 24 hours; CrCl: 0.5–0.6 mL/min/kg (0.008–0.010 mL/s/kg): 60 mg/kg IV every 24 hours; CrCl: 0.4–0.5 mL/min/kg (0.007–0.008 mL/s/kg): 50 mg/kg IV every 24 hours; CrCl < 0.4 mL/min/kg (0.007 mL/s/kg) *or* < 20 mL/min (0.33 mL/s) not recommended *Hepatic*: No dose adjustment

throughout the entire treatment course to ensure adequate concentrations. Carefully selected patients who have close medical monitoring and follow-up may be able to receive a portion of their parenteral meningitis treatment on an outpatient basis.[11,18] A management algorithm for adults with suspected bacterial meningitis, as recommended by the Infectious Diseases Society of America (IDSA), is summarized in Figure 73–2.

Empirical Antimicrobial Therapy

After diagnosis, prompt and aggressive antimicrobial therapy with an appropriate empirical treatment is of the utmost importance in patients with suspected CNS infections. In most patients, a diagnostic LP will be performed before beginning antibiotics, but this should never delay initiation of antimicrobials. Antibiotic pretreatment may alter the CSF profile and complicate interpretation. **KEY CONCEPT** Empirical therapy should be directed at the most likely pathogen(s) for a specific patient, taking into account age, risk factors for infection (including underlying disease and immune dysfunction, vaccine history, and recent exposures), CSF Gram stain results, CSF antibiotic penetration, and local antimicrobial resistance patterns. Results of the CSF Gram stain may be used to help narrow empirical therapy for bacterial meningitis. In the absence of a positive Gram stain, empirical therapy should be continued for at least 48 to 72 hours, when meningitis may, in most cases, be ruled out by CSF findings inconsistent with bacterial meningitis, negative CSF culture, and negative polymerase chain reaction (PCR) evaluations. A repeat LP may be useful in the absence of other findings. Table 73–1 outlines recommendations for empirical antibiotic therapy for bacterial meningitis by most likely pathogen(s) and patient risk factors.

Impact of Antimicrobial Resistance on Treatment Regimens for Meningitis

Development of resistance to β-lactam antibiotics, including penicillins and cephalosporins, has significantly impacted the management of bacterial meningitis with one-fifth of CSF isolates resistant to penicillin and 3.5% of isolates resistant to cephalosporins.[19] The Clinical and Laboratory Standards Institute (CLSI) has set a lower ceftriaxone susceptibility breakpoint for pneumococcal CSF isolates (1 mg/L) than for isolates from non-CNS sites (2 mg/L). Empirical treatment regimens now include the combination of a third-generation cephalosporin plus vancomycin. Recognition of relative and high-level resistance to *N. meningitidis* in the laboratory, as well as in clinical treatment failures, has led to greater use of third-generation cephalosporins for empirical therapy of meningococcal meningitis.[3,11] Treatment of suspected or proven β-lactamase-mediated Hib meningitis also requires a third-generation cephalosporin. Increasing rates of methicillin-resistant *S. aureus* (about one-third of staphylococcal CSF isolates) and coagulase-negative staphylococci require the

Arch Intern Med. 1999;159:1185–1194.)

use of vancomycin for empirical therapy when these staphylococcal pathogens are suspected.[11,18]

The emergence and continued rise of multidrug-resistant strains of gram-negative organisms such as *Pseudomonas aeruginosa*, *Acinetobacter* species, AmpC, and extended-spectrum β-lactamase (ESBL) producing strains of Enterobacteriaceae have become a recognized threat nationally, and broad-spectrum therapy taking into account local resistance patterns should be used.

Pathogen-Directed Antimicrobial Therapy

KEY CONCEPT Empirical antimicrobial therapy should be modified on the basis of laboratory data and clinical response. If cultures, CSF Gram stain, or antigen/antibody testing indicate a specific pathogen, therapy should be adjusted quickly as needed to ensure adequate coverage for the offending pathogen(s). Table 73–3 outlines recommended definitive pathogen-directed treatment regimens, recommended treatment duration, and key adverse effects that should be monitored during antibiotic therapy for meningitis. Table 73–4 provides pediatric doses of selected agents used in bacterial meningitis treatment.

▶ *Neisseria meningitidis* Meningitis

N. meningitidis CNS infections are decreasing in incidence with 0.1 cases per 100,000 population in the United States in 2018.[20] They most commonly occur in children and young adults. From 10% to 20% of survivors of meningococcal meningitis experience long-term sequelae, including hearing loss, limb loss, and neurologic deficits.[20] Nearly all meningococcal disease is caused by five serogroups: A, B, C, Y, and W-135. In the United States, serotypes B, C, and Y each are responsible for approximately 30% of cases.[3,4]

Meningococcal meningitis is observed most commonly in individuals living in close quarters (eg, college students, military personnel). Infants younger than 1 year are at the highest risk, possibly because pneumococcal vaccination reduces bactericidal antibodies.[21] Children, adolescents, and young adults are also at high risk.[20,22] *N. meningitidis* colonizes the nasopharynx and usually is transmitted via inhaled respiratory droplets from patients or asymptomatic carriers. A subclinical bacteremia typically ensues, seeding the meninges. Meningococcal disease is often (approximately 50%) associated with a diffuse petechial rash, and patients may experience behavioral changes. Patients may develop fulminant meningococcal sepsis, characterized by shock, disseminated intravascular coagulation (DIC), and multiorgan failure.[23] Meningococcal sepsis has a poor prognosis and carries a mortality rate of up to 80%, whereas the mortality rate with meningococcal meningitis alone is 13%.[23,24] Patients with suspected meningococcal infection should be kept on respiratory isolation for the first 24 hours of treatment.[20]

Increasing penicillin resistance requires that third-generation cephalosporins now be used for empirical treatment until *in vitro* susceptibilities are known.[11,15] Patients with a history of type I penicillin allergy or cephalosporin allergy may be treated with vancomycin. Treatment should be continued for 7 days, after which no further treatment is necessary.

Prevention of meningococcal disease by vaccination is a key to reducing the incidence of meningococcal meningitis.

Table 73–4

Pediatric Doses of Selected Agents Used in Bacterial Meningitis Treatment

	Neonates, 0–7 Days	Neonates, 8–28 Days	Infants and Children
Ampicillin	150 mg/kg IV per day in divided doses every 8 hours	200 mg/kg IV per day in divided doses every 6–8 hours	300 mg/kg IV per day in divided doses every 8 hours
Cefepime	—	—	150 mg/kg/day in divided doses every 8 hours
Cefotaxime	100–150 mg/kg IV per day in divided doses every 8–12 hours	150–200 mg/kg IV per day in divided doses every 6–8 hours	225–300 mg/kg/day in divided doses every 6–8 hours
Ceftriaxone	—	—	80–100 mg/kg IV per day in divided doses every 12 hours
Gentamicin	5 mg/kg IV per day in divided doses every 12 hours (with dosing based on serum levels)	7.5 mg/kg IV per day in divided doses every 8 hours with dosing based on serum levels	7.5 mg/kg IV per day in divided doses every 8 hours based on serum levels
Meropenem	—	—	120 mg/kg IV per day in divided doses every 8 hours
Nafcillin/oxacillin	75 mg/kg IV per day in divided doses every 8–12 hours	Nafcillin: 100–150 mg/kg IV per day in divided doses every 6–8 hours; Oxacillin: 150–200 mg/kg IV per day in divided doses every 6–8 hours	200 mg/kg IV per day in divided doses every 6 hours max, 2 g pediatrics > 3 months of age
Penicillin G	0.15 million units/kg IV per day in divided doses 8–12 hours	0.2 million units/kg IV per day in divided doses every 6–8 hours	0.3 million units/kg IV per day in divided doses every 4–6 hours
Vancomycin	20–30 mg/kg IV per day in divided doses every 8–12 hours	30–45 mg/kg IV per day in divided doses every 6–8 hours	60 mg/kg IV per day in divided doses every 6 hours

LFTs, liver function tests; MIC, minimum inhibitory concentration.

Adapted, with permission, from Scheld WM, Koedel U, Nathan B, Pfister HW. Pathophysiology of bacterial meningitis: mechanism(s) of neuronal injury. J Infect Dis 2002;186(Suppl 2):S225–S233.

The quadrivalent conjugate meningococcal vaccine protects against four of the five serotypes causing invasive disease (A, C, Y, and W-135). A separate vaccine product confers protection against serogroup B. Meningococcal vaccines can be used in outbreak situations, with protective antibodies measurable within 7 to 10 days. Routine vaccination should be administered between ages 11 and 12 years with a booster dose at age 16 with quadrivalent vaccine that provides protection against serogroups A, C, Y, and W.[20] Additional vaccination against serogroup B can be considered in all patients for short-term disease protection in a shared-decision-making process and is recommended in those with immunocompromising conditions. In addition, individuals aged 2 through 54 years who are immunocompromised (including those with complement deficiencies, who have HIV, or who have asplenia) or those with recent disease exposure during community outbreaks should receive the quadrivalent vaccine and the vaccine against Serogroup B is also recommended for immunocompromised individuals and during outbreaks.[20] Additionally, children less than 2 years may also need quadrivalent vaccine and serogroup B vaccine, depending on risk factors. **KEY CONCEPT** Close contacts of patients with meningococcal infections should be evaluated for antimicrobial prophylaxis. Close contacts include members of the same household, individuals who share sleeping quarters, daycare contacts, and individuals exposed to oral secretions of meningitis patients. After consultation with the local health department, close contacts should receive prophylactic antibiotics to eradicate nasopharyngeal carriage of the organism. Household contacts of patients with meningococcal meningitis have a 400- to 800-fold increased risk of developing meningitis.[23] Prophylactic antibiotics should be started as soon as possible, preferably within 24 hours of exposure and within 14 days. Recommended regimens, all of which are 90% to 95% effective, for adults include rifampin 600 mg orally every 12 hours for 2 days, ciprofloxacin 500 mg orally for one dose, or ceftriaxone 250 mg intramuscularly for one dose. Regimens for children include rifampin 5 mg/kg orally every 12 hours for 2 days (< 1 month of age), rifampin 10 mg/kg orally every 12 hours for 2 days (> 1 month of age), or ceftriaxone 125 mg intramuscularly for one dose (< 12 years of age).[11,23] It is not known whether close contacts who have been vaccinated will benefit from prophylaxis. Patients with meningococcal meningitis who are treated with antibiotics other than third-generation cephalosporins also should be considered for prophylaxis to eradicate the nasopharyngeal carrier state.[22]

▶ *Streptococcus pneumoniae Meningitis*

S. pneumoniae is the most common cause of meningitis in adults and in children younger than 2 years of age. Pneumococcus is associated with the highest mortality observed with bacterial

Patient Encounter 2, Part 1

BB is an 18-year-old college freshman who is brought to the ED with a 1-day history of extreme fatigue and fever. Her roommate brought her to ED because of confusion and vomiting. Vital signs and laboratory values include a rectal temperature of 38.6°C (101.5°F), respirations 24 per minute, heart rate 119 beats/min, and peripheral WBC of $22.1 \times 10^3/mm^3$ ($22.1 \times 10^9/L$), with 72% (0.72) PMNs. Physical examination reveals an unresponsive patient with nuchal rigidity.

What signs and symptoms consistent with meningitis are present in BB?

What clues to causative pathogen are present in BB?

What empiric antimicrobial regimen should be started?

meningitis in adults (14%–18%), and coma and seizures are more common in pneumococcal meningitis.[1-3] Patients at high risk for pneumococcal meningitis include the elderly, alcoholics, post-splenectomy patients, patients with sickle cell disease, and patients with cochlear implants. At least 50% of pneumococcal meningitis cases are due to a primary infection of the ears, sinuses, or lungs.

Due to increases in pneumococcal resistance to high-dose -penicillin G, the preferred empirical treatment now includes a third-generation cephalosporin in combination with vancomycin.[11] All CSF isolates should be tested for penicillin and cephalosporin resistance by methods endorsed by the CLSI. Once *in vitro* sensitivity results are known, therapy may be tailored (see Table 73–3). Patients with a history of type I penicillin or cephalosporin allergy may be treated with vancomycin. Treatment should be continued for 10 to 14 days, after which no further maintenance therapy is required. Antimicrobial prophylaxis is not indicated for close contacts.

Administration of vaccines to high-risk individuals is a key strategy to reduce the risk of invasive pneumococcal disease. Routine use of the 13-valent pneumococcal vaccine (PCV13) has led to sharp declines in pneumococcal disease for adults and children.[25] The 23-valent pneumococcal vaccine targets serotypes that account for more than 90% of invasive disease in high-risk patients. However, the 23-valent vaccine does not produce a reliable immunologic response in children younger than 2 years, nor does it reduce pneumococcal carriage. The 7-valent pneumococcal protein-polysaccharide conjugate vaccine used between 2000 and 2010 targeted the seven most common serotypes in children and provided protection (94% reduction) against invasive pneumococcal disease (such as sepsis and meningitis) in children younger than 5 years.[4,26,27] PCV13, a 13-valent vaccine introduced in 2010, confers protection against additional serotypes 1, 3, 4, 5, 6A, 6B, 7F, 9V, 14, 18C, 19A, 19F, and 23F. Due to observed declines in disease with PCV13, it is now recommended that PCV13 be used for children younger than 18 years.[25] For adults aged ≥ 65 years, the 23-valent vaccine should be routinely administered as a single dose. PCV13 vaccination should be considered in immunocompromised adults.[25] Additionally, immunization schedules provided by Centers for Disease Control and Prevention (CDC) are updated at least annually and should be consulted for more details.

▸ *Haemophilus influenzae Meningitis*

Prior to the introduction of the Hib conjugate vaccine, *H. influenzae* type B was the most common cause of bacterial meningitis in the United States.[3,4] Routine inoculation of pediatric patients against Hib has significantly reduced the incidence of Hib meningitis between 1998 and 2007.[3,4] The Hib vaccine is also recommended for patients undergoing splenectomy. Hib meningeal disease is often associated with a parameningeal focus such as a sinus or middle ear infection. Due to β-lactamase–mediated resistance, the empirical treatment of choice is third-generation cephalosporins (eg, ceftriaxone and cefotaxime). Treatment should be continued for 7 days, after which no further maintenance therapy is required.

KEY CONCEPT Close contacts of patients with H. influenzae type B meningitis should be evaluated for antimicrobial prophylaxis. The risk of Hib meningitis in close contacts may be up to 200- to 1000-fold higher than in the general population.[7] Invasive Hib disease, including meningitis, should be reported to the local health department and the CDC. Prophylaxis to eliminate nasal and oropharyngeal carriage of Hib in exposed individuals should be initiated after consultation with local health officials. Rifampin (600 mg/day for adults; 20 mg/kg/day for children, maximum of 600 mg/day) is administered for 4 days.[11,16] Rifampin prophylaxis is not necessary for individuals who have received the full Hib vaccine series. Exposed, unvaccinated children between 12 and 48 months of age should receive one dose of vaccine, and unvaccinated children 2 to 11 months of age should receive three doses of vaccine, as well as rifampin prophylaxis.[11,16]

Patient Encounter 2, Part 2

BB underwent lumbar puncture. Initial results from CSF studies are WBC $1.82 \times 10^3/\text{mm}^3$ ($1.82 \times 10^9/\text{L}$) with 76% (0.76) PMNs, protein 255 mg/dL (2550 mg/L), glucose 30 mg/dL (1.7 mmol/L), with a concurrent serum glucose of 110 mg/dL (6.1 mmol/L). Gram stain shows gram-positive diplococci and culture results identify *Neisseria* infection with a penicillin MIC of 1 mg/L. The patient is admitted to an acute care unit and remains clinically stable.

What complications is BB at risk for acutely? What potential long-term complications may result?

How can her antibiotic regimen be streamlined at this time?

How long should the antibiotics be continued?

▸ *Listeria monocytogenes Meningitis*

L. monocytogenes is an intracellular gram-positive bacillus that contaminates foods, such as soft cheese, unpasteurized milk, raw meats and fish, processed meats, and raw vegetables. Bacteria from contaminated foods colonize the GI tract, pass into the bloodstream, and overcome natural cellular immune responses to cause infection. *L. monocytogenes* meningitis, usually observed in patients at extremes of age and in immunocompromised patients with depressed cellular immunity (including patients with leukemia, solid-organ transplants, and HIV/AIDS) has an overall mortality rate of up to 30% and is associated with miscarriage when infection occurs during pregnancy.[28,29]

Only a limited number of antibiotics show bactericidal activity against *L. monocytogenes*. The combination of high-dose ampicillin or penicillin G and an aminoglycoside is synergistic and bactericidal against *L. monocytogenes*. A total treatment course of at least 3 weeks is required. Because of concerns about the risk of nephrotoxicity with an extended treatment course of aminoglycosides, patients are treated with combination therapy for 10 days and may finish out the remainder of their treatment with ampicillin or penicillin alone.[29] In penicillin-allergic patients, trimethoprim-sulfamethoxazole is the agent of choice due to documented *in vitro* bactericidal activity against *L. monocytogenes*, as well as good CNS penetration. Vancomycin and cephalosporins are not effective treatments for *L. monocytogenes* meningitis. Prophylaxis is not needed for close contacts, nor is suppressive therapy indicated. Patients with severe depression of cell-mediated immunity should be advised to avoid foods that may be contaminated with *L. monocytogenes.*

▸ *Group B Streptococcus Meningitis*

Infection with GBS (eg, *S. agalactiae*) is the most common cause of neonatal sepsis and meningitis. Around 15% to 35%

of pregnant women are a carrier of GBS in the vagina or rectum. Group B streptococci can be acquired during childbirth after exposure to infected secretions from the mother's birth canal or rectum. Neonates born to women who are carriers are at very high risk (1 of every 100–200 babies) of developing invasive group B streptococcal disease.[30] Neonatal meningitis is associated with significant morbidity and mortality. Synergistic treatment with penicillin or ampicillin, plus gentamicin, for 14 to 21 days is recommended for group B streptococcal meningitis.[11]

To reduce the risk of clinical group B streptococcal disease in neonates, pregnant women should be screened at 35 to 37 weeks' gestation to determine whether they are carriers of group B streptococci.[30] Intrapartum antibiotics (eg, penicillin or ampicillin) are recommended for pregnant women with the following characteristics: group B streptococcal carrier state detected at screening, history of group B streptococcal bacteriuria at any time during pregnancy, and history of delivery of infant with invasive group B streptococcal disease.[30]

▶ *Gram-Negative Bacillary Meningitis*

Meningitis caused by enteric gram-negative bacilli is an important cause of morbidity and mortality in populations at risk, including those with diabetes, malignancy, cirrhosis, immunosuppression, advanced age, parameningeal infection, and/or a defect allowing communication from skin to CNS (eg, neurosurgery, congenital defects, cranial trauma).[7]

The optimal treatment for gram-negative bacillary meningitis is not well defined. The introduction of extended-spectrum cephalosporins has improved patient outcomes significantly. Although the third-generation cephalosporins ceftriaxone and cefotaxime provide good coverage for most Enterobacteriaceae, these antibiotics are not active against *P. aeruginosa*. Ceftazidime, cefepime, and carbapenems are effective in pseudomonal meningitis.[15,17] Addition of an aminoglycoside may improve treatment results; however, CNS penetration of aminoglycosides is extremely poor, even in the setting of inflamed meninges. Intrathecal or intraventricular administration of aminoglycosides may be useful, but intraventricular antibiotics have been associated with increased mortality in neonates.[15,31] Intrathecal therapy is accomplished by administering the antibiotic into the CSF via LP, whereas intraventricular therapy is usually administered in the ventricles of the brain.

Initial therapy of suspected or documented pseudomonal meningitis should include an antipseudomonal β-lactam (eg, cefepime, meropenem) plus an aminoglycoside (eg, tobramycin, amikacin). Although the carbapenem imipenem-cilastatin has similar activity to these β-lactams, its use is not recommended in meningitis because of the risk of seizures. Aztreonam, high-dose ciprofloxacin, and colistin are alternative treatments for pseudomonal meningitis, although local susceptibility rates should be considered before initiating alternative therapy. Local therapy (ie, intrathecal or intraventricular therapy) may be indicated in patients with multidrug-resistant gram-negative bacillary meningitis or in patients who fail to improve on IV antibiotics alone. In cases of multidrug-resistant pathogens, alternative pharmacodynamic dosing strategies such as continuous or extended infusion of β-lactam antimicrobials may be considered to optimize target attainment (time greater than minimum inhibitory concentration [MIC]). Given the differences in local hospital resistance patterns, administration of pathogen-directed treatment is very important after microbiology results become available. Therapy for gram-negative bacillary meningitis should be continued for at least 21 days.

▶ *Healthcare-Associated Meningitis and Ventriculitis*

Patients who undergo neurosurgical procedures or have invasive or implanted foreign devices including CSF shunts, intraspinal pumps or catheters, or epidural catheters are at risk for CNS infections. Key pathogens in postneurosurgical infections include coagulase-negative staphylococci, *S. aureus*, streptococci, propionibacteria, and gram-negative bacilli, including *E. Coli*, Enterobacter species, Citrobacter species, and *P. aeruginosa*.[32] Clinical signs and symptoms may be similar to those of other CNS infections, and there also may be evidence of malfunction of implanted hardware or visible signs of a postoperative wound infection. Diagnosis of these infections includes analysis of CSF fluid, obtained either via lumbar puncture or the implanted device. Additionally, device removal is usually necessary for adequate infection treatment and microbiologic identification from removed devices may be helpful.[32]

Empirical therapy for postoperative infections in neurosurgical patients (including patients with CSF shunts) should include vancomycin in combination with either cefepime, ceftazidime, or meropenem. In patients who cannot receive vancomycin either due to contraindications or resistance, linezolid, daptomycin, or trimethoprim-sulfamethoxazole may be used to treat *Staphylococcal* infection. Evidence with these agents is limited and selection should be based on susceptibility testing.[32] The addition of rifampin is recommended for treatment of intracranial or intraspinal hardware infections including shunts or drains. Removal of infected devices is desirable; aggressive antibiotic therapy (including high-dose IV antibiotic therapy plus intraventricular vancomycin and/or tobramycin) may be effective for patients in whom hardware removal is not possible.[33] The duration of treatment for these infections is 10 to 14 days. The use of prophylactic antibiotics against meningitis post-device placement beyond procedural prophylaxis remains controversial.[34,35] Peri-Procedural antimicrobials are recommended prior to device placement, but prolonged prophylaxis while devices are in place is not recommended.[32]

Brain abscesses are localized collections of pus within the cranium. These infections are difficult to treat due to the presence of walled-off infections in the brain tissue reducing antibiotic penetration. In addition to appropriate antimicrobial therapy (a discussion of which is beyond the scope of this chapter), surgical debridement is often required as an adjunctive measure. Surgical debridement may also be required in the management of neurosurgical postoperative infections.

▶ *Viral Encephalitis and Meningitis*

Viral encephalitis and meningitis may mimic bacterial meningitis on clinical presentation but often can be differentiated by CSF findings (see Table 73–2). The most common viral pathogens are enteroviruses, which cause approximately 85% of cases of viral CNS infections.[7] Other viruses that may cause CNS infections include arboviruses, HSV, cytomegalovirus, varicella-zoster virus, rotavirus, coronavirus, influenza viruses A and B, West Nile virus, and Epstein-Barr virus. Viral CNS infections are acquired through hematogenous or neuronal spread.[7] Most cases of enteroviral meningitis or encephalitis are self-limiting with supportive treatment.[36] However, arbovirus, West Nile virus, and Eastern equine virus infections are associated with a less favorable prognosis.

In contrast to other viral encephalitides, HSV type 1 and 2 encephalitis are treatable. Although rare (one case per 250,000 population per year in the United States), HSV encephalitis is a serious, life-threatening infection.[37] More than 90% of HSV encephalitis in adults is due to HSV type 1, whereas HSV type 2 predominates in neonatal HSV encephalitis (> 70%).[38] HSV encephalitis is the result of reactivation of a latent infection (two-thirds of cases) or a severe case of primary infection (one-third). Without effective treatment, the mortality rate may be as high as 85%, and survivors often have significant residual neurologic deficits. In accordance with 2008 IDSA guidelines, high-dose IV acyclovir is the drug of choice, given for 2 to 3 weeks at a dose of 10 mg/kg IV every 8 hours in adults, based on ideal body weight, and for 3 weeks at a dose of 20 mg/kg IV every 8 hours in neonates.[39] Patients receiving acyclovir should maintain adequate hydration (consider continuous IV hydration) to help prevent acute kidney injury secondary to crystal nephropathy.[41] Foscarnet 120 to 200 mg/kg/day divided every 8 to 12 hours for 2 to 3 weeks is the treatment of choice for acyclovir-resistant HSV.[39]

▶ *Opportunistic CNS Infections*

Cerebral Toxoplasmosis Across the globe, cerebral toxoplasmosis represents the most common focal brain infection in HIV-infected patients. Infection rates in the United States vary but are reported to be approximately 15% among patients with AIDS.[40] The majority of cases occur in patients with $CD4^+$ cell counts less than 100 cells/mm^3 (100×10^6/L). Potent antiretroviral therapy and primary prophylaxis (first-line option is sulfamethoxazole-trimethoprim) in IgG-positive patients have greatly reduced the disease burden.[41] First-line therapy in toxoplasmosis encephalitis is pyrimethamine plus sulfadiazine, given concomitantly with leucovorin to prevent severe hematologic adverse effects secondary to pyrimethamine (see tables for dosing).[41] Clindamycin may be substituted for sulfadiazine in cases of contraindications to sulfa-based therapy. Sulfamethoxazole-trimethoprim may also be an option, specifically in patients unable to take oral therapy. Adjunctive corticosteroids and anticonvulsant therapy should be considered to reduce sequelae from the inflammatory process and control active seizures, respectively.[41]

Cryptococcal Meningitis CNS disease secondary to *Cryptococcus neoformans* is primarily observed in severely immunocompromised hosts, such as those with HIV infection. Potent antiretroviral therapy has significantly reduced the disease burden from preantiretroviral therapy rates of 5% to 8% in developed countries. The majority of disease occurs in patients with $CD4^+$ cell counts less than 50 cells/mm^3 (50×10^6/L). First-line therapy is considered amphotericin B deoxycholate 0.7 mg/kg IV daily plus flucytosine 100 mg/kg/day orally in four divided doses for a minimum of 2 weeks.[41] Therapeutic drug monitoring may be considered for flucytosine to help reduce the risk of adverse effects. Development of renal dysfunction as a result of disease and/or drug toxicity should be closely monitored and may prompt dose reduction or possible switch to alternative lipid formulations of amphotericin, which may be less nephrotoxic. High-dose fluconazole is considered an alternative first-line therapy, especially in resource-limited areas. Secondary prophylaxis with fluconazole for an indefinite period is recommended following the completion of at least 2 weeks of induction therapy and 8 weeks of maintenance therapy with fluconazole.[41]

▶ *Adjunctive Dexamethasone Therapy*

The adjunctive agent dexamethasone improves outcomes in selected patient populations with bacterial meningitis. Dexamethasone inhibits the release of proinflammatory cytokines and limits the CNS inflammatory response stimulated by infection and antibiotic therapy.

Clinical benefit in reducing neurologic deficits (primarily by reducing hearing loss) has been observed in infants and children, if dexamethasone is initiated prior to antibiotic therapy.[1,42] The American Academy of Pediatrics recommends dexamethasone (0.15 mg/kg IV every 6 hours for 2 to 4 days) for infants and children at least 6 weeks of age with Hib meningitis and consideration of dexamethasone in pneumococcal meningitis.[11,43] In contrast to this recommendation, a large multicenter cohort study failed to show any mortality benefit of adjunctive dexamethasone therapy regardless of age or responsible pathogen (*S. pneumoniae* or *N. meningitidis*).[44] Dexamethasone should be initiated 10 to 20 minutes before or no later than the time of initiation of antibiotic therapy; it is not recommended for infants and children who have already received antibiotic therapy because it is unlikely to improve treatment outcome in these patients. There are insufficient data to make a recommendation regarding the use of adjunctive dexamethasone therapy in neonatal meningitis.

In adults, a significant benefit was observed with dexamethasone in reducing meningitis complications, including death, particularly in patients with pneumococcal meningitis.[45] The IDSA recommends dexamethasone 0.15 mg/kg IV every 6 hours for 2 to 4 days (with the first dose administered 10–20 minutes before or with the first dose of antibiotics) in adults with suspected or proven pneumococcal meningitis.[11] Dexamethasone is not recommended for adults who have already received antibiotic therapy. Some clinicians would administer dexamethasone to all adults with meningitis pending results of laboratory tests. Benefit of dexamethasone in bacterial meningitis in an HIV-positive population has not been clearly established.[46]

There is controversy regarding the administration of dexamethasone to patients requiring vancomycin for pneumococcal meningitis. Animal models indicate that concurrent steroid use reduces vancomycin penetration into the CSF by 42% to 77% and delays CSF sterilization.[15] A prospective evaluation in patients with pneumococcal meningitis receiving vancomycin and adjunctive dexamethasone demonstrated that adequate concentrations of vancomycin (nearly 30% of serum concentrations) were achievable in the CSF, provided appropriate vancomycin dosage was utilized.[47] Treatment failures have been reported in adults with resistant pneumococcal meningitis who were treated with dexamethasone, but the risk–benefit of using dexamethasone in these patients cannot be defined at this time. Animal models indicate a benefit of adding rifampin in patients with resistant pneumococcal meningitis whenever dexamethasone is used.[15,17]

Patient Encounter 2, Part 3

Upon review of her records, BB did not receive vaccination against *Neisseria meningitis* prior to college. In addition, her roommates are concerned about getting sick and inquire about measures to help prevent disease.

Who should receive antimicrobial prophylaxis for Neisseria?

Who should receive vaccination against meningococcal disease?

Patient Care Process

Collect Information:

- Obtain a complete patient allergy history, including details on the severity of reactions, and obtain a medication history.
- Determine if patient has received recent antibiotics that may influence LP results or treatment decisions.
- Review laboratory values, past medical history, and vaccination history.

Assess the Information:

- Analyze CSF findings to determine the likely etiology of meningitis.
- Assess the patient history for possible risk factors for specific etiologies of meningitis.
- Determine from a medication history if any medicines may be associated with drug-induced aseptic meningitis.

Develop a Care Plan:

- Based on patient-specific factors and local susceptibility patterns, determine appropriate empirical antimicrobial treatment plan.
- Assess LP results, results of antigenic testing, and culture and susceptibility for additional data to help streamline therapy.

Implement the Care Plan:

- Collaborate with treatment team to ensure timely administration of antibiotic in relation to performing LP and obtaining blood cultures.
- Collaborate with treatment team to determine appropriate administration of adjunctive corticosteroid therapy.

Follow-up: Monitor and Evaluate:

- Monitor patient for any antimicrobial-related adverse events. Provide recommendations for necessary prophylaxis based on causative pathogen and exposure history.
- Determine appropriate length of therapy for diagnosed CNS infection.
- Provide recommendations for outpatient parenteral therapy as needed upon discharge from acute care facility.

OUTCOME EVALUATION

Monitor patients with CNS infections continuously throughout their treatment course to evaluate their progress toward achieving treatment goals, including relief of symptoms, eradication of infection, and reduction of inflammation to prevent death and the development of neurologic deficits. These treatment goals are best achieved by appropriate parenteral antimicrobial therapy, including empirical therapy to cover the most likely pathogens, followed by directed therapy after culture and sensitivity results are known. **KEY CONCEPT** Components of a monitoring plan to assess efficacy and safety of antimicrobial therapy of CNS infections include clinical signs and symptoms and laboratory data (eg, CSF findings, culture, sensitivity data).

During the patient's treatment course, monitor clinical signs and symptoms at least 3 times daily. Trends are more important than one-time assessments. Expect fever, headache, nausea and vomiting, and malaise to begin to improve within 24 to 48 hours of initiation of antimicrobial therapy and supportive care. Evaluate the patient for resolution of neurologic signs and symptoms, such as altered mental status and nuchal rigidity, as the infection is eradicated and inflammation is reduced within the CNS. Expect improvement and subsequent resolution of signs and symptoms as the treatment course continues. At the time of hospital discharge, arrange outpatient follow-up for several weeks to months depending on the causative pathogen, clinical treatment course, and patient's underlying comorbidities.

Monitoring of laboratory tests is important in patients receiving treatment for CNS infections. Monitor CSF and blood cultures so that antimicrobial therapy can be tailored to the etiologic organisms. Follow-up cultures may be obtained to prove eradication of the organism(s) or treatment failure. Although repeat LP generally is not performed, consider repeat LP for patients who do not respond clinically after 48 hours of appropriate antimicrobial therapy, especially those with resistant pneumococcus who receive dexamethasone.[11] Other candidates for repeat LP include those with infection with gram-negative bacilli, prolonged fever, and recurrent meningitis. Repeat the LP in neonates to determine the duration of therapy. Repeat LP also may be performed to relieve elevated intracranial pressure. Expect repeat blood cultures to become negative quickly during therapy and the serum WBC count to improve and normalize with appropriate antimicrobial therapy.

Evaluate antimicrobial dosing regimens to ensure efficacy of the treatment regimen. Trough vancomycin concentrations of 15 to 20 mg/L (10–14 μmol/L) are recommended for the treatment of CNS infections. Some clinicians have shifted to an AUC-based monitoring of vancomycin, however there are limited data for target concentrations in CNS infections at this time.[42] Monitor patients for drug adverse effects, drug allergies, and drug interactions. The specific safety monitoring plan will depend on the antibiotic(s) used (Table 73–3). Pay close attention to concomitant medications in patients on rifampin for treatment or prophylaxis. Rifampin is a potent inducer of hepatic metabolism and may reduce the efficacy of other drugs metabolized by the cytochrome P-450 enzyme pathway.

Abbreviations Introduced in This Chapter

CDC	Centers for Disease Control and Prevention
CLSI	Clinical and Laboratory Standards Institute
CNS	Central nervous system
CSF	Cerebrospinal fluid
DIC	Disseminated intravascular coagulation
ESBL	Extended spectrum β-lactamase
GBS	Group B *Streptococcus*
Hib	*Haemophilus influenzae* type B
HSV	Herpes simplex virus
IDSA	Infectious Diseases Society of America
IL-1	Interleukin 1
LP	Lumbar puncture
MBC	Minimum bactericidal concentration

MIC	Minimum inhibitory concentration
MRSA	Methicillin-resistant *Staphylococcus aureus*
MRSE	Methicillin-resistant *Staphylococcus epidermidis*
NSAIDs	Nonsteroidal anti-inflammatory drugs
PCR	Polymerase chain reaction
PMN	Polymorphonuclear cell
SJS	Stevens-Johnson Syndrome
TNF-α	Tumor necrosis factor-alpha

Lower Respiratory Tract Infections

Diane M. Cappelletty

LEARNING OBJECTIVES

Upon completion of the chapter, the reader will be able to:

1. List the common pathogens that cause community-acquired pneumonia (CAP), ventilator-associated pneumonia (VAP), and hospital-acquired pneumonia (HAP).
2. Explain the pathophysiology of pneumonia and associated host defenses.
3. List the signs and symptoms associated with CAP, HAP, and VAP.
4. Identify patient and organism factors required to guide the selection of a specific antimicrobial regimen for an individual patient.
5. Design an appropriate empirical antimicrobial regimen based on patient-specific data for an individual with CAP, HAP, and VAP.
6. Design an appropriate antimicrobial regimen based on both patient- and organism-specific data.
7. Develop a monitoring plan based on patient-specific information for a patient with one of the three categories of pneumonia.
8. Apply the complete Patient Care Process to caring for patients with any type of pneumonia.
9. Formulate appropriate educational information to be provided to a patient with pneumonia.
10. Explain prevention of pneumonia via immunization and include who the appropriate patient groups are for receiving the various vaccines.

INTRODUCTION

Pneumonia is inflammation of the lung with consolidation. The cause of the inflammation is infection, which can be caused by a wide range of organisms. **KEY CONCEPT** There are three classifications of pneumonia: community-acquired, hospital-acquired, and ventilator-associated. Patients who develop pneumonia in the outpatient setting and have not been in any healthcare facilities, which include wound care and hemodialysis clinics, have community-acquired pneumonia (CAP). Aspiration was once considered a category of pneumonia, now it should be considered a patient factor for possible anaerobic organism involvement. In addition, healthcare-associated pneumonia was once a category of pneumonia but not any longer. It was defined as pneumonia that develops inside or outside the hospital in the presence of risk factors for multidrug-resistant (MDR) pathogens. Now recommendations are for hospitals to generate antibiograms to guide healthcare professionals on the most appropriate empiric therapy for patients who acquire this type of pneumonia and individually assess risk factors for MDR pathogens. Hospital-acquired pneumonia (HAP) is defined as pneumonia that occurs 48 hours or more after admission.[1] Ventilator-associated pneumonia (VAP) requires endotracheal intubation for at least 48 hours before the onset of pneumonia.[1]

EPIDEMIOLOGY AND ETIOLOGY

Etiology and Mortality Rates

KEY CONCEPT The etiology of bacterial pneumonia varies in accordance with the type of pneumonia. Table 74–1 lists the more common pathogens associated with the various types or classifications of pneumonia. *Streptococcus pneumoniae* colonizes the nasopharyngeal flora in up to 50% of healthy adults and may colonize the lower airways in individuals with chronic bronchitis.[2,3] It possesses many virulence factors, enhancing its ability to cause infection in the respiratory tract.

KEY CONCEPT Therefore, it is not surprising that *S. pneumoniae* is the predominant bacterial pathogen associated with CAP. The second-most common pathogen is one of the atypical organisms, *Mycoplasma pneumoniae*. Nontypeable *Haemophilus influenzae* intermittently colonizes about 80% of the population, and the incidence of permanent colonization increases in chronic obstructive pulmonary disease (COPD) patients and those with cystic fibrosis. Therefore, the likelihood of nontypeable *H. influenzae* causing pneumonia increases in COPD patients. *Moraxella catarrhalis* is a more common cause of pneumonia in the very young and the very old. *Chlamydophila pneumoniae* and *Legionella pneumophila* are less frequent causes than the other bacterial and atypical organisms. Community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) is associated with necrotizing and severe pneumonia in healthy children and young adults. Less than 2% of all CA-MRSA infections are pneumonia (most are skin and soft tissue).[4,5]

Viruses are a common cause of CAP in children (about 65%) and in adults ranging from 12% to 29%.[5-7] Mixed infections of viruses and bacteria have been increasingly identified in 11% to 56% of cases.[5-8] Viruses most often associated with pneumonia in adults include influenza A and B and rhinoviruses but can be

Table 74–1

Common Pathogens by Type of Pneumonia

Type of Pneumonia	Common Pathogens
Community	Aerobic bacteria: *Streptococcus pneumoniae, Haemophilus influenzae*, MSSA, *Moraxella catarrhalis* Atypical: *Mycoplasma pneumoniae, Chlamydophila pneumoniae, Legionella pneumophila* Viruses: rhinoviruses and influenza most common, coronaviruses may be increasing in prevalence
Hospital	*S. pneumoniae*, MSSA, *Escherichia coli, Klebsiella pneumoniae* (*M. pneumoniae, C. pneumoniae* are rare) (MDR pathogen risk factors present; MRSA, *Pseudomonas aeruginosa*, extended-spectrum β-lactamase-producing Gram-negative bacilli, carbapenemase-producing Gram-negative bacilli)
Ventilator	MRSA, extended-spectrum β-lactamase-producing Gram-negative bacilli, *P. aeruginosa, Acinetobacter* spp., carbapenemase-producing Gram-negative bacilli

MDR, multidrug resistant; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-susceptible *S. aureus.*

caused by adenoviruses, enteroviruses, cytomegalovirus, varicella-zoster virus, herpes simplex virus, and others. In children, viral pneumonia is more commonly caused by respiratory syncytial virus, influenza A, and parainfluenza, and less commonly by those listed previously for adults. Influenza is associated with seasonal local outbreaks (epidemics) and global outbreaks (pandemics). Influenza viruses are characterized and named for the hemagglutinin (H) and neuraminidase (N) proteins on the surface of the viruses. There are 16 hemagglutinin and 9 neuraminidase subtypes of influenza A, and H1 to H3 and N1 and N2 are the principal antigenic types found in humans.[9] Coronaviruses are emerging as important pathogens associated with pneumonia in predominantly adults and to a lesser extent in pediatric patients. While most coronaviruses are associated with mild respiratory disease, a few strains have been responsible for epidemics such as severe acute respiratory syndrome CoV (SARS-CoV) and Middle East respiratory syndrome CoV (MERS-CoV) in the early-to-mid-2000s and a pandemic by SARS-CoV-2 in 2019 to 2021.[10]

Mortality associated with CAP is dependent on the severity of the illness and the age of the patient. Elderly patients admitted to the hospital with severe pneumonia have mortality rates up to 40%.[11-14] In the outpatient setting (mild-to-moderate disease), the mortality rate is less than 5%.[15] Mortality among case reports of CA-MRSA necrotizing pneumonia is 42%.[4] Pneumonia owing to aspiration of oral contents is caused by a variety of anaerobes (*Bacteroides* spp., *Fusobacterium* spp., *Prevotella* spp., and anaerobic Gram-positive cocci) as well as *Streptococcus* spp. *M. catarrhalis*, and *Eikenella corrodens* may be involved but much less frequently.[15,17] When gastric contents are aspirated, enteric Gram-negative bacilli and *S. aureus* are more commonly the pathogens.[17]

HAP and VAP may be caused by a wide spectrum of organisms. HAP and VAP pathogens are influenced by risk factors for MDR bacteria. These factors include: intravenous antibiotic use within the past 90 days (HAP and VAP) and for VAP septic shock at the time of VAP, acute respiratory distress syndrome (ARDS) preceding VAP, 5 or more days of hospitalization, and acute renal replacement therapy.[1] MDR organisms include extended spectrum β-lactamase and/or carbapenemase-producing enteric Gram-negative bacilli, *Pseudomonas aeruginosa*, *Acinetobacter* spp., or MRSA. The number of infections caused by MDR bacteria is increasing significantly in hospitalized patients.[1,5,14,18-20]

PATHOPHYSIOLOGY

Local Host Defenses

Local host defenses of both the upper and lower respiratory tract along with the anatomy of the airways are important in preventing infection. Upper respiratory defenses include the mucociliary apparatus of the nasopharynx, nasal hair, normal bacterial flora, IgA, and complement. Local host defenses of the lower respiratory tract include cough, mucociliary apparatus of the trachea and bronchi, antibodies (IgA, IgM, and IgG), complement, and alveolar macrophages. Mucous lines the cells of the respiratory tract, forming a protective barrier for the cells. This minimizes the ability of organisms to attach to the cells and initiate the infectious process. The squamous epithelial cells of the upper respiratory tract are not ciliated, but those of the columnar epithelial cells of the lower tract are. The cilia beat in a uniform fashion upward, moving particles up and out of the lower respiratory tract.

Particles greater than 10 μm are efficiently trapped by mechanisms of the upper airway and are removed from the nasopharynx either by swallowing or by expulsion. The mucociliary apparatus of the trachea and bronchi along with the sharp angles of the bronchi often are effective at trapping and eliminating particles that are 2 to 10 μm in size. Particles in the range of 0.5 to 1 μm may consistently reach the alveolar sacs of the lung. Microorganisms fall within this size range, and if they reach the alveolar sacs, then infection may result if alveolar macrophages and other defenses cannot contain the organisms.

Aspiration

Aspiration is a fairly common occurrence in adults during sleep.[1] Aspiration of the oropharyngeal or gastric contents may lead to aspiration pneumonia or chemical (acid) pneumonitis. Risk factors for aspiration include dysphagia, change in oropharyngeal

Patient Encounter 1, Part 1

A 72-year-old African American woman presents to your ED with difficulty breathing, coughing, confusion, and shortness of breath. Her son brought her to the ED. Her physical examination reveals that she is easily confused and oriented to name and place (×2), has decreased breath sounds on the right side, and has rales and crackles in the right lower lobe. Her temperature is 38.7°C (101.6°F), respiratory rate is 24 breaths/min, oxygen saturation 88% on room air, and blood pressure is 110/70 mm Hg. She is coughing up greenish sputum.

What are her signs and symptoms of pneumonia?

What are the most common two bacterial organisms that could be causing the pneumonia?

What is the most common atypical organism, as well as the most common two viruses that could be causing the pneumonia?

Patient Encounter 2, Part 1

A 66-year-old man was admitted to the hospital for abdominal aortic aneurysm surgery. He developed complications postoperatively and was intubated 7 days ago. The nurses note an increase in the amount and purulence of his sputum. Attempts yesterday and today to wean him off the ventilator have failed. He is sedated but does respond to commands. His temperature is 38.9°C (102°F), blood pressure is 115/74 mm Hg, and white blood cell (WBC) $22.6 \times 10^3/\text{mm}^3$ (22.6×10^9/L) with a cell differential of 75% (0.75) neutrophils, 8% (0.08) bands, 14% (0.14) lymphocytes, and 3% (0.03) monocytes. The chest X-ray revealed left middle lobe infiltrates.

What are his signs and symptoms of pneumonia?

What are the most common three bacterial organisms that could be causing the pneumonia?

colonization, gastroesophageal reflux (GER), and decreased host defenses.

Dysphagia can be caused by stroke or other neurologic disorders, seizures, alcoholism, and aging.[15] Oropharyngeal colonization may be altered by oral/dental disease, poor oral hygiene, tube feedings, or medications. This could result in a higher number of anaerobic organisms in the oral cavity or colonization with enteric Gram-negative bacilli.[16] Acid suppression is an important factor in the treatment of GER disease, which may allow enteric Gram-negative bacilli to colonize the gastric contents. Finally, impaired mucous production or cilia function, decreased immunoglobulin in secretions, and an altered cough reflex may increase the likelihood of infection following an aspiration. The infection can result in a necrotizing pneumonia or lung abscess.

Inflammatory Response

Once breakdown of the local host defenses occurs and organisms invade the lung tissue, an inflammatory response is generated either by the organisms causing tissue damage or by the immune response to the presence of the organisms. This inflammatory response either can remain localized in the infected tissue or can become systemic. The role of the alveolar macrophages is twofold. First, to engulf the organisms to contain the infection, and second, to process the antigens for presentation in regional lymph nodes in order to generate a specific immune response by either the cell-mediated or humoral system, or both. The macrophages release cytokines in the area of the infection, which result in increased mucous production, constricting the local vasculature and lymphatic vessels and attraction of other immune cells to the site. The increase in mucus is associated with symptoms such as cough and sputum production. If tumor necrosis factor alpha (TNF-α) and interleukins (ILs)-1 and -6 are released systemically, then the symptoms become more severe and can include hypotension, organ dysfunction, and/or a septic or septic-shock clinical presentation.

CLINICAL PRESENTATION AND DIAGNOSIS

Several scoring systems are available for assessing the severity of the pneumonia: the pneumonia severity index (PSI); confusion, uremia, respiratory rate, blood pressure (CURB); CURB-65 (for those ≥ 65 years of age), and systolic BP, oxygenation, age, and respiratory rate (SOAR).[11,14] These models are used to help determine the severity of illness, prognosis (mortality risk), and the need for hospitalization.[11,14,15] PSI has a higher discriminative power in predicting mortality over CURB and is preferred by the CAP guidelines for assessing severity of illness.

TREATMENT

KEY CONCEPT The goal of antibiotic therapy is to eliminate the patient's symptoms, minimize or prevent complications, and decrease mortality. Potential complications secondary to pneumonia include further decline in pulmonary function in patients with underlying pulmonary disease, prolonged mechanical ventilation, bacteremia/sepsis/septic shock, and death. The use of an antimicrobial agent with the narrowest spectrum of activity that covers the suspected pathogen(s) without having activity against organisms not involved in the infection is preferred to minimize the development of resistance and secondary infections such as *Clostridioides difficile* diarrhea/colitis.

General Approach to Treatment

Designing a therapeutic regimen for any patient with any type of pneumonia begins with three general categories of consideration:

1. Patient-specific factors that will impact therapy.
2. The most common two to three organisms likely causing the infection and resistance issues associated with each organism.
3. The antimicrobials that will cover these organisms. Local resistance patterns, which can be obtained from hospital or clinic antibiograms, will influence the choice of antimicrobial. The spectrum should not be too broad or narrow; they should penetrate the site of infection and be the most cost effective.

Patient factors that need to be considered include age, renal function, drug allergies and/or drug intolerances, immune status (diabetes, neutropenia, or immunocompromised host), cardiovascular (cardiomyopathy, pulmonary hypertension, congenital heart disease, heart failure, or coronary artery disease), pulmonary disease (COPD, cancer, cystic fibrosis, pulmonary fibrosis, moderate-to-severe asthma, smoking, and vaping), pregnancy, medical insurance and prescription coverage, exposure to resistant organisms, and prior antibiotic exposure(s). Patients with these comorbid conditions are at increased risk of severe pneumonia from any organism but markedly important for coronavirus.

- The most common pathogens vary with the type of pneumonia and are listed in Table 74–1. *M. pneumoniae* lack a cell wall; therefore, β-lactam drugs have no activity against this organism. The atypical organisms have not changed in recent years with respect to antibiotic resistance. β-Lactamase production in *H. influenzae* has remained relatively steady over the last 5 to 10 years, and the rate is approximately 25%.[21] *S. pneumoniae* has developed resistance mechanisms against many classes of antimicrobials, and the mechanisms include the following:
- Alteration of the penicillin-binding proteins (PBPs), inactivating β-lactams
- Efflux or methylation of the ribosome-inactivating macrolides
- Ribosome protection (tetM gene) inactivating tetracyclines
- Alteration of DNA gyrase or topoisomerase IV inactivating fluoroquinolones

S. pneumoniae resistance to commonly prescribed antimicrobials such as the penicillins and macrolides/azalides dramatically increased in the late 1980s through the mid-to-late 1990s and has

Clinical Presentation of CAP or Aspiration Pneumonia

General

Patients may experience nonrespiratory symptoms in addition to respiratory symptoms. With increasing age, both respiratory and nonrespiratory symptoms decrease in frequency.

KEY CONCEPT Symptoms

- Respiratory—cough (productive or nonproductive), shortness of breath, and difficulty breathing
- Nonrespiratory—fever, fatigue, sweats, headache, myalgias, mental status changes

KEY CONCEPT Signs

- Temperature may increase or decrease from baseline, but most often it is elevated. The temperature may be sustained or intermittent.
- Respiratory rate is often increased. Cyanosis, increased respiratory rate, and use of accessory muscles of respiration are suggestive of severe respiratory compromise.
- Breath sounds may be diminished. Rales or rhonchi may be heard.
- Confusion, lethargy, and disorientation are relatively common in elderly patients.

Diagnostic Tests

- Chest X-ray should reveal single or multiple infiltrates.
- Oxygen saturation on room air should be more than 90% (0.90), as determined by pulse oximetry.
- Arterial blood gases are beneficial primarily in patients with severe pneumonia.

Laboratory Tests

- The WBC may or may not be elevated. In elderly patients, a drop in WBCs also can be a sign of infection. The differential should show a predominance of neutrophils if a bacterial infection is present. The presence of bands also could be an indicator of bacterial infection. Elevated lymphocytes are an indication of viral infection.
- Blood urea nitrogen (BUN) and serum creatinine are needed to dose antibiotics appropriately and to minimize or prevent drug toxicity (especially in the elderly patient).

Microbiology Tests

- Sputum Gram stain should demonstrate the presence of WBCs and the absence of squamous epithelial cells. It may or may not show a predominance of one type of organism.
- Sputum culture and susceptibility are not obtained in the outpatient setting. The value of culturing is debated owing to the rapidity in which *S. pneumoniae* dies in transport media and the inability to reliably or routinely culture atypical organisms.
- Bronchoscopy may be performed to improve the ability to diagnose pneumonia. Tracheal secretions often are better specimens than sputum owing to the lack of oral contamination.
- Serology (IgM and IgG) is useful in determining the presence of atypical organisms such as *Mycoplasma* and *Chlamydophila*.
- Urinary *Legionella* antigen is used to diagnose *L. pneumophila*.
- Polymerase chain reaction (PCR) is being used more frequently to detect the DNA of respiratory pathogens.
- Blood cultures should be obtained in all patients admitted to the ICU with pneumonia. Positive blood cultures are present in about 1% to 20% of patients with CAP.

Clinical Presentation of Severe CAP

General

In approximately 10% of patients, CAP will be severe enough to require intensive care or mechanical ventilation.

KEY CONCEPT Symptoms

Respiratory—cough (productive or nonproductive), shortness of breath, difficulty breathing

- Nonrespiratory—fever, fatigue, sweats, headache, myalgias, mental status changes

Signs

- Temperature may increase or decrease from baseline, but most often it is elevated. The temperature may be sustained or intermittent.
- Respiratory rate is greater than 30 breaths/min, cyanosis and use of accessory muscles of respiration are suggestive of severe respiratory compromise.
- Hypotension (systolic blood pressure < 90 mm Hg or diastolic blood pressure < 60 mm Hg).
- Requirement for vasopressors.
- Breath sounds may be diminished. Rales or rhonchi may be heard.
- Urine output less than 20 mL/hour or less than 80 mL over 4 hours.
- Confusion, lethargy, and disorientation are relatively common in elderly patients.

Diagnostic Tests

As stated in the clinical presentation of community-acquired pneumonia. Nasal swab MRSA PCR testing has a strong negative predictive value for MRSA pneumonia.

Laboratory Tests

As stated in the clinical presentation of community-acquired pneumonia.

Microbiology Tests

As stated in the clinical presentation of community-acquired pneumonia.

Diagnosis of VAP

Clinical Strategy

- Chest X-ray should reveal a new infiltrate *plus* two of the following:
- Temperature greater than 38.0°C (100.4°F)
- Leukocytosis or leukopenia
- Purulent secretions
- Semiquantitative cultures obtained identify the pathogen(s).
- Tracheal aspirates grow more organisms than invasive quantitative cultures and often result in the overuse of antibiotics.

remained relatively flat in the 2000s. Resistance information collected nationally along with susceptibility testing for new antimicrobials demonstrates that average national rates of resistance to penicillin and macrolides were approximately 13% and 38%, respectively.[22,23] Resistance to trimethoprim/sulfamethoxazole is approximately 25%, and fluoroquinolone resistance remains less than 0.5%.[23]

For HAP, and VAP, the risk of infection from an MDR pathogen is relatively high. The number and type of organisms that are MDR vary from hospital to hospital, making it more difficult to generate guidelines for treatment. Therefore, the treatment recommendations may be too broad or too narrow for any given institution and local antibiogram data should influence the choice of therapeutic regimens. Risk factors for developing infection caused by a resistant pathogen are as follows:

- intravenous antibiotic use within the past 90 days
- septic shock at the time of HAP or VAP
- ARDS preceding VAP
- 5 or more days of hospitalization
- acute renal replacement therapy

The patient- and drug-related categories are common to all types of pneumonia, but the organisms vary with the type of pneumonia. Guidelines have been generated by experts in the field for all types of pneumonia. These guidelines were generated to provide practitioners with evidence-based therapeutic options for the management of patients with pneumonia.

Pharmacologic Therapy for CAP

KEY CONCEPT Treatment of CAP is predominantly empiric, that is, treatment is started without knowing the causative pathogen. The most recent guidelines are the result of collaboration between the Infectious Diseases Society of America (IDSA) and the American Thoracic Society (ATS).[24] The approach to patient care is based on the classification of patients into two broad categories, outpatient and inpatient, and then further dividing the groups by comorbid conditions and location in the hospital, respectively. These guidelines use patient-specific data along with predominant pathogen information to design appropriate empirical antimicrobial regimens. Table 74–2 summarizes these therapeutic options.

▶ *Adult Outpatient Previously Healthy*

First-line therapeutic options for treating previously healthy adults without risk factors for MRSA or *P. aeruginosa* include the use of amoxicillin or doxycycline, a macrolide (erythromycin, clarithromycin) or an azalide (azithromycin) only if local pneumococcal resistance rates are less than 25%.[24] If a patient has failed therapy with a first-line agent, one has to consider why the patient failed. The most common reasons are either medication adherence issues or the presence of resistant organisms. If a resistant organism is suspected, then the use of one of the respiratory

Patient Encounter 1, Part 2: Medical History, Physical Examination, and Diagnostic Tests

A 72-year-old African American woman presents to your ED with difficulty breathing, coughing, confusion, and shortness of breath.

PMH: Hypertension for 38 years, noninsulin dependent diabetes for 15 years, currently controlled

FH: Father died of lung cancer at the age of 68 years; mother died of natural causes

SH: Denies alcohol, smokes 1/2 pack per day. Lives alone and has two children. She is 5′3″ (160 cm) and weighs 250 lb (113.6 kg).

Allergies: sulfa—hives, red-burning skin, doxycycline—rash

Meds: Lisinopril/hydrochlorothiazide 20/25 mg orally once daily; metformin 1000 mg orally twice daily

ROS: (+) difficulty breathing and shortness of breath; (–) chest pain, N/V/D, change in appetite

PE:

VS: BP 110/70 mm Hg, P 88 beats/min, RR 24 breaths/min, T 38.7°C (101.6°F)

CV: RRR, normal S1, S2; no murmurs, rubs, or gallops

Lungs: Decreased breath sounds on the right side, and has rales and crackles in the right lower lobe, greenish sputum production

Abd: Soft, nontender, nondistended; (+) bowel sounds, no hepatosplenomegaly, heme (–) stool

Neuro: Oriented to name and place, easily confused

Diagnostic Tests: Chest X-ray: right lower lobe infiltrate; oxygen saturation 88% (0.88) on room air

Labs: WBCs 22.4 × $10^3/\text{mm}^3$ (22.4 × 10^9/L) with a cell differential of 70% (0.70) neutrophils, 2% (0.02) bands, 20% (0.20) lymphocytes, and 8% (0.08) monocytes; BUN 10 mg/dL (3.57 mmol/L), SCr 0.8 mg/dL (70.74 μmol/L), fasting glucose 110 mg/dL (6.1 mmol/L); sputum Gram stain: moderate Gram-positive diplococci, few Gram-negative bacilli, rare squamous epithelial cells, many WBCs; sputum culture is pending.

Given this additional information, what is your assessment of the patient's condition?

Identify your treatment goals for the patient.

What organisms should you include in your list of potential pathogens?

What pharmacologic agents are available for treating this patient?

Table 74–2

Summary of CAP Treatment

Adult outpatient otherwise healthy	*Monotherapy*
Empirical coverage against *Streptococcus pneumoniae, Haemophilus influenzae, Staphylococcus aureus, (Mycoplasma pneumoniae, Chlamydophila pneumoniae* much less common)	Amoxicillin 1 g three times daily, or doxycycline 100 mg twice daily (or azithromycin 500 mg × 1 then 250 mg once daily, clarithromycin 500 mg twice daily or clarithromycin ER 1000 mg once daily, only if local pneumococcal resistance rates are < 25%)
Adult outpatient comorbidities	*Combination therapy*
Empirical coverage against *S. pneumoniae, H. influenzae, S. aureus*, (*M. pneumoniae, C. pneumoniae* much less common)	Amoxicillin-clavulanate 500/125 mg three times daily or 875/125 mg twice daily or 2000/125 mg twice daily or cefpodoxime 200 mg twice daily, or cefuroxime 500 mg twice daily, *plus* azithromycin, or clarithromycin or, doxycycline (see dosing above)
	Monotherapy
	Gemifloxacin 320 mg once daily, levofloxacin 750 mg once daily, moxifloxacin 400 mg once daily
Adult inpatient (non-ICU)	*Combination therapy*
Empirical coverage against *S. pneumoniae, H. influenzae, S. aureus*, (*M. pneumoniae, C. pneumoniae* much less common)	Cefotaxime 1–2 g q8h, or ceftriaxone 1–2 g q24h, or ampicillin-sulbactam 1.5–3 g q6h, or ertapenem 1 g q24h *plus* azithromycin, or clarithromycin, or doxycycline (see dosing above)
	Monotherapy
	Levofloxacin, moxifloxacin (see dosing above)
Adult inpatient ICU (no Pseudomonas)	*Combination therapy*
Empirical coverage against *S. pneumoniae, Legionella pneumophila, H. influenzae,* enteric GNB, and *S. aureus*	Cefotaxime or ceftriaxone *plus* azithromycin, or levofloxacin, or moxifloxacin (see dosing above)
Adult inpatient ICU (Pseudomonas is a concern)	*Combination therapy*
Empirical coverage against *Pseudomonas aeruginosa, S. pneumoniae, L. pneumophila, H. influenzae,* enteric GNB, and *S. aureus*	Cefepime, or ceftazidime, or piperacillin–tazobactam, or imipenem, or meropenem *plus* or ciprofloxacin or levofloxacin or an aminoglycoside (see Table 74–4 for dosing) If an aminoglycoside is chosen, then add azithromycin or levofloxacin or moxifloxacin
Adult inpatient non-ICU or ICU (MRSA is a concern)	
Empirical coverage against *S. pneumoniae, L. pneumophila, H. influenzae,* enteric GNB, and *S. aureus* (*Pseudomonas* if ICU)	Add vancomycin or linezolid to the regimens listed above (see Table 74–4 for dosing)
Pediatric outpatient	*Monotherapy*
Empirical coverage against *S. pneumoniae, M. pneumoniae,* and *C. pneumoniae*	High-dose amoxicillin, or high-dose amoxicillin-clavulanate, or intramuscular ceftriaxone, or azithromycin, or clarithromycin
Pediatric inpatient (non-ICU)	*Monotherapy*
Empirical coverage against *S. pneumoniae*	Fully immunized child—ampicillin or penicillin G Partially immunized child—ceftriaxone or cefotaxime
	Combination therapy
Empirical coverage against *S. pneumoniae, H. influenzae, M. pneumoniae,* and *C. pneumoniae*	IV cefuroxime, or cefotaxime, or ceftriaxone, or ampicillin-sulbactam plus azithromycin, or clarithromycin
Pediatric inpatient ICU	*Combination therapy*
Empirical coverage against *S. pneumoniae, L. pneumophila, H. influenzae,* enteric GNB, and *S. aureus*	Cefotaxime, or ceftriaxone plus azithromycin, or clarithromycin

CA-MRSA, community-acquired methicillin-resistant *S. aureus*; GNB, Gram-negative bacteria; ICU, intensive care unit.

fluoroquinolones active against *S. pneumoniae* (gemifloxacin, levofloxacin, or moxifloxacin) is warranted.

▶ *Adult Outpatient With Comorbid Conditions*

The comorbid conditions that can impact therapy and outcomes in patients with CAP include diabetes mellitus, chronic heart, liver, lung, or renal disease, alcoholism, malignancy, or asplenia.[24] If the patient did not receive antibiotics in the last 3 months, then either a respiratory fluoroquinolone alone or a combination of amoxicillin-clavulanate or oral cephalosporin agent plus a macrolide/azalide or doxycycline is recommended. If the patient received an antibiotic in the last 3 months, the recommendation is to use an agent from a different class.

▶ *Adult Inpatient Not in the ICU*

For patients admitted to the hospital with CAP, the severity of illness is generally increased (caused either by the organism itself or underlying comorbidities in the patient), and the pathogens are essentially the same as in the outpatient setting. Recommendations for patients without risk factors for MRSA or *P. aeruginosa* are to use either a respiratory fluoroquinolone alone or a combination of an IV β-lactam antimicrobial agent plus an advanced macrolide/azalide (clarithromycin/azithromycin) or doxycycline. Macrolides are preferred over doxycycline in combination with the β-lactam antimicrobial agent. Recommended β-lactams include cefotaxime, ceftriaxone, or ampicillin-sulbactam.[24] Omadacycline, a tetracycline, and lefamulin, a pleuromutilin, are new agents that have demonstrated efficacy for treating CAP. The guidelines do not recommend their use at this time and suggest further studies establishing safety and efficacy are needed. The first antibiotic dose should be administered within the first 24 hours of admission. Conversion to oral therapy should occur when the patient is hemodynamically stable, improving clinically, and able to take oral medications, which often is within 48 to 72 hours for most patients. Discharge from the hospital should be as soon as the patient is stable and without other medical

Patient Encounter 2, Part 2: Medical History, Physical Examination, and Diagnostic Tests

A 66-year-old man was admitted to the hospital for abdominal aortic aneurysm surgery. He developed complications postoperatively and was intubated 7 days ago. The nurses note an increase in the amount and purulence of his sputum. Attempts yesterday and today to wean him off the ventilator have failed.

PMH: Hypertension for 15 years, currently controlled.

FH: Father and mother deceased from natural causes. Both had hypertension, mother had hypothyroidism.

SH: Smoked a pack per day for 22 years quit 10 years ago, social alcohol two to three beers or liquor per week. He lives with his wife; he is a plumber. He is 5′10″ (177.8 cm) and weighs 96.4 kg (212 lb).

Allergies: Amoxicillin—hives, difficulty breathing

Meds: Losartan 50 mg orally once daily, atorvastatin 40 mg orally once daily

PE:

VS: BP 105/70 mm Hg, P 80 beats/min, T 38.8°C (101.9°F).

CV: RRR, normal S_1, S_2; no murmurs, rubs, or gallops.

Abd: Soft, nontender, nondistended; (+) bowel sounds, no hepatosplenomegaly.

Diagnostic Tests: Chest X-ray: left middle and lower lobe infiltrates; oxygen saturation 98% (0.98) on ventilator.

Labs: WBC is 25.4×10^3/mm^3 (25.4×10^9/L) with a cell differential of 70% (0.70) neutrophils, 9% (0.09) bands, 15% (0.15) lymphocytes, and 6% (0.06) monocytes; BUN 10 mg/dL (3.6 mmol/L), SCr 0.9 mg/dL (80 μmol/L); sputum Gram stain: many Gram-negative bacilli, many WBCs; culture is pending.

Given this additional information, what is your assessment of the patient's condition?

Identify your treatment goals for the patient.

What pharmacologic agents are available for treating this patient?

complications. The need to observe the patient in the hospital on their oral antibiotic is not necessary.[24]

▶ *Adult Inpatient in the ICU*

Patients admitted to the ICU have severe pneumonia, and the likely etiology includes *S. pneumoniae* and *H. influenzae* as in the other pneumonia categories; however, the incidence of *L. pneumophila* increases in this setting and should be considered a potential pathogen. In addition, enteric Gram-negative bacilli and *S. aureus* are more frequently the cause of the pneumonia in these patients. The recommendations for treating patients with no risk factors for MRSA or *P. aeruginosa* are to treat with an IV β-lactam plus either azithromycin or a respiratory fluoroquinolone. These combination therapies minimize the risk of treatment failure due to a resistant pathogen as well as provide broad coverage.[24] The β-lactams are the same as for inpatient non-ICU treatment. If the patient is allergic to β-lactams, then aztreonam can be substituted for the β-lactam.

If *P. aeruginosa* is suspected, then the antimicrobial treatment must be broadened to cover *Pseudomonas* as well as the organisms listed previously. Owing to the high resistance rates observed with *Pseudomonas*, regimens empirically double covering the *Pseudomonas* to ensure at least one of the antibiotics is active against it can be employed. The regimens include the use of an antipneumococcal, antipseudomonal β-lactam (cefepime, ceftazidime, piperacillin/tazobactam, imipenem, or meropenem),[24] plus either ciprofloxacin or levofloxacin or an aminoglycoside. If the aminoglycoside is chosen, then either IV azithromycin or a respiratory fluoroquinolone should be added to cover the atypical bacterial organisms.

Patient Encounter 1, Part 3: Creating a Care Plan

A 72-year-old African American woman presents to your ED with difficulty breathing, coughing, confusion, and shortness of breath.

Based on the information presented, create a care plan for this patient's pneumonia. Your plan should include: (a) a statement of drug-related needs and/or problems; (b) a patient-specific detailed therapeutic plan; and (c) monitoring parameters to assess efficacy and safety.

If MRSA is suspected in the patient, then vancomycin or linezolid should be considered. Daptomycin cannot be used because surfactant in the lung inactivates the drug, thus rendering it ineffective for pneumonia. CA-MRSA can cause a necrotizing pneumonia, and the cause is believed to be due to its many virulence factors, including the Panton-Valentine leukocidin toxin.[4] In these patients the use of an agent that decreases toxin production may be beneficial. Linezolid decreases toxin production; the other recommended agents to decrease toxin production and added to vancomycin therapy are clindamycin or a respiratory fluoroquinolone.[24]

▶ *Aspiration in the Inpatient Setting*

Empirical coverage for anaerobes is not recommended if a patient aspirates unless there is a lung abscess or empyema.[24] The rationale for this recommendation is that aspiration commonly occurs in adults while sleeping and the difficulty in separating aspiration pneumonia from other types of pneumonia. Aspiration of gastrointestinal contents often results in chemical pneumonitis and not infection although alteration of gastric pH due to use of proton pump inhibitors might influence this.

▶ *Influenza*

Influenza viruses A and B can cause pneumonia in pediatric and adult patients. Amantadine and rimantadine were available oral agents with activity against influenza virus type A. If started within 48 hours of the onset of the first symptoms, they reduce the duration of the illness by about 1.3 days. However, resistance to the adamantanes is over 90%.[25] Oseltamivir and zanamivir are oral agents active against both type A and B influenza that reduce the duration of the illness by about 1.3 days if initiated within 40 to 48 hours of the first symptoms.[26] Baloxavir marboxil is an oral agent and a prodrug that is converted by hydrolysis to baloxavir, the active form that inhibits the endonuclease activity of the polymerase acidic (PA) protein found in influenza virus.[27]

Baloxavir activity is similar to oseltamivir with respect to timeline for decreasing patient symptoms. Peramivir is an intravenous neuraminidase inhibitor approved as a single dose for adults with uncomplicated influenza. It may be used in hospitalized patients in whom oral therapy is contraindicated or not tolerated.[28] For active infection beyond the first 48 hours, none of these agents are effective in treating infection, and supportive care is the best treatment for these patients. Neuraminidase resistance rates in influenza A strains prevalent prior to 2009 were high and rates in strains prevalent after 2009 are low.[25] Seasonal information on resistance patterns and treatment recommendations should be evaluated.

▶ *Coronavirus*

Coronavirus causes pneumonia in adults more than in children. The spectrum of the diseases causes by coronavirus range from mild to severe and treatment recommendations are based on the severity of illness as well as the time frame for severe disease. This chapter was written during the pandemic and clinical trials to clearly define treatment options were limited and remdesivir was the only FDA-approved antiviral for coronavirus. As clinical trials are performed, these treatment recommendations could change. For mild-to-moderate disease and the patient is not hospitalized, no antiviral or antibody treatment is recommended, and patients should not receive corticosteroids.[29] Treatment of body aches or fever with over-the-counter acetaminophen or nonsteroidal anti-inflammatory drugs can be used.

If a patient is hospitalized but oxygen therapy is not required, and risk of disease progression is high, then remdesivir 200 mg IV × 1, then 100 mg IV q24h for 4 days or until discharge from the hospital can be administered. It is not recommended to use corticosteroids in these patients.[29]

For patients hospitalized and requiring non-high-flow supplemental oxygen and not intubated, the recommendation is based on the amount of oxygen needed. For those who require minimal oxygen, remdesivir monotherapy is recommended.[29] If the patient requires increasing amounts of oxygen, then remdesivir plus dexamethasone 6 mg IV or PO q24h (or equivalent dose of other corticosteroids) for 10 days or until discharge is recommended.[29] Monotherapy with a corticosteroid should only be used if remdesivir is not available or cannot be used in a patient.

Patients hospitalized and receiving high-flow oxygenation, the recommendations are for a corticosteroid monotherapy or in combination with remdesivir.[29] If a patient is mechanically ventilated, the recommendation is to administer corticosteroids monotherapy.[29] These patients are often later in the disease process and it is believed the symptoms are driven by an overactive immune and inflammatory response to the virus.

Other antiviral therapies that have been used but are not recommended at this time due to the lack of clinical trials are chloroquine, hydroxychloroquine, lopinavir/ritonavir combination, or other protease inhibitors. Several immune-based therapies are under investigation but not recommended at this time include: COVID-19 convalescent plasma, immunoglobulins (specific and nonspecific for SARS-CoV-2), interferons, IL-6 inhibitors, IL-1 inhibitors, Bruton tyrosine kinase inhibitors, and Janus kinase inhibitors.[29]

▶ *Pediatric Outpatient*

Guidelines have been published for treating CAP in children. The most predominant pathogens in preschool children in the outpatient setting are viruses, and often supportive therapy (maintaining hydration, antipyretics) is all that is needed.[30] For appropriately immunized infants, children, and adolescents

Patient Encounter 2, Part 3: Creating a Care Plan

A 66-year-old man was admitted to the hospital for abdominal aortic aneurysm surgery. He developed complications postoperatively and was intubated 7 days ago. The nurses note an increase in the amount and purulence of his sputum. Attempts yesterday and today to wean him off the ventilator have failed. Your hospital antibiogram for Gram-negative organisms is below; values are percentage of isolates susceptible to the antibiotic. Boxes without values indicate you should not use that antibiotic for that organism.

	Total No. Tested	Amikacin	Ampicillin	Amp/Sulbactam	Cefazolin	Cefepime	Ceftriaxone	Ciprofloxacin	Gentamicin	Imipenem/ Meropenem	Levofloxacin	Piperacillin/ Tazobactam	TMX/SMX	Tobramycin	Nitrofurantoin
Acinetobacter baumannii	29	62	0	69	0	45	17	34	48	66	38	55	41	62

Pseudomonas aeruginosa	132	52				85		45	50	70	45	90		65	

Based on the information presented, create a care plan for this patient's pneumonia. Your plan should include: (a) a statement of drug-related needs and/or problems; (b) a patient-specific detailed therapeutic plan; and (c) monitoring parameters to assess efficacy and safety.

Table 74–3

CAP Antimicrobial Dosing in Pediatric Patients

	Body Weight < 2000 g		Body Weight > 2000 g		
Drug (Route)	**0–7 Days Old**	**7–28 Days Old**	**0–7 Days Old**	**7–28 Days Old**	**> 28 Days Old**
Amoxicillin (po)				15 mg/kg every 12 hours	17 mg/kg every 8 hours
Amoxicillin-clavulanate (po)			15 mg/kg every 12 hours	15 mg/kg every 12 hours	45 mg/kg every 12 hours
Cefotaxime (IV)	50 mg/kg every 12 hours	50 mg/kg every 8 hours	50 mg/kg every 12 hours	50 mg/kg every 8 hours	50 mg/kg every 8 hours
Ceftriaxone (IM/IV)				50 mg/kg every 24 hours	50 mg/kg every 24 hours
Cefuroxime (po)					15 mg/kg every 12 hours
Azithromycin (po/IV)	5 mg/kg every 24 hours	10 mg/kg every 24 hours	5 mg/kg every 24 hours	10 mg/kg every 24 hours	10 mg/kg every 24 hours
Clarithromycin (po)					7.5 mg/kg every 12 hours

with mild-to-moderate pneumonia in an area lacking high-level penicillin-resistant pneumococcus, high-dose amoxicillin is the recommended first-line therapy. If atypical organisms are considered likely, then a macrolide is recommended. If moderate-to-severe CAP is diagnosed, and it is during influenza season, then treatment with oseltamivir, zanamivir (Relenza), amantadine, or rimantadine is recommended; however, seasonal resistance rates need to be evaluated.[29] Fluoroquinolones and tetracyclines should not be used in children younger than 5 years. Dosing of antibiotics for pediatric patients is presented in Table 74–3.

▶ *Pediatric Inpatient*

If the infant or child is fully immunized, then the guidelines recommend the use of IV penicillin G or ampicillin. Alternative β-lactams include IV cefotaxime or ceftriaxone. If the infant or child is not fully immunized, then the third-generation cephalosporins (eg, cefotaxime or ceftriaxone) should be administered.[30] If atypical organisms are suspected, add azithromycin to the β-lactam. If community-acquired MRSA is suspected, then vancomycin or clindamycin should be added to the regimen.[30]

Pharmacologic Therapy for HAP/VAP

Nosocomial pneumonia has since been replaced by the terms *HAP*, and *VAP*. **KEY CONCEPT** Empirical selection of antimicrobial therapy for ventilator- and hospital-associated pneumonia is broad spectrum; however, once culture and susceptibility information is available, the therapy should be narrowed (de-escalation) to cover the identified pathogen(s). Three factors important to the empirical selection of antibiotics for these types of pneumonia are risk of mortality, MRSA risk factors predominantly being in a hospital unit with an incidence of MRSA ≥ 20%, and the intravenous use of antibiotics in the prior 90 days.[1] MDR organisms that need to be considered include *P. aeruginosa*, extended-spectrum β-lactamase–producing *K. pneumoniae*, *Acinetobacter* spp., and MRSA. Empirical therapy for HAP and VAP is listed in Table 74–4 and is stratified by these three factors. If there is low risk of mortality and no MRSA risk factors, then recommended antibiotics include cefepime, piperacillin/tazobactam, or levofloxacin. If risk of mortality is high, or intravenous antibiotics have been used in the prior 90 days, then double coverage for Gram-negative bacilli including *P. aeruginosa* is recommended. If MRSA is suspected, then either vancomycin or linezolid should be added to the regimen.[1]

Currently, there is debate over whether or not double coverage for *Pseudomonas* is required. In vitro studies have shown that aminoglycosides exhibit synergistic killing against Gram-negative bacilli when combined with β-lactams. Dosing of the aminoglycosides is dependent on the patient's renal function. A high-dose once-daily regimen (eg, 4–7 mg/kg gentamicin or tobramycin or 15–20 mg/kg amikacin) can be utilized in patients with good renal function. Most of the studies enrolled patients with estimated creatinine clearances of at least 70 mL/min (1.17 mL/s). Meta-analyses have shown high-dose once-daily regimens to be as efficacious as and less toxic than divided-daily dosing.[31-35] Divided-daily dosing (eg, 1–2 mg/kg gentamicin or tobramycin or 7.5 mg/kg amikacin) has been utilized since the 1970s, and the dosing interval is based on the patient's renal function to achieve a trough concentration of less than 2 mcg/mL (2 mg/L; 4 μmol/L) for gentamicin and tobramycin and less than 5 mcg/mL (5 mg/L; 9 μmol/L) for amikacin.

In addition to obtaining a synergistic effect, the primary reason for double coverage when treating VAP, or HAP, is to broaden the coverage empirically to increase the likelihood of covering the majority of resistant pathogens. VAP is the most studied of these types of pneumonias and is often the most severe. There is an increase in mortality when inadequate therapy is initiated for VAP. Crude mortality ranges are quite large (35%–92%) compared with estimates of attributable mortality (approximately 9%); however, attributable mortality studies are limited by the large sample size needed to accurately measure this outcome.[36-38]

KEY CONCEPT Once a pathogen or pathogens have been identified, therapy should be narrowed (de-escalated) to cover only those pathogens. Use of broad-spectrum antibiotics for prolonged durations increases the risk of colonization with MDR pathogens.

Duration of Antimicrobial Therapy

KEY CONCEPT The duration of therapy for pneumonia should be kept as short as possible and depends on several factors: type of pneumonia, inpatient or outpatient status, patient comorbidities, bacteremia/sepsis, and the antibiotic chosen. If the duration of therapy is too prolonged, then it can have a negative impact on the patient's normal flora in the respiratory and gastrointestinal tracts, vaginal tract of women, and on the skin. This can result in colonization with resistant pathogens, *C. difficile*, or overgrowth of yeast. In addition, the longer antibiotics are administered, the greater the chance for toxicity from the agent, as well as an increase in cost.

Table 74–4

Empirical Therapy HAP in Adults

Low Risk of Mortality and No Risk Factors for MRSA	Low Risk of Mortality With Risk Factors for MRSA	High Risk of Mortality or Received Intravenous Antibiotics in the Prior 90 Days
One of the following Piperacillin/tazobactam[c] 4.5 g IV q6h OR Cefepime[c] 2 g IV q8h OR Levofloxacin 750 mg PO/IV once daily	One of the following Piperacillin/tazobactam[c] 4.5 g IV q6h OR Cefepime[c] or Ceftazidime 2 g IV q8h OR Levofloxacin 750 mg PO/IV once daily Ciprofloxacin 400 mg IV q8h OR Imipenem[c] 500 mg IV q6h Meropenem[c] 1 g IV q8h OR Aztreonam[a] 2 g IV q8h PLUS Vancomycin[d] 15 mg/kg IV q8–12h OR Linezolid 600 mg IV/PO q12h	Two of the following Piperacillin/tazobactam[c] 4.5 g IV q6h OR Cefepime[c] or Ceftazidime 2 g IV q8h OR Levofloxacin 750 mg PO/IV once daily Ciprofloxacin 400 mg IV q8h OR Imipenem[c] 500 mg IV q6h Meropenem[c] 1 g IV q8h OR Aztreonam[a] 2 g IV q8h OR Amikacin[b] 15–20 mg/kg IV q24h Gentamicin[b] or Tobramycin[b] 5–7 mg/kg IV q24h PLUS Vancomycin[d] 15 mg/kg IV q8–12h OR Linezolid 600 mg IV/PO q12h

[a] Aztreonam should be reserved for a patient with a severe β-lactam allergy.

[b] Trough concentrations ideally should be nondetectable; < 1 mcg/mL for gentamicin and tobramycin (1 mg/L; 2 μmol/L) and < 4–5 mcg/mL (4–5 mg/L; 7–9 μmol/L) for amikacin.

[c] Extended infusions can be utilized.

[d] Target area under the curve (AUC) > 400 (400–650) or target trough concentration of 15–20 mcg/mL.

The IDSA recommends treatment for CAP for a minimum of 5 days, and if the patient has been afebrile for 48 to 72 hours and has no more than 1 CAP-associated sign of instability (heart rate ≤ 100 beats/min, respiratory rate ≤ 24 breaths/min, systolic blood pressure ≥ 90 mm Hg, oxygen saturation ≥ 90% on room air, tolerating oral intake or normal mental status) then treatment can be discontinued.[24] For treatment of CAP in adult patients admitted to the hospital, the duration is dependent on whether or not blood cultures were positive. In the absence of positive blood cultures, the criteria for the 5-day duration of therapy listed above was validated for hospitalized patients and demonstrated similar clinical success as compared to longer durations of therapy.[39] If blood cultures were positive, the duration of therapy should be 2 weeks from the day blood cultures first became negative. The duration of therapy in pediatric patients is 10 days for uncomplicated CAP, with the exception of azithromycin, which is approved for 5 days.[30]

The duration of therapy cited in the literature for HAP or VAP ranges from 10 to 21 days. The ATS and IDSA guidelines (Table 74–5) recommend a shortened duration of therapy from the traditional 14 to 21 days to 7 days.[1] The ratings for the recommendations is a strong recommendation with moderate quality of evidence for VAP and a strong recommendation with very low quality of evidence for HAP.[1] Shorter or longer durations of therapy could be appropriate and should be based on the rate of improvement of clinical, radiological, and laboratory parameters. Shortening the duration of therapy was found to be beneficial with regard to secondary infections, colonization, toxicity, and cost issues. Several studies evaluated mortality, clinical success, recurrence, or the development of resistance with shorter courses of therapy for VAP and found no differences when compared with longer courses of therapy.[37,40]

OUTCOME EVALUATION

For CAP, outcomes include preventing hospitalization, shortening the duration of hospitalization, and minimizing mortality. Improvement of symptoms should occur within 24 to 72 hours after initiation of therapy for most patients with CAP. Response to therapy could be slowed in patients with underlying pulmonary disease such as moderate-to-severe asthma, COPD, or emphysema. In patients not responding to therapy, consider patient comorbid conditions, other infectious and noninfectious reasons, and a drug-resistant pathogen as a causative agent. Noninfectious reasons to consider include pulmonary embolus, congestive heart failure, carcinoma, lymphoma, intrapulmonary hemorrhage, and certain inflammatory lung diseases.

Outcome parameters for VAP and HAP are similar to those with CAP. Clinical improvement should occur within 48 to 72 hours of the start of therapy. If a patient is not responding to therapy, then, again, consider infectious and noninfectious reasons. Infectious explanations are the same as for CAP stated above, but noninfectious are not. They include atelectasis, ARDS, pulmonary embolism or hemorrhage, cancer, empyema, or lung abscess.

PREVENTION

KEY CONCEPT Prevention of both pneumococcal and influenza pneumonia by the use of vaccination is a national goal (Table 74–6). Vaccination is used to prevent or minimize the severity of pneumonia caused by *S. pneumoniae* or the influenza virus. Further information on vaccination can be found in Chapter 86.

The influenza vaccine is available in two forms: trivalent and quadrivalent. The trivalent vaccines are injectable and inactivated,

Table 74–5

Empirical Therapy VAP in Adults[a,b]

MRSA Coverage	Gram-Negative β-Lactam Antibiotics with Antipseudomonal Activity	Gram-Negative Non-β-Lactam Antibiotics with Antipseudomonal Activity
Vancomycin[c] 15 mg/kg IV q8–12h	Piperacillin/tazobactam[d] 4.5 g IV q6h	Levofloxacin 750 mg PO/IV once daily Ciprofloxacin 400 mg IV q8h
OR	OR	OR
Linezolid 600 mg IV/PO q12h	Cefepime[e] or Ceftazidime 2 g IV q8h	Amikacin[e] 15–20 mg/kg IV q24h Gentamicin[e] or Tobramycin[b] 5–7 mg/kg IV q24h
	OR	OR
	Imipenem[d] 500 mg IV q6h or Meropenem[d] 1 g IV q8h	Colistin 5 mg/kg IV × 1 followed by 2.5 mg × (1.5 × CrCl + 30) IV q12h Polymyxin B 2.5–3 mg/kg/day IV divided in two daily doses
	OR	
	Aztreonam[f] 2 g IV q8h	

[a] Choose one agent for MRSA coverage PLUS one β-lactam antibiotic PLUS one non-β-lactam antibiotic.

[b] The hospital antibiogram or intensive care unit specific antibiogram should influence the selection from each column.

[c] Target area under the curve (AUC) > 400 (400–650) or target trough concentration of 15–20 mcg/mL.

[d] Extended infusions can be utilized.

[e] Trough concentrations ideally should be nondetectable; < 1 mcg/mL for gentamicin and tobramycin (1 mg/L; 2 μmol/L) and < 4–5 mcg/mL (4–5 mg/L; 7–9 μmol/L) for amikacin.

[f] Aztreonam should be reserved for a patient with a severe β-lactam allergy.

consisting of 2 type A and 1 type B influenza viruses, and are being phased out.[41]

The quadrivalent vaccines contain 2 type A and 2 type B influenza viruses. Each manufacturer has different age approvals and should be evaluated prior to use in pediatric patients.[41] The ability of influenza vaccine to protect a person depends on two key factors: the age and health status of the person getting the vaccine, and the similarity or "match" between the virus strains in the vaccine and those in circulation. Protective antibodies are detected approximately 2 weeks after vaccination. The Centers for Disease Control and Prevention (CDC) adopted a universal influenza vaccination policy, thus recommending all persons 6 months of age and older to be vaccinated annually prior to the start of during influenza season.

Table 74–6

Immunizations

Type	Approved Ages and Conditions
Influenza	
Quadrivalent—Killed	>6 months of age
• High dose, killed	Adults 65 years and older
• Live-attenuated	Healthy individuals 2–49 years, not during pregnancy
Trivalent	Adults 65 years and older
Pneumococcal	
PSV 23 valent	Adults 65 years and older; individuals 19–64 years at increased risk due to health conditions[a,b]
Conjugated 13 valent	2–15 months, recommended schedule; adults 65 years and older based on shared decision-making; children or adults at increased risk due to health conditions[b]

[a] Chronic heart (excluding hypertension), lung, or liver disease, diabetes, alcoholism, or cigarette smoking.

[b] Chronic heart disease; chronic lung disease; diabetes mellitus; cerebrospinal fluid leak; cochlear implants, sickle cell disease; hemoglobinopathies; asplenic; congenital or acquired immunodeficiencies; HIV infection; chronic renal failure; nephrotic syndrome; leukemia; Hodgkin disease; malignancy; long-term immunosuppressive therapy; solid organ transplant; multiple myeloma.

There are currently three different types of coronavirus, specifically COVID-19 vaccines under development or approved for emergency use authorization (EUA) by the FDA. Two different mRNA vaccines are approved for EUA in December 2020. The mRNA vaccines are taken up into host cells to allow expression of the SARS-CoV-2 S antigen by host cells, eliciting an immune response to the S antigen. Vector vaccines use a weakened/attenuated virus (not coronavirus), which contains COVID-19 genes for making COVID-19 proteins/antigens, to elicit an immune response. The third type of vaccines are protein subunit vaccines, which are pieces of the COVID-19 virus to elicit an immune response.[42] (please refer to Upper Respiratory Tract Infections Chapter 75).

Pneumococcal conjugate vaccine (PCV) comprises 13 serotypes and is recommended for all babies and children younger than 2 years old, adults 65 years or older based on shared decision making, and people 2 through 64 years old with certain medical conditions. Pneumococcal polysaccharide vaccine (PSV) comprises 23 serotypes and is recommended for all adults 65 years or older, people 2 through 64 years old who are at increased risk for disease due to certain medical conditions, and adults 19 through 64 years old who smoke cigarettes. The serotypes in the PCV13 are the most common disease-causing strains of pneumococcus.[43,44] A reliable immunologic response to the PCV13 has been demonstrated, along with a favorable safety profile.[44,45] The 23 capsular types in the PPSV23 represent at least 85% to 90% of the serotypes that cause invasive pneumococcal infections among children and adults in the United States. Ten years after vaccination, a sample of elderly individuals demonstrated significant quantity of protective antibodies.[46] Individuals 65 years and older should receive the PSV23 vaccine every 5 years for a maximum of three doses.[47] Additional information on these vaccines is available on the CDC website, Advisory Committee on Immunization Practices (ACIP; https://www.cdc.gov/vaccines/acip/index.html).

Patient Care Process

KEY CONCEPT Monitoring response to therapy is essential for determining efficacy, identifying adverse reactions, and determining the duration of therapy.

Collect Information:

- Perform a medication history for the use of prescription and nonprescription medications and dietary supplements.
- Identify allergies to medications, including the reaction.
- Review the medical history and physical assessment findings.
